	Tulipa gesneriana L.	Cultivated
	Tulipa kosovarica Kit Tan, Shuka & Krasniqi	Subendemic (Albania and Kosovo)
	Tulipa sylvestris L.	Native
	Tulipa sylvestris subsp. *australis* (Link) Pamp.	Native

Table 2 summarizes the currently accepted genera and taxa of the family Liliaceae occurring in Albania, according to contemporary taxonomic concepts. The table also provides information on the phytogeographical status of each taxon in Albania, including native, endemic, subendemic, cultivated, and doubtful taxa.

Among the represented genera, *Fritillaria* is the richest in taxa, comprising several species and subspecies distributed across different ecological and mountainous regions of the country. The genus is of particular phytogeographical importance due to the presence of Balkan subendemics such as *Fritillaria ionica* Halácsy, restricted to Albania and Greece. The occurrence of multiple infraspecific taxa within *Fritillaria messanensis* Raf. further reflects the taxonomic complexity of the genus in the Balkan Peninsula. One taxon, *Fritillaria messanensis* Raf. subsp. *messanensis*, is considered doubtful in Albania, indicating the need for additional field investigations and herbarium revision to confirm its distribution.

The genus *Gagea* is represented by several native taxa, most of which are characteristic elements of open grasslands, rocky habitats, and montane ecosystems. Although none of the Albanian representatives are endemic, the genus contributes significantly to the spring geophyte flora of the country and demonstrates considerable ecological diversity.

The genus *Lilium* includes taxa of high ornamental and conservation value. Particularly noteworthy is *Lilium albanicum* Griseb., an important Balkan species associated with mountainous habitats. *Lilium chalcedonicum* L. is treated as a subendemic species shared between Albania and Greece, emphasizing the floristic connections between southwestern Balkan territories. The presence of cultivated taxa such as *Lilium lancifolium* Thunb. indicates the inclusion of non-native ornamental elements occasionally recorded in floristic sources.

The genus *Tulipa* is especially significant from a biogeographical and conservation perspective. *Tulipa albanica* Kit Tan & Shuka represents one of the most important endemic taxa of the Albanian flora and highlights Albania as a center of plant diversity in the Balkan Peninsula. In addition, *Tulipa kosovarica* Kit Tan, Shuka & Krasniqi is considered subendemic to Albania and Kosovo, further emphasizing the regional importance of the western Balkans for the diversification of the genus. Native representatives such as *Tulipa sylvestris* L. and its subspecies *australis* remain characteristic components of natural and semi-natural habitats, whereas *Tulipa gesneriana* L. is mainly cultivated.

Overall, the updated circumscription of Liliaceae in Albania reflects a substantial reduction in the number of included genera compared to the traditional treatment in *Flora e Shqipërisë*. The remaining taxa largely consist of bulbous geophytes with high floristic, phytogeographical, ornamental, and conservation significance. The presence of endemic and subendemic taxa further underlines the importance of Albania within the Balkan floristic region and highlights the need for continued taxonomic, chorological, and conservation-oriented studies on the family.

ABSTRACT

The replacement of synthetic food colorants with natural alternatives has become an important strategy for developing clean-label bakery products. This study investigated the effects of pumpkin, red cabbage, spinach, red beet, and red bell pepper powders on the color, physical, textural, moisture, and sensory properties of wheat bread. Bread samples were prepared by replacing wheat flour with 4% vegetable powder using the straight dough method. Instrumental color measurements (L*, a*, b*, SI, and hue) were performed on both crust and crumb. Loaf weight, loaf volume, specific volume, moisture content, and texture profile parameters (hardness, adhesiveness, springiness, cohesiveness, chewiness, and resilience) were determined. Sensory evaluation was conducted using a 7-point hedonic scale to assess appearance, taste, odor, crumb structure, and overall acceptability. Vegetable powder incorporation significantly affected bread quality characteristics ($P < 0.05$). Spinach bread exhibited the lowest lightness, loaf volume, and specific volume, together with the highest hardness and chewiness, indicating the formation of a compact crumb structure. In contrast, red beet and red bell pepper breads maintained loaf volume and specific volume comparable to the control while producing attractive natural coloration. Moisture content varied significantly among formulations, ranging from approximately 36.4% to 39.2%, with spinach bread showing the highest moisture level and red beet bread the lowest. Sensory evaluation revealed that pumpkin and red bell pepper breads received sensory scores comparable to the control for most attributes, whereas red cabbage bread showed significantly lower consumer acceptance, particularly for taste and odor. Overall, the results demonstrate that vegetable powders can successfully replace synthetic colorants in bread production while generating distinctive natural colors. Among the evaluated vegetables, red bell pepper and pumpkin showed the greatest potential for developing clean-label colored breads by maintaining desirable technological quality together with high consumer acceptability.

Keywords: bread, vegetable powders, natural colorants, clean-label, sensory evaluation, texture profile analysis.

INTRODUCTION

Bread is one of the oldest and most widely consumed cereal-based foods worldwide, providing a substantial proportion of daily dietary energy and nutrients in many populations. Owing to its affordability, convenience, and consumer acceptance, bread has become an ideal vehicle for nutritional enrichment and functional ingredient incorporation (Cauvain, 2015; Gómez & Martinez, 2018). In recent years, increasing consumer awareness of the relationship between diet and health has encouraged the bakery industry to develop products with enhanced

nutritional quality while maintaining desirable technological and sensory properties (Dziki et al., 2021; Mir et al., 2017).

Visual appearance is among the first quality attributes influencing consumers' purchasing decisions, and color is considered one of the most critical factors affecting product acceptability. Consumers frequently associate bright and natural colors with freshness, quality, and nutritional value. Consequently, there has been growing interest in replacing synthetic food colorants with naturally derived pigments obtained from plant materials. This trend is strongly associated with the increasing demand for clean-label foods, where consumers prefer products formulated with recognizable, minimally processed, and naturally sourced ingredients (Asioli et al., 2017; Sigurdson et al., 2017).

Vegetables are excellent sources of natural pigments as well as bioactive compounds including phenolic compounds, carotenoids, betalains, chlorophylls, vitamins, minerals, and dietary fiber. Besides imparting attractive colors, these compounds may contribute antioxidant activity and improve the nutritional profile of bakery products (Sharma et al., 2022; Ktenioudaki & Gallagher, 2012). Pumpkin is particularly rich in carotenoids, especially β-carotene, which produces desirable yellow-orange coloration while serving as an important precursor of vitamin A (Murkovic et al., 2002). Red cabbage contains anthocyanins responsible for its characteristic purple coloration together with remarkable antioxidant capacity (Wu & Prior, 2005). Spinach provides chlorophyll pigments, lutein, minerals, and folates that contribute both nutritional value and green coloration (Ferruzzi & Blakeslee, 2007). Red beet is recognized as one of the richest dietary sources of betalains, pigments exhibiting high coloring capacity and antioxidant activity (Clifford et al., 2015). Likewise, red bell pepper contains considerable amounts of carotenoids such as capsanthin and capsorubin, which contribute vivid red coloration and antioxidant potential (Howard et al., 2000).

The incorporation of vegetable powders into bread formulations may significantly influence dough rheology and bread quality because these ingredients contain considerable amounts of dietary fiber and non-gluten components. Fiber competes with gluten proteins for water, interrupts gluten network formation, and alters gas retention during fermentation, thereby affecting loaf volume, crumb structure, and texture (Rosell et al., 2009; Gómez et al., 2011). Depending on the type and concentration of vegetable powder, changes in hardness, cohesiveness, springiness, chewiness, moisture retention, and crumb porosity have been reported in numerous studies (Ktenioudaki & Gallagher, 2012; Dziki et al., 2021).

Several researchers have investigated vegetable-enriched breads produced with pumpkin, beetroot, spinach, carrot, tomato, broccoli, or other vegetable powders. These studies generally reported improvements in antioxidant capacity, dietary fiber, mineral composition, and consumer perception of naturalness. However, technological responses varied considerably depending on the vegetable source because pigment composition, particle size, fiber characteristics, and water absorption capacity differ substantially among vegetables (Bhol & Bosco, 2014; Sharma et al., 2022). Therefore, comparative studies evaluating different vegetable powders under identical processing conditions remain limited and are necessary to identify suitable natural colorants capable of providing both desirable appearance and acceptable technological performance.

In the present study, wheat breads enriched with pumpkin, red cabbage, spinach, red beet, and red bell pepper powders were comparatively evaluated. Instrumental color measurements were performed to determine the effects of different vegetable pigments on bread color. In addition, loaf weight, loaf volume, specific volume, and texture profile parameters, including hardness, adhesiveness, springiness, cohesiveness, chewiness, and resilience, were determined to evaluate technological quality. The results provide valuable insights into the application of vegetable powders as natural coloring agents for developing clean-label bread products with improved visual appeal while maintaining satisfactory physical quality.

MATERIAL AND METHODS

Materials

Commercial refined wheat flour, compressed baker's yeast, salt, and tap water were used for bread production. Pumpkin (*Cucurbita moschata*), red cabbage (*Brassica oleracea* var. *capitata* f. rubra), spinach (*Spinacia oleracea*), red beet (*Beta vulgaris*), and red bell pepper (*Capsicum annuum* L.) powders were incorporated into the bread formulations as natural coloring agents. All ingredients were obtained from local suppliers and stored under appropriate conditions until use.

Bread preparation

Bread samples were prepared according to the straight dough method with slight modifications. The control formulation consisted of wheat flour, compressed yeast (3.0 g/100 g flour), salt (1.5 g/100 g flour), and water. Wheat flour was partially replaced with each vegetable powder at the predetermined substitution level 4%.

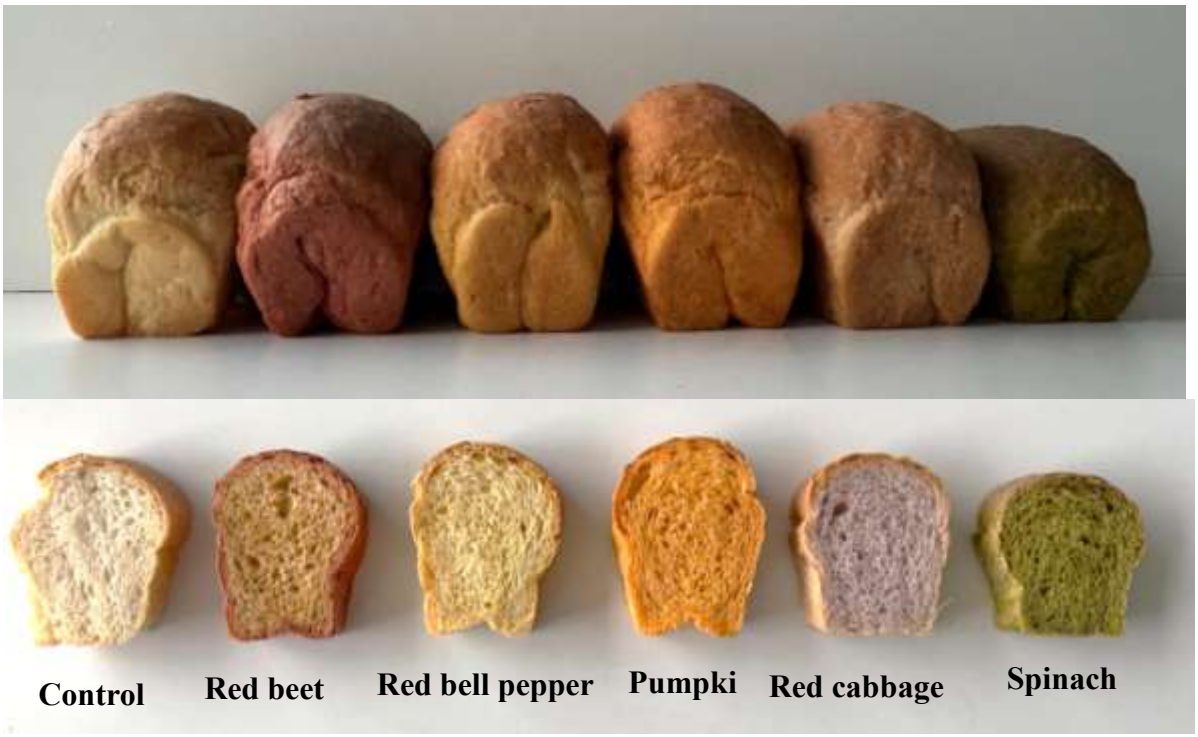

Figure 1. Representative external and crumb appearances of the control and vegetable-powder-enriched breads.

The ingredients were mixed using a laboratory mixer (Hobart N50, Offenburg, Germany) until optimum dough development. Doughs were fermented in a fermentation cabinet (Fimak FMD 16, Konya, Türkiye) at 30°C and 75–80% relative humidity for two successive 30-min bulk fermentation periods, with folding after each fermentation step. Subsequently, the doughs were moulded and subjected to a final proofing at 30°C for 60 min. Baking was carried out in a deck oven (Fimak Rokon Classic FRN10 G, Konya, Türkiye) preheated to 230 ± 5°C. After baking, loaves were cooled at room temperature for 60 min prior to physical analyses. Crust color, loaf weight, loaf volume, and specific volume were determined after cooling. Crumb color and texture profile analyses were performed after 24 h of storage (**Figure 1**).

Color measurement

The color characteristics of bread crust and crumb were determined using the procedure described in Section 2.2 (ham madde renk analiziyle aynı yöntem). Crumb color was measured on bread slices with a thickness of 2.5 cm, while crust color was measured directly on the loaf

surface. Five measurements were taken from different locations of each loaf, and the mean values were reported. Color parameters including L* (lightness), a* (redness/greenness), and b* (yellowness/blueness) were recorded.

Loaf weight, loaf volume, and specific volume

Bread loaves were weighed after cooling for 60 min following baking. Loaf volume was determined using the rapeseed displacement method according to Elgün et al. (2001). Specific volume was calculated as the ratio of loaf volume to loaf weight and expressed as cm^3/g.

$$\textit{Specific volume } (cm^3/g) = \textit{loaf volume } (cm^3) / \textit{loaf weight } (g)$$

Texture profile analysis (TPA)

Texture profile analysis was carried out using a TA.XT Plus Texture Analyzer (Stable Micro Systems Ltd., Surrey, UK) equipped with a 30-kg load cell and a 36-mm cylindrical probe. Bread slices (2.5 cm thickness) were analyzed after 24 h of storage at room temperature. The test conditions were set as follows: pre-test speed of 1 mm/s, test speed of 5 mm/s, post-test speed of 5 mm/s, and compression distance of 5 mm. The parameters determined included hardness, adhesiveness, springiness, cohesiveness, chewiness, and resilience.

Moisture content

Crumb moisture content was determined 24 h after baking by the oven-drying method. Homogenized crumb samples were dried at 105 °C to constant mass, and moisture content was expressed as percentage wet basis (AACC, 2000).

Sensory evaluation

Sensory evaluation was conducted with 20 untrained panelists from Necmettin Erbakan University who regularly consumed bakery products. Coded bread samples were presented in randomized order under ambient conditions. Taste, odor, appearance, crumb structure, and overall acceptability were evaluated using a 7-point hedonic scale (1 = dislike extremely; 7 = like extremely). Drinking water was provided for palate cleansing between samples (Meilgaard et al., 2016).

Statistical analysis

All analytical measurements were carried out in triplicate, and results were expressed as mean ± standard deviation. Data were analyzed using JMP statistical software, version 10.0 (SAS Institute Inc., Cary, NC, USA). One-way analysis of variance (ANOVA) was performed, and means were compared using Tukey's HSD test at $p < 0.05$.

RESULTS AND DISCUSSION

Crust color characteristics

The color parameters of breads enriched with different vegetable powders are presented in **Figure 2**. Incorporation of vegetable powders significantly affected the color characteristics of the bread samples ($P < 0.05$), confirming that the natural pigments present in the vegetables were retained to varying extents after the baking process. The extent of color modification depended on the pigment composition of each vegetable powder, resulting in distinct changes in lightness, redness, yellowness, color saturation, and hue angle. The L* value, representing lightness, decreased significantly in all vegetable-enriched breads compared with the control sample ($P < 0.05$). The control bread exhibited the highest L* value, indicating the lightest crumb, whereas spinach bread showed the lowest L* value, producing the darkest crumb among all formulations. Red beet bread also displayed relatively low lightness, while pumpkin, red cabbage, and red bell pepper breads exhibited intermediate L* values. The reduction in lightness can be attributed to the intrinsic color intensity of the vegetable powders, which replaced part of the wheat flour and consequently darkened the crumb. Similar decreases in L* values have been reported in breads fortified with spinach, beetroot, carrot, and other vegetable powders, where the presence of natural pigments reduced crumb brightness after baking

(Ktenioudaki & Gallagher, 2012; Sharma et al., 2022). In addition, thermal reactions occurring during baking, including Maillard reactions and caramelization, may further contribute to crumb darkening, particularly in formulations containing vegetables rich in reducing sugars.

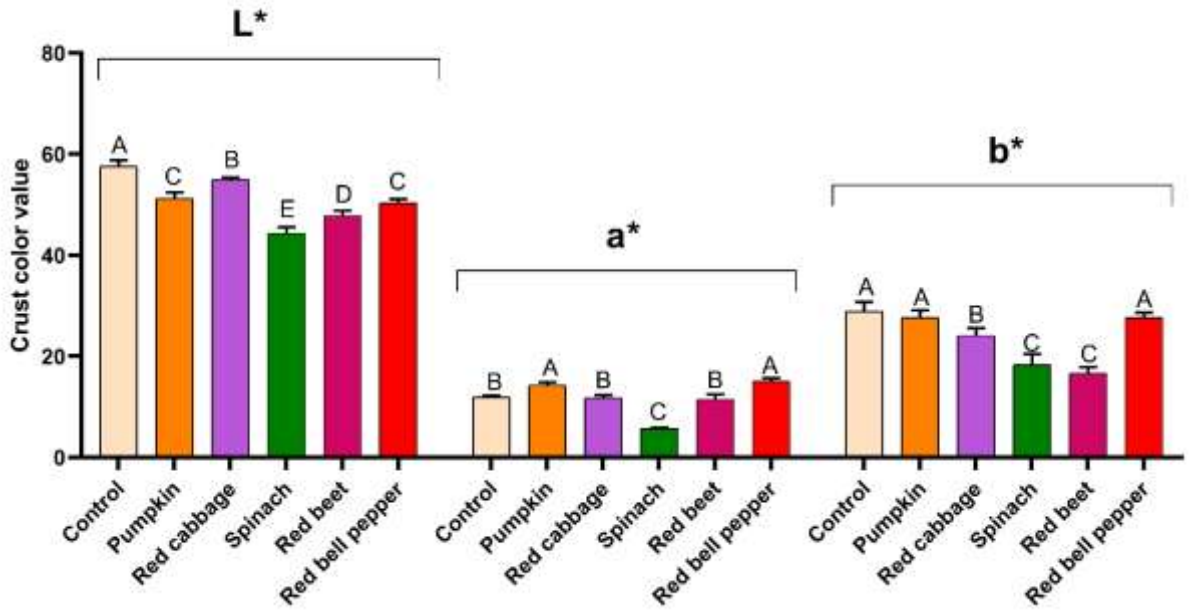

Figure 2. Crust L*, a*, and b* values of breads containing different vegetable powders. Different letters indicate significant differences ($p < 0.05$).

Significant differences were also observed in the a* values among bread samples. Red bell pepper and pumpkin breads exhibited the highest positive a* values, indicating enhanced redness, whereas spinach bread showed the lowest a* value because of the predominance of chlorophyll pigments that shifted the color toward the green region. Red cabbage and red beet breads produced intermediate redness values despite containing anthocyanins and betalains, respectively. The relatively moderate a* value observed in beet bread may be associated with the partial thermal degradation of betalains during baking, whereas anthocyanins in red cabbage are known to be sensitive to pH and temperature changes, which may also reduce color intensity. Previous studies have demonstrated that chlorophylls are susceptible to thermal degradation, while anthocyanins and betalains may undergo structural changes under baking conditions, resulting in reduced color stability compared with carotenoid pigments (Sigurdson et al., 2017; Clifford et al., 2015).

The b* values were likewise significantly influenced by vegetable powder incorporation. The highest b* values were observed in the control, pumpkin, and red bell pepper breads, whereas spinach and red beet breads exhibited the lowest values ($P < 0.05$). These findings are consistent with the pigment composition of the vegetables. Pumpkin and red bell pepper are rich in carotenoids, particularly β-carotene, capsanthin, and capsorubin, which impart yellow-orange coloration and therefore increase positive b* values. In contrast, chlorophyll-rich spinach and betalain-rich beetroot shifted the color away from the yellow axis, resulting in lower b* values. Similar trends have been reported in vegetable-fortified bakery products, where carotenoid-rich ingredients increased yellowness while green leafy vegetables reduced b* values because of chlorophyll dominance (Howard et al., 2000; Murkovic et al., 2002).

Color saturation, expressed as the saturation index, differed significantly among formulations **(Figure 3**). The control, pumpkin, and red bell pepper breads exhibited the highest chroma values, indicating brighter and more vivid colors. Conversely, spinach and red beet breads

presented significantly lower chroma values, suggesting less saturated and comparatively duller crumb colors. Chroma reflects the purity and intensity of color; therefore, higher values indicate a more vivid appearance that may enhance consumer perception of freshness and attractiveness. The reduced chroma observed in spinach bread may result from partial degradation of chlorophyll pigments during baking, whereas pigment interactions within the bread matrix could also contribute to lower saturation.

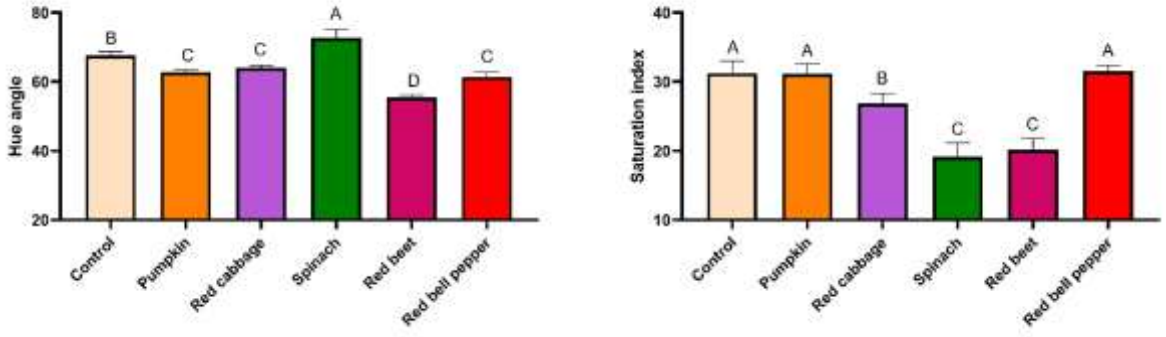

Figure 3. Crust hue angle and saturation index of breads containing different vegetable powders. Different letters indicate significant differences ($p < 0.05$).

The hue angle further differentiated the color characteristics of the bread samples. Spinach bread exhibited the highest hue angle, reflecting the dominance of green pigments, whereas red beet bread showed the lowest hue angle because of the strong contribution of red-purple betalains. Pumpkin, red cabbage, and red bell pepper breads displayed intermediate hue values, indicating balanced yellow, orange, and red color characteristics. Variations in hue angle demonstrate that each vegetable powder generated a distinct visual appearance, emphasizing the importance of pigment composition in determining the final bread color.

Crumb color characteristics

The instrumental color characteristics of bread crumbs prepared with different vegetable powders are presented in Figure 2. Similar to crust color, vegetable powder incorporation significantly affected all color parameters of the bread crumb ($P < 0.05$). However, the differences observed in crumb color more accurately reflect the contribution of the vegetable pigments because the crumb is less affected by Maillard browning and caramelization than the crust.

The L* values of bread crumbs decreased significantly following the incorporation of vegetable powders ($P < 0.05$). The control bread exhibited the highest lightness, whereas spinach bread showed the lowest L* value, indicating the darkest crumb among all formulations. Pumpkin bread remained relatively light, while red cabbage and red bell pepper produced intermediate L* values. The reduction in crumb lightness is mainly associated with the intrinsic color intensity of the incorporated vegetable powders, which diluted the white color of refined wheat flour. Spinach powder produced the greatest decrease in L* because of its high chlorophyll concentration, whereas the relatively high lightness of pumpkin bread can be attributed to the naturally lighter yellow pigments of carotenoids. Similar reductions in crumb lightness have been reported for breads enriched with spinach, beetroot, carrot, and other vegetable ingredients, where the replacement of wheat flour with pigmented plant materials resulted in darker crumb structures (Ktenioudaki & Gallagher, 2012; Dziki et al., 2021).

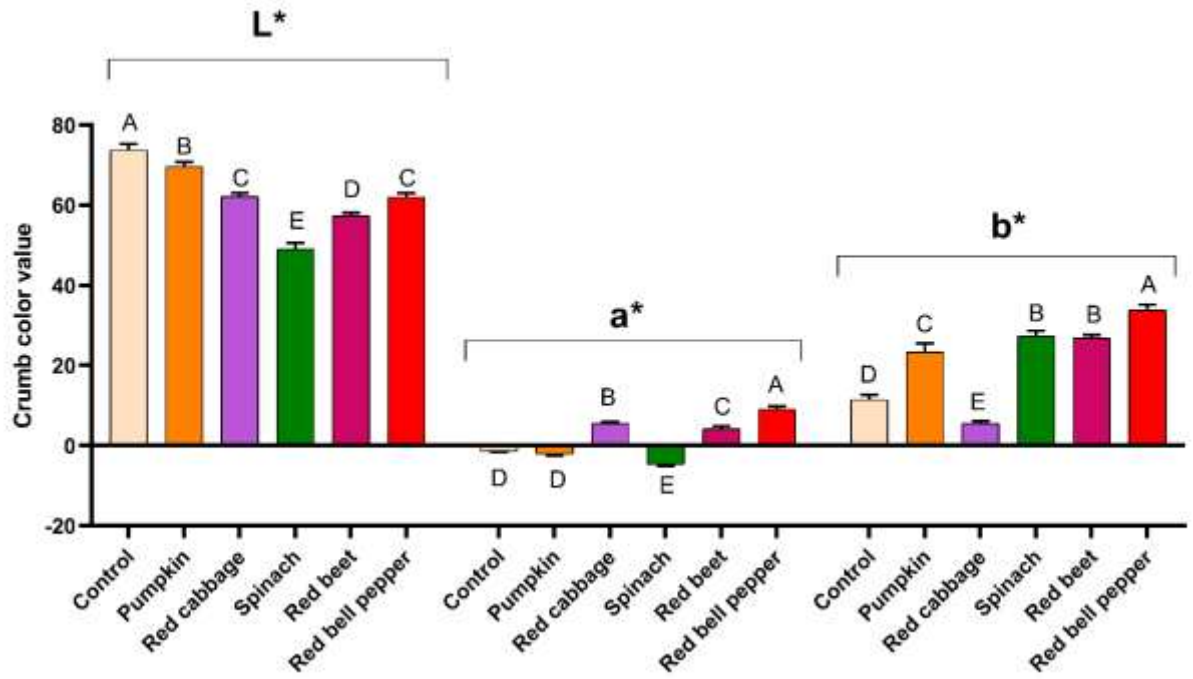

Figure 4. Crumb L*, a*, and b* values of breads containing different vegetable powders. Different letters indicate significant differences ($p < 0.05$).

Marked differences were also observed in the a* values. Pumpkin and control breads exhibited slightly negative a* values, indicating a tendency toward green rather than red. In contrast, red cabbage, red beet, and especially red bell pepper significantly increased positive a* values ($P < 0.05$), demonstrating enhanced redness of the crumb. Red bell pepper bread exhibited the highest a* value, reflecting the high concentration of carotenoid pigments, particularly capsanthin and capsorubin. Red cabbage and red beet also increased redness owing to anthocyanins and betalains, respectively. Conversely, spinach bread showed negative a* values because chlorophyll pigments shifted the color toward the green axis. These findings clearly demonstrate that the botanical origin of the vegetable powder largely determines the chromatic properties of bread crumb. Previous studies have similarly reported that chlorophyll-rich vegetables decrease a* values, whereas carotenoid-, anthocyanin-, and betalain-containing ingredients enhance redness in cereal products (Sigurdson et al., 2017; Clifford et al., 2015).

The b* values were significantly affected by vegetable type. Red bell pepper bread exhibited the highest b* value, followed by spinach and red beet breads, whereas the control bread showed comparatively lower yellowness. The lowest b* value was observed in red cabbage bread. The high yellowness of red bell pepper bread is attributed to its abundant carotenoid composition, while pumpkin also produced a noticeable increase in b* because of β-carotene. Although spinach contains green chlorophyll pigments, the presence of lutein and other yellow carotenoids likely contributed to its relatively high b* value. In contrast, anthocyanin-rich red cabbage shifted the overall color toward the purple region, thereby reducing yellowness. Similar behavior has been reported in previous studies evaluating the influence of vegetable pigments on bakery products (Howard et al., 2000; Murkovic et al., 2002).

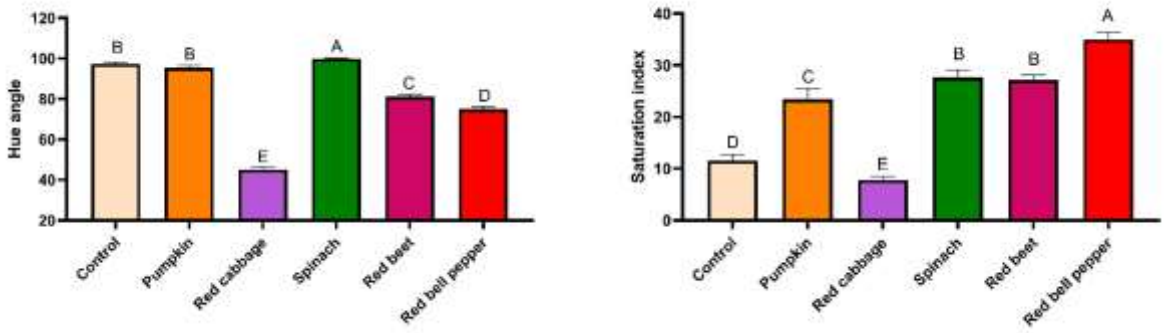

Figure 5. Crumb hue angle and saturation index of breads containing different vegetable powders. Different letters indicate significant differences ($p < 0.05$).

The saturation index demonstrated considerable variation among bread samples (**Figure 5**). Red bell pepper bread exhibited the highest chroma value, indicating the most vivid and saturated crumb color, whereas the control and red cabbage breads showed significantly lower chroma values ($P < 0.05$). Pumpkin, spinach, and red beet breads displayed intermediate saturation levels. Chroma represents color intensity, and higher values indicate stronger visual impact. The pronounced chroma of red bell pepper bread suggests that carotenoid pigments remained relatively stable during baking, whereas the lower saturation observed in red cabbage bread may be explained by the thermal sensitivity of anthocyanins, which are susceptible to degradation under baking conditions.

Significant differences were likewise observed for the hue angle, confirming that each vegetable powder generated a distinct color tone in the crumb. Spinach bread exhibited the highest hue angle, reflecting the predominance of green pigments. In contrast, red cabbage bread showed the lowest hue angle because of the strong contribution of anthocyanins, producing a purple-reddish crumb. Red beet and red bell pepper breads also exhibited reduced hue angles compared with the control, indicating a shift toward red coloration, whereas pumpkin bread maintained hue values close to those of the control due to its yellow-orange carotenoid profile.

Physical properties

Vegetable powder type significantly influenced loaf weight, loaf volume, and specific volume (**Figure 6**). Loaf weight was highest in spinach bread, while red cabbage bread was intermediate; the control, pumpkin, red beet, and red bell pepper breads formed a lower statistical group. Because dough pieces were prepared on an equal flour basis but water was added to obtain optimum dough development, the higher baked weight of spinach bread is consistent with greater water retention rather than greater dry-matter input.

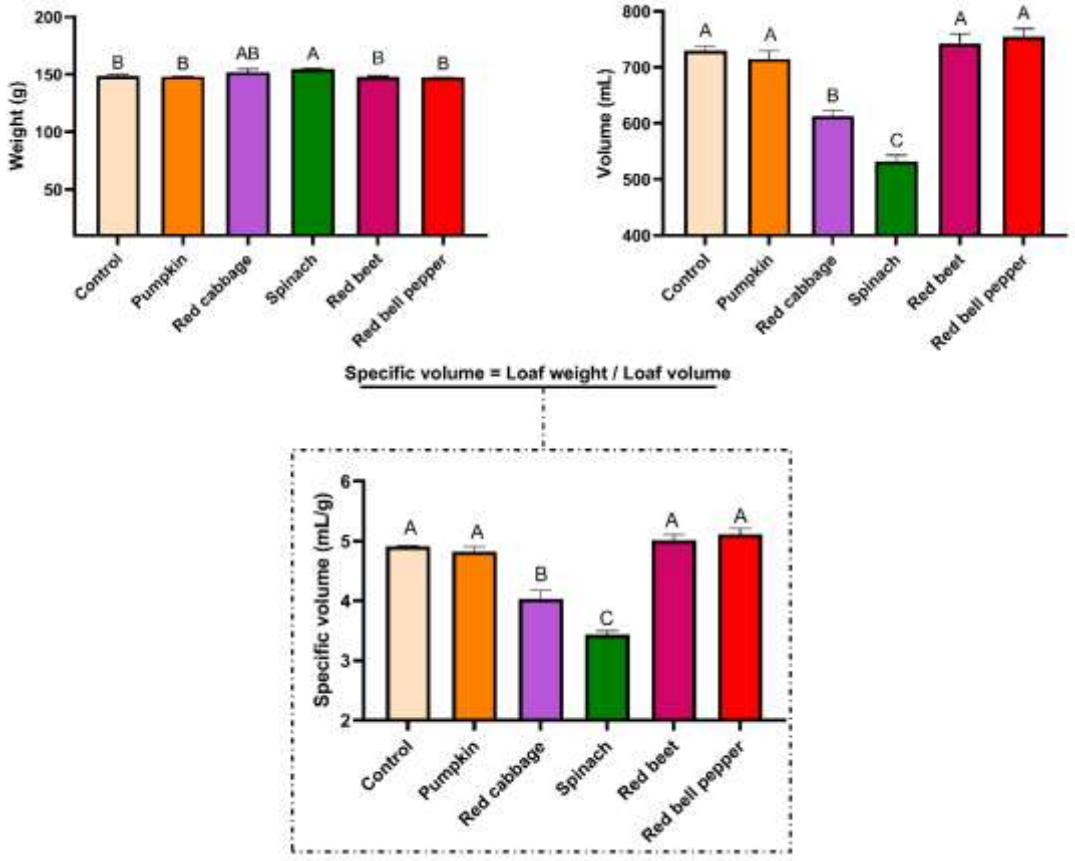

Figure 6. Loaf weight, loaf volume, and specific volume of breads containing different vegetable powders. Different letters indicate significant differences ($p < 0.05$).

The control, pumpkin, red beet, and red bell pepper breads had comparable loaf volumes and specific volumes. Red cabbage caused a moderate decrease, whereas spinach produced the lowest values for both parameters. These results indicate that the effect was not an inevitable consequence of adding 4% vegetable powder, but depended on powder composition. Fiber and non-gluten particles can dilute or disrupt the gluten network and modify water distribution, thereby reducing gas retention and loaf expansion (Ktenioudaki and Gallagher, 2012). Reduced volume after pumpkin enrichment has been reported at higher substitution levels (Różyło et al., 2014; Aljahani, 2022), while spinach powder has also been shown to alter the physicochemical properties of bread (Junejo et al., 2021). In the present study, the limited changes observed for pumpkin, red beet, and red bell pepper show that these powders were technologically compatible with the formulation at 4%.

Moisture content

Crumb moisture content differed significantly among the formulations ($p < 0.05$) and ranged from approximately 36.4 to 39.2% (Figure 7). Spinach bread had the highest moisture content, followed by red cabbage, whereas the control had an intermediate value. Pumpkin and red bell pepper were statistically similar to the control, while red beet bread had the lowest moisture content. The high moisture of spinach bread corresponded with its greater loaf weight and may reflect the water-binding capacity of its fiber-rich solids. Conversely, the lower moisture of red beet bread indicates that pigment source alone does not predict water retention. Ingredient-specific fiber structure, soluble solids, and interactions with the starch–gluten matrix are likely involved. Because formulation water was adjusted to optimum dough development, the

moisture differences should be interpreted as the combined result of water requirement and retention during baking.

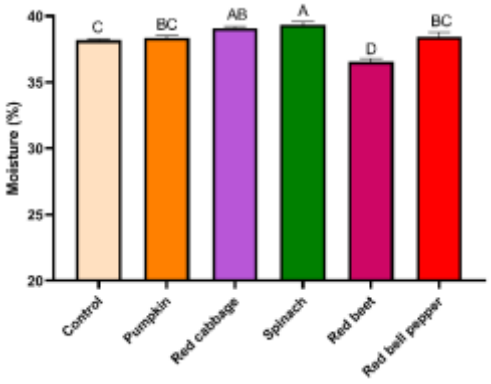

Figure 7. Moisture content of breads containing different vegetable powders. Different letters indicate significant differences ($p < 0.05$).

Texture profile properties

The texture profile parameters of the breads are presented in Table 1. Spinach bread had the highest hardness (2197.95 g) and chewiness (1097.29 g), consistent with its lower loaf volume and specific volume. A smaller, denser loaf generally contains less expanded gas-cell structure and therefore requires greater force during compression. Red cabbage bread also showed increased hardness (1574.12 g), although its chewiness did not differ from the control because its cohesiveness was significantly lower. By contrast, red bell pepper bread exhibited the lowest hardness (979.48 g), while pumpkin and red beet breads remained statistically comparable with the control.

Adhesiveness was markedly more negative in red cabbage bread, whereas the remaining samples did not differ significantly. Springiness was unaffected by vegetable powder type, indicating that the crumb recovered similarly after compression. Cohesiveness and resilience were lowest in red cabbage bread; spinach retained values comparable with the control despite its greater firmness. Thus, hardness alone did not describe the entire crumb response. The combination of high hardness and high chewiness in spinach bread points to a compact but internally cohesive matrix, whereas the red cabbage crumb was firm yet structurally less cohesive. Similar ingredient-dependent changes in loaf structure and texture have been observed in breads enriched with pumpkin, spinach, and beetroot ingredients (Różyło et al., 2014; Junejo et al., 2021; Cui et al., 2022).

Table 1. Texture profile parameters of breads containing different vegetable powders.

	Hardness (g)	Adhesiveness	Springiness	Cohesiveness	Chewiness (g)	Resilience
Control	1054.20±124.98bc	-6.77±11.12a	0.92±0.02a	0.53±0.04a	526.09±93.70b	0.16±0.02a
Pumpkin	1140.43±128.34bc	-6.79±5.51a	0.95±0.01a	0.47±0.02ab	510.32±79.64b	0.14±0.01ab
Red cabbage	1574.12±113.91b	-36.72±4.19b	0.91±0.05a	0.41±0.03b	565.85±49.37b	0.10±0.02b
Spinach	2197.95±377.89a	-2.51±2.17a	0.95±0.02a	0.52±0.05a	1097.29±25.28a	0.17±0.03a
Red beet	1154.41±131.83bc	-5.51±19.48a	0.90±0.07a	0.47±0.02ab	489.26±39.23b	0.14±0.01ab
Red bell pepper	979.48±112.32c	-1.47±1.00a	0.96±0.02a	0.48±0.03ab	444.37±26.95b	0.14±0.01ab

Values are mean ± standard deviation. Different lowercase letters within the same column indicate significant differences ($p < 0.05$).

Sensory properties

Sensory scores differed according to vegetable source (Figure 8). Control and red bell pepper breads received the highest taste scores, while pumpkin remained statistically close to the

control. Spinach and red beet received intermediate scores, and red cabbage was least preferred for taste. A similar pattern was observed for odor: control and red bell pepper breads had the highest ratings, pumpkin and spinach were comparable or only slightly lower, whereas red cabbage obtained the lowest score. The lower acceptance of red cabbage may be related to its characteristic sulfurous notes and the unfamiliar flavor–color combination in bread.

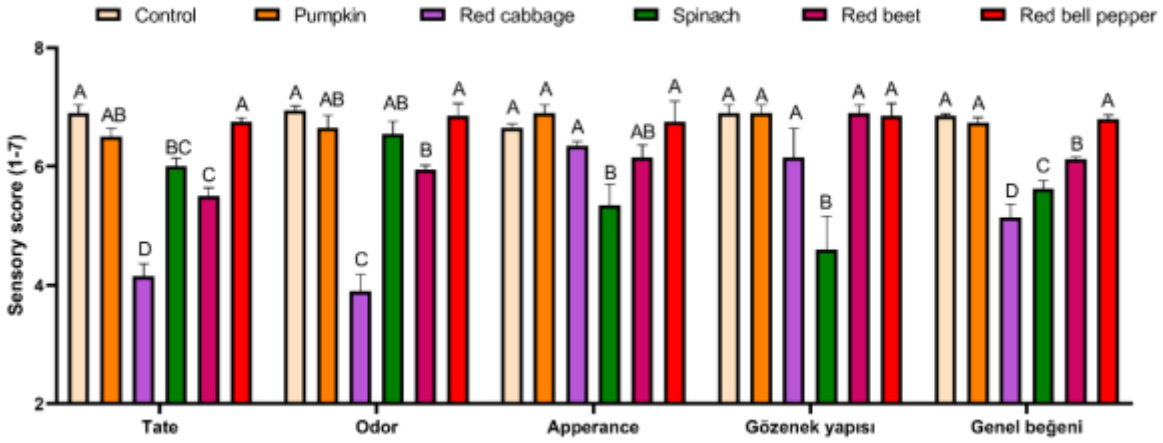

Figure 8. Sensory scores of breads containing different vegetable powders. Different letters within each attribute indicate significant differences ($p < 0.05$).

Appearance scores were high for the control, pumpkin, red bell pepper, and red beet breads. Red cabbage remained acceptable but was lower than the leading formulations, while spinach received the lowest appearance score. For crumb structure, the control, pumpkin, red beet, and red bell pepper breads formed the highest statistical group. Spinach received the lowest crumb-structure score, in agreement with its low specific volume and high instrumental hardness. Overall acceptability was highest for red bell pepper and was statistically comparable with the control and pumpkin breads. Red beet received a moderately high score, whereas spinach and especially red cabbage were less preferred. These findings demonstrate that a strong natural color does not by itself ensure acceptance; flavor compatibility and crumb structure are also decisive. The favorable performance of pumpkin agrees with reports that modest pumpkin incorporation can retain acceptable bread quality (Różyło et al., 2014; Aljahani, 2022), while the lower rating of spinach is consistent with the sensory limitations reported as spinach enrichment increases (Junejo et al., 2021).

CONCLUSION

Pumpkin, red cabbage, spinach, red beet, and red bell pepper powders produced clearly distinguishable natural colors in wheat bread at a 4% flour-replacement level. Their technological effects, however, were strongly dependent on vegetable type. Spinach caused the greatest structural change, as evidenced by higher moisture and loaf weight, lower loaf volume and specific volume, and increased hardness and chewiness. Red cabbage also reduced loaf expansion and cohesiveness and received the lowest taste, odor, and overall-acceptability ratings. In contrast, pumpkin and red bell pepper breads maintained physical and textural properties close to the control and achieved high sensory acceptance. Red beet produced attractive coloration and acceptable texture and sensory quality, although it had the lowest crumb moisture. Overall, red bell pepper and pumpkin powders were the most promising natural colorants under the tested conditions. The results apply specifically to the 4% incorporation level; future work should evaluate concentration-dependent responses, pigment

retention, antioxidant capacity, storage stability, and formulation-specific water absorption before industrial application.

ABSTRACT

The valorization of agro-industrial by-products offers a sustainable approach to reducing food-processing waste and developing value-added food products. Black cumin (*Nigella sativa* L.) seed cake, remaining after cold-pressed oil extraction, contains appreciable amounts of dietary fiber, protein, residual oil, and bioactive compounds and may therefore be utilized in gluten-free food formulations. This study investigated the effects of replacing chickpea flour with black cumin seed cake powder at levels of 1, 2, 3, 4, and 5% (w/w) on the quality characteristics of gluten-free chickpea chips. Instrumental color (L*, a*, b*, saturation index, and hue angle), physical properties (diameter, thickness, and spread ratio), textural characteristics (hardness and fracturability), and sensory acceptability were evaluated. Black cumin seed cake incorporation significantly affected the color and hardness of the chips ($p < 0.05$). Increasing the seed cake level progressively reduced L*, a*, b*, and saturation index values, resulting in darker and less saturated products. Chip diameter increased slightly, whereas thickness and spread ratio were not significantly affected. Hardness decreased progressively with increasing seed cake incorporation, while instrumental fracturability remained unchanged. Sensory evaluation showed that all formulations received scores above 5 on a 7-point hedonic scale. However, the samples containing 4 and 5% seed cake had significantly lower overall acceptability scores than the control, whereas formulations containing up to 3% maintained comparable overall acceptability. These findings indicate that cold-pressed black cumin seed cake can be incorporated into gluten-free chickpea chips, with 3% representing the highest tested level that maintained sensory acceptance comparable to the control. Its use provides a potential strategy for valorizing an oil-processing by-product in gluten-free snack formulations.

Keywords: black cumin seed cake, gluten-free chips, chickpea flour, by-product utilization, texture, color.

INTRODUCTION

The demand for gluten-free foods has increased in recent years due to the growing awareness of celiac disease, non-celiac gluten sensitivity, and consumer interest in alternative cereal and legume-based products. However, many commercially available gluten-free products are formulated mainly with refined starches and generally contain lower amounts of protein, dietary fiber, minerals, and bioactive compounds than their gluten-containing counterparts. Therefore,

the development of nutritionally improved gluten-free products using naturally gluten-free and nutrient-dense raw materials remains an important area of food research.

Chickpea (*Cicer arietinum* L.) flour is a promising ingredient for gluten-free food formulations because of its favorable nutritional and technological properties. It is an important source of protein, complex carbohydrates, dietary fiber, vitamins, minerals, and unsaturated fatty acids. Compared with starch-based gluten-free ingredients, chickpea flour can improve the protein and fiber contents of gluten-free bakery and snack products. Its water-binding and structure-forming properties also support its use in products such as bread, biscuits, crackers, and chips (Melini et al., 2017; Vinod et al., 2023). Previous studies have demonstrated that chickpea flour can be successfully used as the principal ingredient in gluten-free crackers and can provide acceptable physical, textural, and sensory characteristics (Tomić et al., 2022).

In parallel with the development of nutrient-rich foods, the valorization of agro-industrial by-products has become increasingly important for reducing food-processing waste and promoting sustainable production. Cold-pressed oil production generates considerable quantities of seed cake, which is often used as animal feed or discarded despite containing valuable nutrients and bioactive constituents. Incorporating these by-products into food formulations can reduce waste while creating value-added functional ingredients.

Black cumin (*Nigella sativa* L.) is an oilseed traditionally used as a spice and valued for its characteristic aroma and bioactive components. After cold-press oil extraction, the remaining black cumin seed cake retains substantial amounts of protein, dietary fiber, residual oil, minerals, phenolic compounds, and other bioactive constituents (Zaky et al., 2021; Krawęcka et al., 2022). Black cumin seed cake has consequently attracted attention as a potential functional ingredient for the enrichment of bakery products, pasta, gluten-free foods, muffins, and fermented beverages. Its incorporation may increase the protein, dietary fiber, mineral, and antioxidant contents of food products while supporting the sustainable utilization of an oil-processing by-product (Krawęcka et al., 2022; Yabacı Karaoğlan, 2025). Despite its nutritional and sustainability advantages, the use of black cumin seed cake may also modify product quality. Its naturally dark color can decrease product lightness, while its fiber, protein, and residual lipid fractions can affect water absorption, dough structure, expansion, hardness, and fracture behavior. Moreover, the characteristic aroma and slightly bitter or intense flavor of black cumin may restrict its use at high incorporation levels (Yabacı Karaoğlan, 2025). Therefore, determining an appropriate incorporation level is important for balancing functional enrichment with technological quality and sensory acceptance. Oilseed press cakes have previously been evaluated in chickpea-based gluten-free products. Tomić et al. (2022), for example, demonstrated that pumpkin seed press cake could be successfully combined with chickpea flour to produce gluten-free crackers with improved nutritional and functional characteristics. Similarly, black cumin seed cake has been incorporated into pasta and bakery formulations, where it significantly affected product composition and technological properties (Krawęcka et al., 2022). Nevertheless, information concerning the use of cold-pressed black cumin seed cake in gluten-free chickpea chips, particularly its effects on color, physical dimensions, texture, and sensory acceptance, remains limited.

Therefore, the objective of the present study was to develop gluten-free chickpea chips enriched with cold-pressed black cumin seed cake powder at incorporation levels of 1, 2, 3, 4, and 5%. The effects of replacing chickpea flour with black cumin seed cake powder on the instrumental color, physical properties, textural characteristics, and sensory acceptability of the chips were investigated. The study also aimed to identify an appropriate incorporation level that would enable the valorization of black cumin seed cake without adversely affecting the technological and sensory quality of the final product.

MATERIAL AND METHODS

Materials

Chickpea flour, salt, garlic powder, red pepper powder, and cumin were obtained from a local retail market in Konya, Türkiye. Black cumin (*Nigella sativa* L.) seed cake, which remained after cold-press oil extraction, was obtained from (Superex Supercritical, Konya, Türkiye). Before use, the seed cake was ground using a laboratory mill and passed through a 300 µm sieve to obtain a uniform powder. All ingredients were stored under dry conditions at room temperature until use.

Experimental Design

Six gluten-free chickpea chip formulations were prepared: a control without black cumin seed cake powder and five formulations containing 1, 2, 3, 4, and 5% (w/w) seed cake powder. Black cumin seed cake powder was incorporated by replacing the corresponding amount of chickpea flour. The quantities of salt, garlic powder, red pepper powder, and cumin were kept constant in all formulations.

Production of Gluten-Free Chickpea Chips

Gluten-free chickpea chips were produced using a modified version of the method described by Aslan et al. (2023). Chickpea flour, black cumin seed cake powder, salt, garlic powder, red pepper powder, and cumin were mixed using a planetary mixer (Hobart N50; Hobart Canada Inc., Ontario, Canada). Water was gradually added during mixing until a homogeneous, firm, and workable dough was obtained. Because the water absorption capacity of the formulations varied depending on the seed cake level, the amount of water was adjusted according to the consistency of each dough.

The resulting dough was wrapped in cling film and rested in the dark at room temperature for 30 min to ensure adequate hydration. After hydration, the dough was divided into portions weighing 2.5 g. Each dough portion was compressed and baked between two Teflon-coated plates preheated to 300 °C for 2.5 min. The chips were subsequently cooled to room temperature (25 ± 2 °C), sealed in polyethylene bags, and stored at room temperature until analysis.

Color analysis

The surface color of the chickpea chip samples was measured using a Minolta CR-400 colorimeter (Minolta Camera Co., Ltd., Osaka, Japan). The results were expressed according to the CIELAB color system as L* (lightness; 0 = black and 100 = white), a* (redness-greenness), and b* (yellowness-blueness) (Francis, 1998).

The saturation index (SI), representing color intensity, was calculated using Equation (1):

$$SI = \sqrt{a^{*2} + b^{*2}}$$

The hue angle (h°) was calculated from the a* and b* values using Equation (2), with quadrant correction where necessary:

$$h^{\circ} = \tan^{-1}\left(\frac{b^{*}}{a^{*}}\right)$$

For samples with a* < 0 and b* > 0, 180° was added to the calculated value.

Determination of Physical Properties

The diameter and thickness of the chip samples were measured using a digital caliper with a precision of 0.01 mm (Mitutoyo, Japan). Measurements were performed at five different positions for each sample, and the mean values were reported in millimeters.
The spread ratio was calculated as the ratio of chip diameter to chip thickness according to Equation (3) (AACC, 2000):

$$Spread\ ratio = \left(\frac{Diameter\ (mm)}{Thickness\ (mm)}\right)$$

Instrumental Texture Analysis

The textural properties of the chickpea chips were determined 2 h after baking using a TA-XT2i Texture Analyzer (Stable Micro Systems, Surrey, UK) equipped with a three-point bending rig (HDP/3PB). The instrument was operated under the following conditions: 30 kg load cell, 1.0 mm/s pre-test speed, 3.0 mm/s test speed, 10.0 mm/s post-test speed, 5 mm test distance, and 50 g trigger force.
Hardness was defined as the maximum force required to break the sample and was expressed in grams. Fracturability was determined from the distance at which the first major break occurred on the force-distance curve and was expressed in millimeters. Measurements were performed on five individual chips from each formulation.

Sensory Evaluation

Sensory evaluation was conducted with 20 untrained panelists from Necmettin Erbakan University (Konya, Türkiye) who regularly consumed snack and bakery products. The samples were coded with randomly assigned three-digit numbers and presented to the panelists in randomized order under ambient conditions. Color appearance, odor, taste, crispness, and overall acceptability were evaluated using a 7-point hedonic scale (1 = dislike extremely and 7 = like extremely). Drinking water was provided for palate cleansing between samples.

Statistical analysis

All analyses were carried out in duplicate. The data were analyzed using JMP statistical software, version 10.0 (SAS Institute Inc., Cary, NC, USA). One-way analysis of variance (ANOVA) was used to determine the effect of black cumin seed cake incorporation level on the measured quality characteristics. When the effect was statistically significant, mean values were compared using Tukey's honestly significant difference (HSD) test. Differences were considered statistically significant at $p < 0.05$. The results were expressed as mean ± standard deviation.

RESULTS AND DISCUSSION

Color Properties of Gluten-Free Chickpea Chips

The color properties of the gluten-free chickpea chips enriched with black cumin seed cake powder are presented in **Figure 1.** Color is an important quality attribute of snack products because it directly influences product appearance and initial consumer perception. The incorporation of black cumin seed cake powder significantly affected all measured color parameters of the chips ($p < 0.05$).

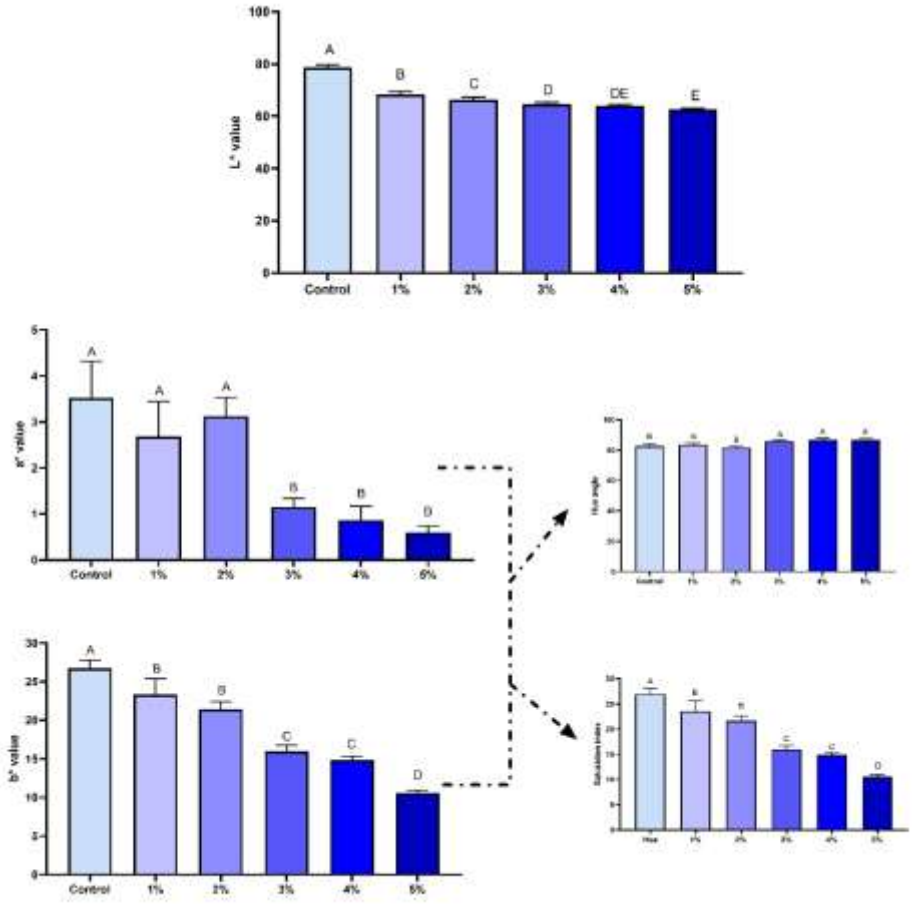

Figure 1. Effect of black cumin seed cake powder incorporation on the L*, a*, b*, hue angle, and saturation index values of gluten-free chickpea chips. Bars represent mean ± standard deviation. Different uppercase letters above the bars indicate significant differences among formulations according to Tukey's HSD test ($p < 0.05$).

The control chips exhibited the highest L* value, approximately 78, indicating a comparatively light-colored product. Increasing the black cumin seed cake level from 1 to 5% caused a progressive and significant reduction in L*, with the value decreasing to approximately 62 in the formulation containing 5% seed cake. The control and all enriched formulations were assigned to different statistical groups, except for the partial similarity observed between the 4 and 5% formulations. These findings demonstrated that even a relatively low level of black cumin seed cake produced a noticeable darkening of the chickpea chips. The reduction in lightness was primarily associated with the intrinsically dark color of black cumin seed cake. The high baking temperature may also have contributed to color development through non-enzymatic browning reactions. Różyło et al. (2021) similarly found that the addition of black cumin pressing waste progressively reduced the L* value of gluten-free starch bread, confirming the strong influence of this dark-colored by-product on product appearance. A comparable effect has also been reported in chickpea-based gluten-free crackers enriched with pumpkin seed press cake, in which the type and level of press-cake flour markedly affected instrumental color (Tomić et al., 2022). These findings support the view that the color response observed in the present chips resulted from both the replacement of light-colored chickpea flour and the thermal behavior of seed-cake components during baking.

The a* values of the chips also decreased with increasing seed cake incorporation. The control, 1%, and 2% formulations exhibited comparatively higher a* values and were statistically similar to one another ($p > 0.05$). However, the a* value decreased sharply when the seed cake level reached 3%, and the formulations containing 3–5% seed cake formed a separate statistical group. This decrease indicated a reduction in the red component of the chip surface color. A similar concentration-dependent trend was observed for b*. The control chips had the highest b* value, approximately 26–27, whereas the 5% seed cake formulation had the lowest value, approximately 10–11. Incorporation of only 1% seed cake significantly reduced b*, while further reductions occurred as the substitution level increased. The decreased b* values indicated that the characteristic yellow color of chickpea flour became less dominant as the proportion of the dark-colored seed cake increased.

The saturation index (SI) progressively decreased from approximately 27 in the control to approximately 10–11 in the 5% formulation. This result indicated a gradual reduction in color intensity or chromaticity. The decrease in SI was consistent with the simultaneous reductions in a* and b*. In contrast, the hue angle increased slightly at seed cake levels of 3% and above. The control, 1%, and 2% formulations were statistically similar, while the samples containing 3–5% seed cake formed a second statistical group with higher hue-angle values. Therefore, black cumin seed cake not only darkened the chips but also shifted their overall surface color toward a less saturated and more neutral appearance. Overall, replacing the relatively light-colored chickpea flour with black cumin seed cake produced darker and less saturated chips. This behavior agrees with the darkening reported for black cumin pressing-waste-enriched starch bread (Różyło et al., 2021), while the study of Tomić et al. (2022) demonstrates that press-cake enrichment can produce ingredient-specific color changes in chickpea-based gluten-free crackers. The effect of this visual change on product preference was therefore considered together with the sensory color-appearance scores in the present study.

Physical Properties of Gluten-Free Chickpea Chips

The diameter, thickness, and spread ratio values of the gluten-free chickpea chips are presented in **Figure 2.** Black cumin seed cake incorporation had a limited effect on the physical dimensions of the products. The diameter of the control chips was approximately 40.8 mm. The diameter remained statistically unchanged at the 1% incorporation level, whereas a slight increase was observed with further increases in black cumin seed cake. The formulations containing 3, 4, and 5% seed cake exhibited the highest diameter values, approximately 42–43 mm, and were statistically similar to one another. The 2% formulation showed an intermediate value and did not differ significantly from either the lower- or higher-incorporation groups. The slight increase in diameter may have resulted from changes in dough consistency and deformation during compression. Yüksel et al. (2025) showed that cold-pressed black cumin seed meal altered dough rheological behavior, particularly extensograph energy and extensibility, although farinograph water absorption did not differ significantly from the control. Tomić et al. (2022) likewise demonstrated that replacing chickpea flour with seed press-cake flour modified the physicochemical behavior of gluten-free cracker formulations. Because all dough portions in the present study had the same mass and were compressed under the same conditions, formulation-related differences in dough deformability may have contributed to lateral expansion. However, water was added according to dough workability rather than at a fixed level; consequently, the contributions of ingredient composition and formulation-specific water addition cannot be separated. In contrast to diameter, chip thickness was not significantly affected by black cumin seed cake incorporation ($p > 0.05$). The thickness values were approximately 1.6–1.9 mm, and all formulations were included in the same statistical group. Although the 5% formulation showed a numerically lower mean thickness than the other samples, the relatively high variability prevented this difference from reaching statistical significance.

The spread ratio showed a numerical increase from approximately 21.5 in the control to 26 in the formulation containing 5% black cumin seed cake. However, no statistically significant differences were observed among the formulations ($p > 0.05$). The numerical increase in spread ratio at the highest incorporation level resulted from the combination of a slightly greater diameter and a lower mean thickness. Nevertheless, the statistical results demonstrated that replacing up to 5% of chickpea flour with black cumin seed cake did not adversely affect the overall shape or dimensional stability of the chips. These findings are technologically important because major changes in diameter, thickness, or spread ratio could result in nonuniform baking, undesirable appearance, and inconsistencies in packaging. The absence of substantial changes in these parameters indicated that black cumin seed cake powder could be incorporated at levels of up to 5% without requiring major modification of the shaping and baking process.

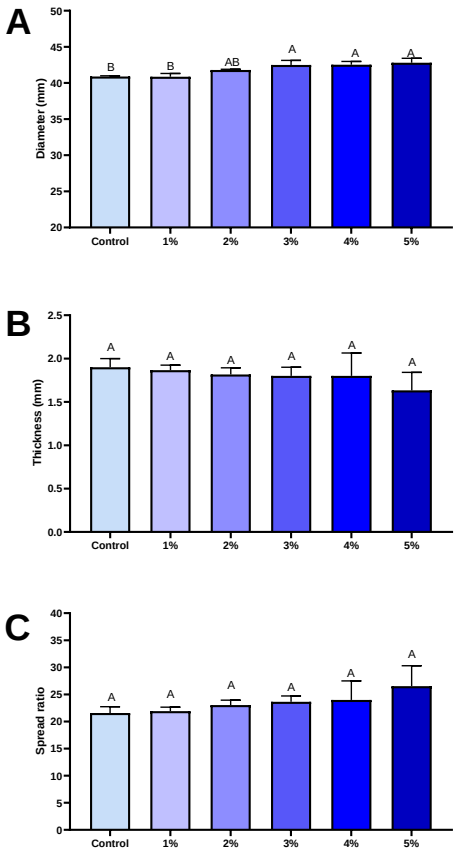

Figure 2. Effect of black cumin seed cake powder incorporation on the diameter, thickness, and spread ratio of gluten-free chickpea chips. Bars represent mean ± standard deviation. Different uppercase letters above the bars indicate significant differences among formulations according to Tukey's HSD test ($p < 0.05$).

Textural Properties of Gluten-Free Chickpea Chips

The hardness and fracturability values of the gluten-free chickpea chips are shown in Figure 3. Black cumin seed cake incorporation caused a progressive reduction in hardness. The control chips exhibited the highest value, approximately 2,400 g, whereas the 5% formulation displayed the lowest value, approximately 950 g. The control was significantly harder than the samples containing 3-5% seed cake, while the 1 and 2% formulations showed intermediate values. A

hardness-reducing effect of black cumin pressing waste was also observed by Różyło et al. (2021) in gluten-free starch bread. In chickpea-based gluten-free crackers, Tomić et al. (2022) further showed that the origin and level of seed press-cake flour can substantially modify product texture. In the present formulation, dilution of the chickpea starch matrix together with the fiber, protein, and residual lipid fractions of the seed cake may have contributed to the reduction in breaking force. Nevertheless, because dough rheology and microstructure were not measured, the mechanism responsible for this change cannot be conclusively established.

The direction and magnitude of textural changes caused by press-cake ingredients depend on the food matrix, substitution level, water content, and processing conditions. Krawęcka et al. (2022) reported that black cumin cake affected the processing and texture of pasta, whereas Różyło et al. (2021) observed reductions in hardness, springiness, and chewiness in gluten-free starch bread. Tomić et al. (2022) also documented formulation-dependent textural responses in chickpea-based crackers containing pumpkin seed press cake. Despite the marked reduction in hardness in the present study, fracturability remained statistically unchanged ($p > 0.05$), with values within a narrow range of approximately 33-34 mm. Thus, black cumin seed cake reduced the maximum breaking force without significantly changing the instrumental fracture distance. Sensory crispness nevertheless declined at the higher incorporation levels, indicating that instrumental fracture distance alone did not fully represent perceived crispness.

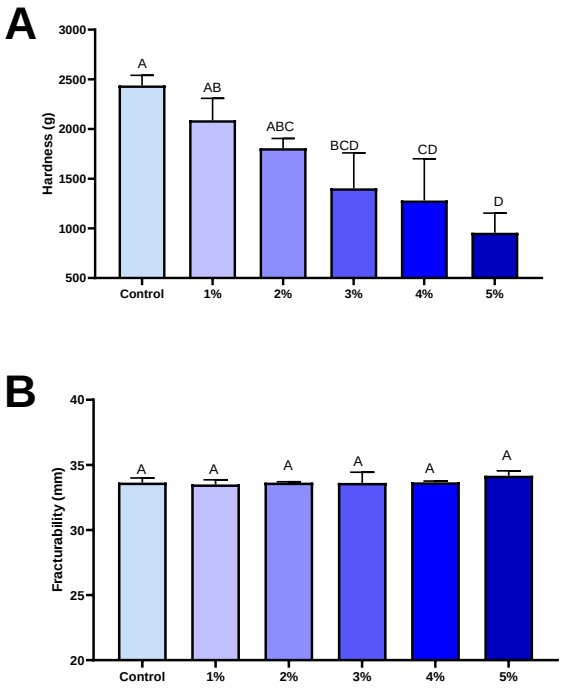

Figure 3. Effect of black cumin seed cake powder incorporation on the hardness (A) and fracturability (B) of gluten-free chickpea chips. Bars represent mean ± standard deviation. Different uppercase letters above the bars indicate significant differences among formulations according to Tukey's HSD test ($p < 0.05$).

Sensory Properties of Gluten-Free Chickpea Chips

The sensory scores of gluten-free chickpea chips enriched with black cumin seed cake powder are presented in Figure 4. All formulations received mean scores above 5 on the 7-point hedonic scale for color appearance, odor, taste, crispness, and overall acceptability. Thus,

although increasing the seed cake level caused reductions in some sensory scores, none of the formulations was evaluated negatively by the panelists.

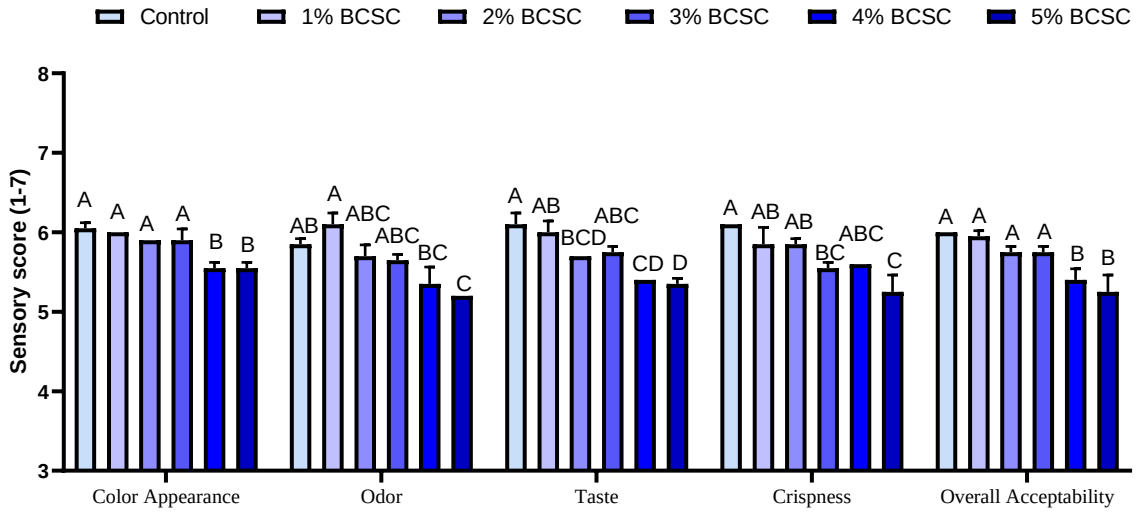

Figure 4. Sensory scores of gluten-free chickpea chips containing different levels of black cumin seed cake (BCSC) powder. Samples were evaluated for color appearance, odor, taste, crispness, and overall acceptability using a 7-point hedonic scale. Bars represent mean ± standard deviation. Different uppercase letters within each sensory attribute indicate significant differences among formulations according to Tukey's HSD test ($p < 0.05$).

The color appearance scores generally decreased with increasing black cumin seed cake incorporation. The control and the formulations containing 1, 2, and 3% seed cake received similar scores of approximately 5.8–6.1 and did not differ significantly from one another ($p > 0.05$). By contrast, the 4 and 5% formulations received significantly lower scores of approximately 5.5. This decrease was consistent with the instrumental color results, which showed progressive reductions in L*, a*, b*, and saturation index values. Therefore, the darker and less saturated appearance produced at higher seed cake concentrations was also perceived by the panelists. Nevertheless, the scores of the 4 and 5% formulations remained above the midpoint of the hedonic scale, indicating that their darker appearance was still reasonably acceptable.

Odor scores showed a similar concentration-dependent tendency. The formulation containing 1% black cumin seed cake received the highest odor score, slightly exceeding that of the control. This finding suggests that a low concentration of the seed cake contributed a characteristic aroma that was favorably perceived. However, odor scores gradually decreased as the incorporation level increased, and the 5% formulation received the lowest score. Black cumin contains characteristic volatile compounds, particularly those associated with its essential-oil fraction, which can provide a desirable aroma at low concentrations but may become dominant at higher levels. The statistical grouping showed substantial overlap among the control and intermediate formulations, whereas the difference was most evident between the 1 and 5% samples.

Black cumin seed cake incorporation also significantly affected taste scores ($p < 0.05$). The control and 1% formulations received the highest scores, approximately 6.0–6.1, while the 2 and 3% formulations showed moderately lower values. Taste scores declined further in the 4 and 5% formulations, which formed the lowest statistical groups. The reduction observed at higher substitution levels may be associated with the intense characteristic taste of black cumin

and the increased contribution of phenolic and other flavor-active compounds remaining in the seed cake after cold pressing. Previous research has similarly demonstrated that increasing black cumin concentration can reduce the sensory scores of enriched bakery products, despite improving their nutritional and functional properties (Awulachew et al., 2025). Therefore, the amount incorporated into a snack formulation should be carefully controlled to balance functional enrichment with taste acceptance.

Crispness scores decreased progressively as the black cumin seed cake level increased. The control received the highest score, approximately 6.1, whereas the 5% formulation received the lowest score, approximately 5.2. The control and lower seed cake levels showed overlapping statistical groups, while the highest incorporation level differed significantly from the control. This sensory trend partly agreed with the instrumental texture results. Instrumental hardness decreased markedly with increasing seed cake incorporation, indicating that the enriched chips required less force to break. Although fracturability remained statistically unchanged, panelists perceived some reduction in crispness at the higher substitution levels. This difference is reasonable because instrumental fracture measurements quantify specific mechanical properties, whereas sensory crispness is a complex perception involving sound, brittleness, hardness, and the breakdown behavior of the product during mastication.

Overall acceptability was highest for the control and the formulation containing 1% black cumin seed cake, with scores close to 6.0. The 2 and 3% formulations received slightly lower scores but remained statistically similar to the control. A significant reduction was observed at the 4 and 5% incorporation levels, which received scores of approximately 5.4 and 5.2, respectively. The decline in overall acceptability at these levels was consistent with the lower color appearance, taste, odor, and crispness scores. Despite these reductions, all samples had overall acceptability scores above 5, demonstrating that chickpea chips containing up to 5% black cumin seed cake remained sensorially acceptable. However, the 1–3% formulations provided a better balance between seed cake incorporation and consumer acceptance. In particular, the 3% formulation may be considered the highest suitable enrichment level without a significant loss of overall acceptability compared with the control. By contrast, although the 4 and 5% formulations contained greater quantities of the value-added ingredient, their darker color, more pronounced flavor, and lower perceived crispness reduced panelists' preference.

Overall, the sensory findings showed that black cumin seed cake could be successfully incorporated into gluten-free chickpea chips at low-to-moderate levels. Considering the sensory results together with the instrumental measurements, an incorporation level of up to 3% appears most appropriate for maintaining consumer acceptance while enabling the valorization of this cold-pressed oil by-product.

CONCLUSION

This study demonstrated that cold-pressed black cumin seed cake can be successfully utilized as a value-added ingredient in the production of gluten-free chickpea chips. Its incorporation at levels of 1–5% significantly affected the color, texture, and sensory properties of the chips, while causing only limited changes in their physical dimensions. Increasing the black cumin seed cake level resulted in darker and less saturated products, as indicated by the reductions in L*, a*, b*, and saturation index values. The diameter increased slightly, whereas thickness and spread ratio remained statistically unchanged. Hardness progressively decreased with increasing seed cake incorporation, while fracturability was not significantly affected. These results indicated that the enriched chips became easier to bite without losing their characteristic brittle structure.

Although all formulations received sensory scores above 5 on the 7-point hedonic scale, the samples containing 4 and 5% black cumin seed cake had significantly lower overall acceptability scores. In contrast, incorporation levels of up to 3% maintained overall

acceptability comparable to that of the control. Therefore, 3% black cumin seed cake can be recommended as the most suitable maximum incorporation level for achieving functional enrichment without adversely affecting the sensory quality of gluten-free chickpea chips.

Overall, the use of black cumin seed cake in chickpea-based chips offers a promising strategy for the valorization of a cold-pressed oil-processing by-product and the development of more sustainable gluten-free snack products. Further studies should investigate the nutritional composition, bioactive compounds, antioxidant activity, storage stability, and consumer acceptance of the developed chips.

ABSTRACT

The genus *Ziziphus* L. belongs to the family Rhamnaceae and is widely distributed throughout tropical and subtropical regions of the world. Species of this genus are of considerable economic, nutritional, and medicinal importance. The present study aimed to investigate the anatomical characteristics of the leaf and stem tissues, with particular emphasis on the cellular inclusions and internal tissue organization, in *Ziziphus* species naturally distributed in Iraq. A field survey was conducted during which four species *Ziziphus jujuba*, *Z. mauritiana*, *Z. nummularia* and *Z. spina-christi*, were collected and examined. The outcome showed cross-sections of stem appeared a difference characters among the taxa in the shape, in *Z. lotus* and *Z. nummularia* was oval, *Z. mauritiana* elliptical, and circular in the species *Z. spina-christi*. epidermis consist of a single cells, oval in shaped, covered by trichomes in species *Z. mauritiana* only, and the cortex is featured into angular collenchyma tissue, and the second of the tissues is the parenchyma tissue. Druces crystals diffusion in the phloem and xylem. in the *Z. jujuba* pith there were many lysigenous intercellular spaces, it was formed of vacuoles, and in the species, *Z. nummularia*, these vacuoles were specialized intercellular spaces, The LS of the leaf midrib appeared a in the stomata scattered only in the abaxial epidermis with anonmocytic type except *Ziziphus jujuba* was anisocytic type. The unglandular trichomes are distributed on the abaxial, they are uniseriate-unicellular, excluding *Z. nummularia* . The druces crystals diffuse in the adaxial and abaxial. Comparative anatomical analyses revealed clear interspecific variations in anatomical characters, demonstrating the taxonomic value of these traits for distinguishing the studied species.
KEYWORDS: *Ziziphus,* Rhamnaceae, Comparative anatomy, Iraq sider.

INTRODUCTION

The jujube tree, scientifically known as *Ziziphus*, is a perennial and blessed desert tree belonging to the Rhamnaceae family; it is renowned for its high tolerance to drought and salinity and is native to the Arabian Peninsula and North Africa (Jin, 2018). The jujube produces delicious, spherical fruits rich in minerals, and its leaves, flowers, and fruits are used in traditional medicine to treat various ailments. The tree is also considered an important environmental heritage site (Joker, 2003).It is an evergreen, thorny, and densely leafy tree that can reach several meters in height. Its small, fleshy fruits (berries) turn from green to yellow, then red and reddish-brown when ripe, and are eaten fresh or dried (AI-Turki, 2004). It has numerous health benefits as its fruits are rich in minerals such as calcium and iron (Godini, 2009).The fruits are used as an appetite stimulant, blood purifier, and are beneficial for the digestive system. Traditionally, the ground leaves of the jujube tree are used as a natural hair

and skin wash, and its wood is used in construction and as fuel (Chaudhary, 2001). It also has significant environmental importance as it is considered one of the best trees for soil stabilization and combating desertification, and it acts as a windbreak (Miller and Morris, 1988). Historically, the jujube tree is mentioned in ancient cultures and holy books, and it is considered a tree of hot and arid regions (Al-Farhan, 2000). The jujube tree an evergreen tree with abundant branching, reaching a height of 15 meters, the branches are long, smooth, white, and ascending upwards, spreading in all directions (Migahid, 1996). The leaves are alternate, and the branches are thorny and numerous, the flowers are grayish-yellow and appear in early summer in small, axillary inflorescences, the fruit is spherical, yellow, and edible. It is a tree traditionally cultivated in many regions for its shade, its valuable wood, and its edible fruit, it thrives in direct sunlight and is very fast-growing and propagates by seed (Wood, 1997 and Guo *et al.*, 2020).

This study aims to compare the species of Sidr anatomically to confirm the characteristics of each species and to discriminate among the tissues in terms of living and non-living contents, intercellular spaces, and other important components in plant cells and tissues

MATERIALS AND METHODS

The plants of the genus *Ziziphus* were collected from the Salman Pak located about 30 kilometers southeast of central Baghdad, the coordinates: 33°06' N, 44°35' E. We collected 4 taxa (*Ziziphus jujube, Ziziphus mauritiana, Ziziphus nummularia*, and *Ziziphus spina-christi*) (Figure 1). The parts of the plant samples were preserved in the 70% ethyl alcohol.

The cross-sections of the parts including stems and leaves were set by hand sectioning following by (Al-Khazraji and Aziz 1989). with some modifications according to (AL-Hadeethi *et al.*, 2020).

RESULTS AND DISSECTIONS

CROSS SECTION OF STEM

Stem cross-sections appeared a difference characters among the taxa in the shape, when the shape of the stem in the species *Z. lotus* and *Z. nummularia* was oval, in the species *Z. mauritiana* elliptical, and circular in the species *Z. spina-christi*. In all taxa the epidermis consist of a single cells, oval in shaped, covered by trichomes in species *Z. mauritiana* only, and the cortex is featured into angular collenchyma tissue, and the second of the tissues is the parenchyma tissue. The vascular bundle was in secondary growth stage, and can show the ring pours type of vessels, druces crystals diffusion in the phloem and xylem. the pith region located in the center consist from a parenchyma tissue in all taxa (Table 1 and Fig. 2), in the *Z. jujuba* pith there were many lysigenous intercellular spaces, it was formed of vacuoles, and in the species, *Z. nummularia*, these vacuoles were specialized intercellular spaces, Sharm and Gaur (2013) shared that the stem are secondary growth and and the epidermis is thick, lignified and beneath this lies a cortex, and the vascular bundles in cross sections show rings of xylem and phloem.

Longitudinal sections of leaves

The longitudinal-section of the leaf midrib appeared a crescent shape in all taxa distinguishes to epidermis, cortex, and vascular bundle. The vascular bundle central collateral, open, and crescent shape consists of xylem and phloem (Table 1 and Fig. 3), the results agree with (Arndt *et al.*, 2001) who founded the leaves of *Ziziphus* taxa are simple, and alternate. The epidermis of leaves (Table 1 and Fig. 4) consist from ordinary epidermis cells straight walls in all the taxa, and in the abaxial epidermis were sinuous walls in all taxa except the species *Z. mauritiana* are straight, also the stomata scattered only in the abaxial epidermis and the adaxial epidermis free of it and this results agree with (El Maaiden *et al.*, 2020) that referred there are often

stomata sunken on the lower (abaxial) surface to minimize transpiration. The stomata was anonmocytic type in all taxa except the species *Ziziphus jujuba* was anisocytic type consist of three subsidiary cells one of its small and the other two cells largest from it. The unglandular trichomes are distributed on the abaxial epidermis, they are uniseriate-unicellular, appeared in all taxa epidermis excluding the epidermis of *Z. nummularia* do not have trichomes also the druces crystals diffuse in the adaxial and abaxial epidermis. These results be acceptable with (Zarinkamar, 2006 and Wang, 2025) who mention that the Sider, which features a very thick epidermis covered by a thick cuticle to protect the cortex, which is packed with parenchyma cells, and the xylem is diffuse-porous. and contain druse crystals

Table 1. Stem and leaf characteristics of the studied plant measured in micrometers

No.	Taxon	Stem				leaf					
		epidermis	cortex		Vascular bundles	Abaxial Stomata		Midrib			
			Collenchyma layers	Parenchyma		Dimensions		Epidermis	Cortex	Vascular bundle	Shape
						Length	Width				
1	*Z. JUJUBE*	47.2-58.5 (56.2)	2	59.7-65.2 (62.3)	139.1-144.3 (140.5)	55.6-63.5 (61.3)	48.1-55.5 (50.5)	22.9-26.5 (24.3)	54.4-66.5 (61.5)	131.1-139.2 (133.5)	Ovate
2	*Z.MAURITIANA*	45.1-52.5 (50.7)	3-4	44.7-53.2 (50.5)	122.5-130.1 (126.7)	54.5-62.1 (58.4)	48.5-58.4 (55.7)	25.4-28.1 (27.5)	58.9-65.5 (64.1)	113.1-120.1 (118.5)	crescent
3	*Z.NUMMULARIA*	33.1-39.5 (38.5)	1-2	45.2-55.5 (50.1)	166.5-178.4 (177.4)	47.6-53.4 (50.2)	24.6-34.1 (28.5)	30.1-36.2 (33.5)	54.2-60.1 (55.7)	174.1-180.3 (177.5)	crescent
4	*Z.SPINACHRISTI*	50.2-61.1 (60.4)	2-3	33.1-39.5 (38.5)	147.5-155.4 (153.5)	49.3-58.1 (57.5)	35.4-40.5 (37.1)	33.9-37.5 (35.1)	55.5-63.4 (62.7)	112.2-120.5 (116.5)	Ovate

Figure 1: the outline shape of the species studied.

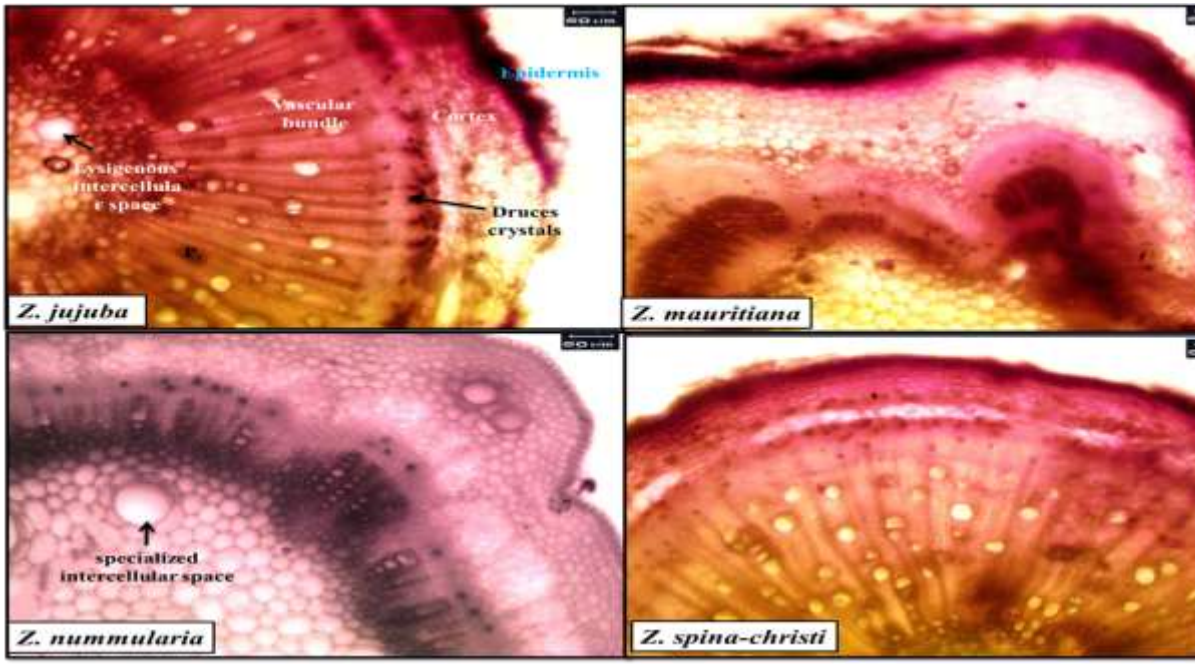

Figure 2: the stems cross-sections in the taxa,

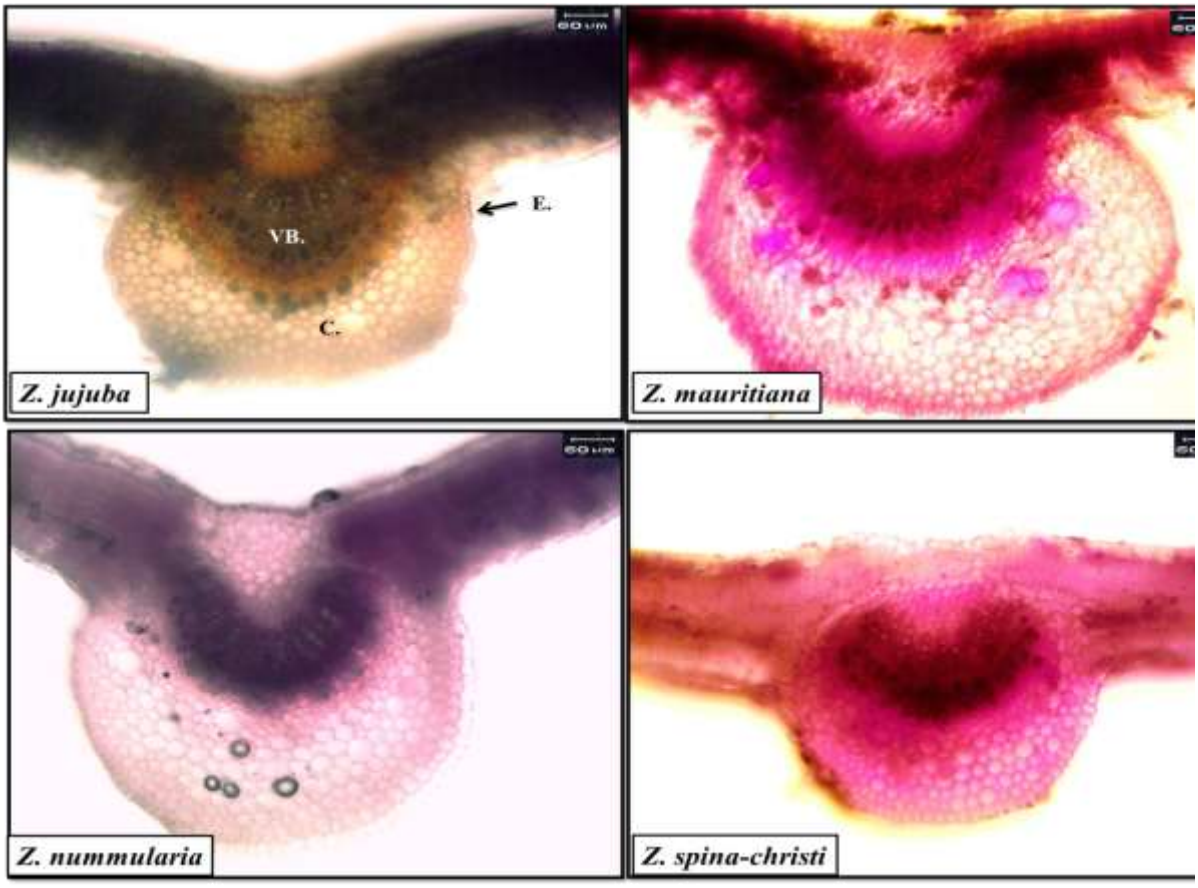

Figure 3: the midrib of the leaf in the species studied.

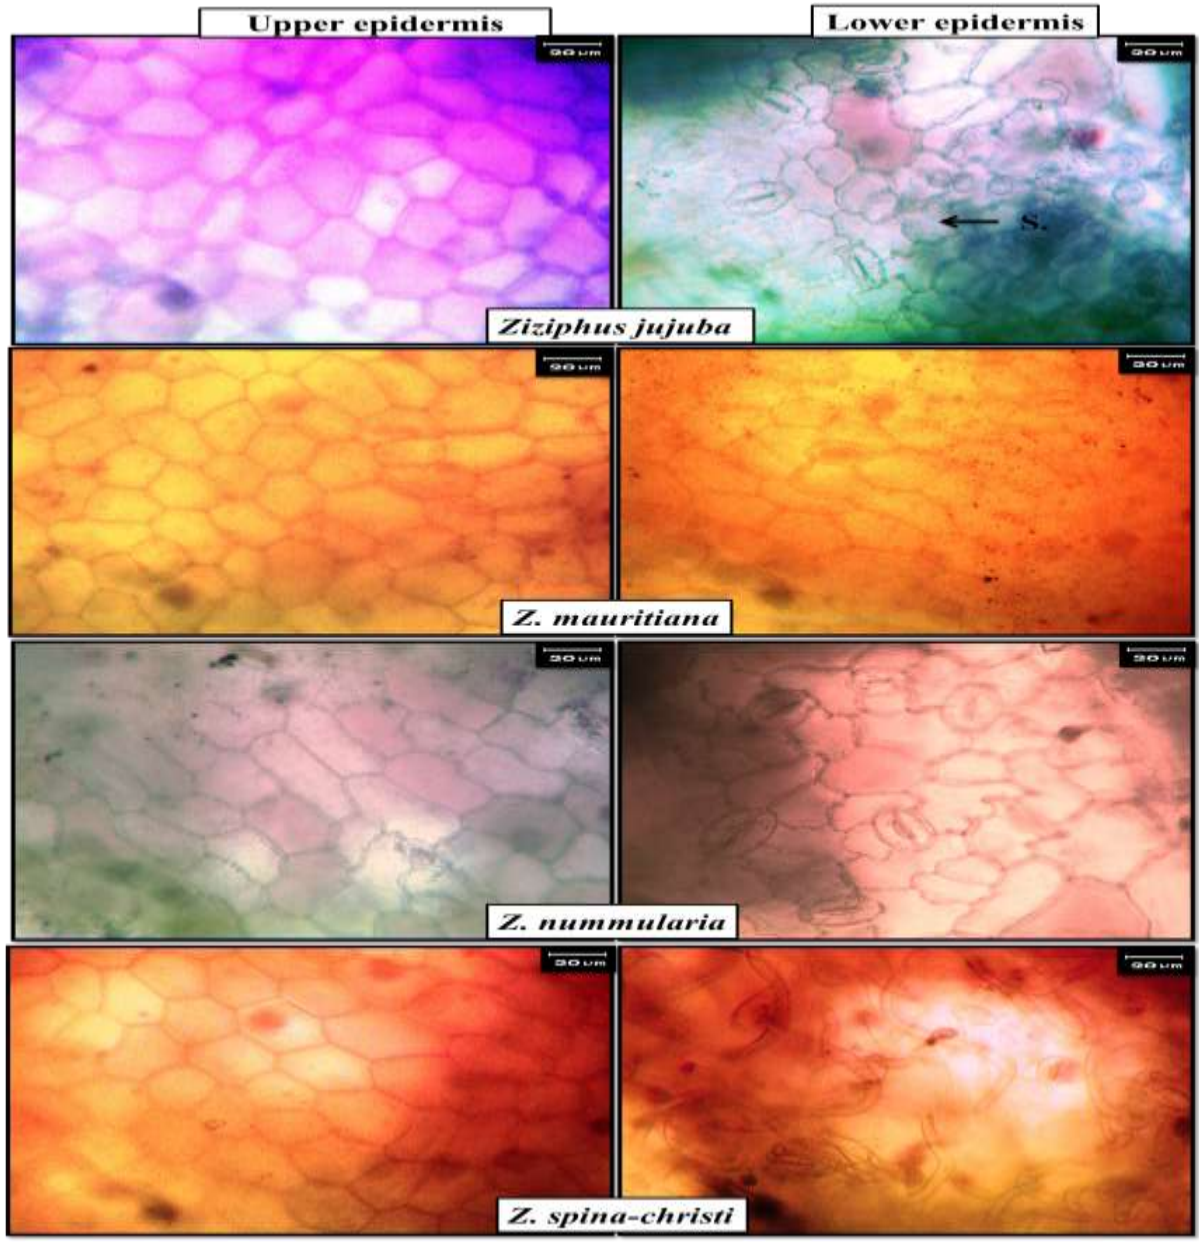

Figure 4: the epidermis of the leaf in the taxa appears the adaxial and Abaxial epidermis.

CONCLUSIONS

Variations were observed among the studied species, primarily regarding cross-sectional shape and the presence of trichomes in a specific species. Conversely, the leaf midrib region exhibited structural similarity, displaying a crescent shape—a feature consistent with the anatomical characteristics observed in the stem. The upper epidermis of all species was characterized by cells with straight walls, whereas the cells of the (lower) epidermis lacked straight walls and exhibited undulate patterns. Stomata were restricted to the lower (abaxial) surface, and the stomatal pattern remained consistent across all species; this pattern reflects interspecific variation while simultaneously preserving shared characteristics and affinities at the genus level.

ABSTRACT

Plant genetic resources (PGR) constitute a fundamental component of agricultural biodiversity and include genetic material of actual or potential value for food and agriculture. Their effective conservation and sustainable utilization require not only appropriate storage conditions but also a reliable, standardized and continuously updated documentation system. The Bulgarian system for plant genetic resources documentation was developed as an integrated information framework supporting the conservation, management, characterization, evaluation, exchange and utilization of germplasm maintained in the National Genebank at the Institute of Plant Genetic Resources "Konstantin Malkov" – Sadovo. The documentation system integrates passport information, taxonomic and geographical data, collecting and acquisition information, biological status, storage conditions, regeneration, evaluation and characterization data, as well as information related to the distribution and use of accessions. Its structure follows the FAO/Bioversity Multi-Crop Passport Descriptors and the requirements of the European Search Catalogue for Plant Genetic Resources (EURISCO), thereby providing compatibility and interoperability with European and international information networks. The system incorporates functional modules for accession registration, passport data management, expedition documentation, accession searching, storage and regeneration management, and controlled data access. An important feature of the system is the distinction between a public interface for researchers and other users and a protected management environment for authorized genebank specialists. Open access to passport information, including mobile access, increases the visibility and usability of Bulgarian plant genetic resources. The system also supports the National Inventory of plant genetic resources and the transfer of validated and harmonized data to EURISCO. The documentation framework provides traceability of accessions from acquisition and registration through storage, regeneration, characterization and distribution. Its implementation contributes to the modernization and digitalization of genebank management and strengthens the role of the Bulgarian National Genebank as a national and international information centre for plant genetic resources.

Keywords: Accession, GeneBankSystem, Descriptors, Expedition, Introduction, Crop breeding.

INTRODUCTION

Plant genetic resources for food and agriculture represent an essential component of agricultural biodiversity and provide the genetic basis for crop improvement, adaptation and sustainable food production. The diversity of crops, traditional varieties, landraces, breeding materials and crop wild relatives provides genetic variation that may be valuable for adaptation to changing environmental conditions, emerging pests and diseases, and new production systems. The

conservation of this diversity is therefore directly associated with long-term food security and the resilience of agricultural systems (Salgotra & Chauhan, 2023).

Modern agriculture relies increasingly on a relatively limited number of high-performing cultivars. This tendency may contribute to genetic erosion and the loss of traditional varieties and locally adapted populations. Landraces and traditional populations may contain valuable characteristics associated with adaptation to local environmental conditions, disease resistance, quality traits and specific consumer preferences. Consequently, their conservation in genebanks, combined where possible with in situ and on-farm conservation, is an important component of sustainable management of agricultural biodiversity (Raggi et al., 2021).

Ex situ conservation in genebanks provides an effective mechanism for the long-term preservation of plant genetic resources. However, the biological material alone is insufficient to ensure its effective future use. The scientific and practical value of an accession depends strongly on the availability, accuracy and completeness of information associated with it. Documentation has to allow the identity, origin, biological status, storage history, reproduction, characterization and utilization of each accession to be traced throughout its conservation cycle. The documentation of plant genetic resources is therefore an integral part of genebank management (FAO, 2013; ECPGR, 2021).

The Bulgarian National Genebank, located at the Institute of Plant Genetic Resources "Konstantin Malkov" – Sadovo, maintains collections comprising local populations, traditional varieties, modern cultivars, breeding lines, genetic stocks and crop wild relatives. The collections are managed through a specialized documentation system that integrates information generated during accession acquisition, registration, conservation, regeneration, characterization, evaluation and distribution. The system was developed through long-term interdisciplinary cooperation between researchers from IPGR-Sadovo and computer scientists (Stoyanova-Doycheva et al., 2020; Malinov et al., 2025).

The development of a standardized documentation framework in Bulgaria is also closely related to European and international initiatives for harmonization and exchange of plant gene pool information (Goritschnig et al., 2024). The Bulgarian National Genebank participates in the European Search Catalogue for Plant Genetic Resources (EURISCO) and coordinates the maintenance of the Bulgarian National Inventory. The system applies the FAO/Bioversity Multi-Crop Passport Descriptors, which provide a common structure for passport information and facilitate data exchange between national and international information systems.

The importance of interoperable documentation systems has increased with the development of digital infrastructures for plant genetic resources. Standardized information enables data aggregation, validation, searching and dissemination, while open access increases the potential for researchers, breeders and other stakeholders to identify and use conserved germplasm. Digitalization is therefore not simply a technical transformation of records into databases, but a means of improving the quality, accessibility, interoperability and long-term value of plant genetic resources information (Mendel et al., 2017; Cicova et al., 2026).

The objective of this study was to describe the design, structure and current status of the Bulgarian plant genetic resources documentation system, with particular emphasis on the information architecture of the GeneBankSystem at IPGR-Sadovo, the implementation of standardized descriptors, the documentation of enrichment of collections, data management and the integration of national information with EURISCO.

MATERIAL AND METHOD

Source of information

The study was based on the methodological framework for plant genetic resources enrichment and documentation developed for the Bulgarian National Genebank at IPGR-Sadovo. The documentation procedures, database structure, passport descriptors, expedition records, GeneBankSystem modules and principles of data exchange were analyzed.

The methodological framework follows international standards, particularly the FAO/Bioversity Multi-Crop Passport Descriptors (FAO/Bioversity, 2017), the FAO Genebank Standards for Plant Genetic Resources for Food and Agriculture (FAO, 2013), and the documentation and quality-management principles promoted by European program (ECPGR).

Structure of accession documentation

The basic documentation unit is the accession. Each accession receives a unique identification – catalogue number (COLLNUMB) at registration, which remains associated with the genetic resource throughout its storage, evaluation, regeneration and utilization.

The national accession number (ACCENUMB) is generated according to the established registration system and is not reused for another genetic resource.

The passport database is structured according to the FAO/Bioversity MCPD and EURISCO standards. The main groups of descriptors include:

taxonomic identification;
accession identification;
origin and acquisition;
collecting information;
geographical coordinates;
elevation;
biological status;
breeding and ancestral information;
collecting/acquisition source;
donor information;
storage conditions;
access and exchange status;
additional identifiers and remarks.

Four core fields – NICODE (National Inventory code), INSTCODE (Institute code), ACCENUMB and GENUS, provide the essential identification structure of an accession within the EURISCO framework. Their combination is intended to ensure uniqueness of the record and reduce duplication.

The system also supports the use of persistent unique identifiers PUID (Digital Object Identifier from FAO), which provide the possibility of unambiguous identification of a genetic resource at the global level.

Documentation of collecting expeditions

Expeditions constitute an important mechanism for enriching the Bulgarian genebank collections, particularly through the collection of local varieties, landraces, farmer populations and crop wild relatives. During collecting missions, seed or vegetative material is collected together with information concerning geographic location, environmental conditions, local names, cultivation practices and traditional uses.

The documentation system includes a dedicated expedition module. It records the participants, financing organization, project, geographic and ecological characteristics of the area, and the collected accessions. Search filters facilitate retrieval of expedition records according to different criteria.

A standardized questionnaire has also been developed for interviews with farmers maintaining local varieties. The questionnaire includes expedition identification, collection date, collector, geographic location, environmental characteristics, information about the farmer, taxonomic information and local accession name, as well as information about farm size, reasons for growing the accession, production destination, seed sources and traditional uses.

GenaBankSystem (https://genbank.uni-plovdiv.net/) architecture

The Bulgarian genebank documentation system is a web-based platform designed for integrated management of information associated with the conservation, study and distribution of plant genetic resources. It consists of two interconnected functional environments.

The public component provides external users with access to accession information and searching by passport data. The protected component is available to authorized users through authentication and is intended for documentation specialists and collection curators responsible for managing accessions in the active and base collections.

The system integrates several functional modules, including:

registration of new accessions;
passport-data management;
accession searching;
expedition documentation;
storage and regeneration information;
characterization and evaluation data;
accession distribution;
data administration and updating.

This modular structure allows information associated with an accession to be maintained as a continuous record rather than as isolated datasets.

Data quality, updating and protection

Data quality is maintained through continuous updating, validation and correction. Curators are responsible for maintaining reliable information for the collections under their responsibility, while documentation specialists are responsible for the quality of passport information introduced during accession registration.

When information for a particular descriptor is unavailable and cannot be established from other sources, the field remains unfilled rather than being populated with unsupported information. Data entered into the system must remain compatible with the European exchange format to facilitate automated transfer to international information networks.

The system also provides data protection and continuity through electronic registration and archival copies maintained on primary and backup servers.

RESULTS AND DISCUSSION

Integrated documentation framework

The analysis demonstrates that the Bulgarian documentation system has evolved from a MS Access database register Phyto 2000 into an integrated digital framework for the management of plant genetic resources. GeneBankSystem connects accession identity with information generated at different stages of the conservation process.

The documentation starts with accession acquisition and registration and continues through storage, regeneration, evaluation, characterization and distribution. Consequently, the accession record represents not only a passport description but also a dynamic information resource reflecting the history and status of the genetic material.

The main categories of operational data include evaluation and characterization results, germination information, regeneration and multiplication records, storage type and distribution to users. Regular updating of these records supports the reliability and traceability of the

collections. This approach corresponds to the principle that documentation should support the complete management cycle of a genebank accession rather than only its initial registration.

Standardization of passport data

One of the main strengths of the Bulgarian system is its alignment with the FAO/Bioversity Multi-Crop Passport Descriptors and EURISCO. Standardization makes it possible to describe accessions using a common taxonomy and data structure.

The database contains descriptors for taxonomic identity such as GENUS, SPECIES, SPAUTHOR, SUBTAXA and CROPNAME. Origin and collecting descriptors include COLLNUMB, COLLCODE (Collecting institute code), ORIGCTY (Country of origin), COLLSITE (Location of collecting site), COLLDATE (Collecting date) and COLLSRC (Collecting/acquisition source). Geographic information is represented through latitude, longitude and elevation.

The biological status descriptor SAMPSTAT (Biological status) allows accessions to be differentiated as wild material, traditional cultivars/landraces, breeding and research material, genetic stocks, and advanced or improved cultivars. This provides an important basis for distinguishing different categories of genetic resources within the national collection.

The system also documents storage categories, including seed collections, medium- and long-term storage, field collections, *in vitro* collections.

Such standardization is particularly important when national data are incorporated into international catalogues. EURISCO uses standardized passport descriptors to enable data exchange and facilitate access to information on European genebank collections.

Unique identification and traceability

Traceability is a central principle of the Bulgarian documentation system. Each accession receives a unique national accession number, while additional identifiers may link it to collecting institutions, donor institutions, previous catalogue numbers or other databases. The ACCENUMB identifier is assigned at registration and cannot subsequently be reused for another accession. The system therefore preserves the identity of an accession even if the original biological material is lost. This approach provides continuity between physical germplasm and its digital representation. It also supports the identification of duplicates, the management of regeneration activities and the interpretation of research data associated with individual accessions. The use of additional identifiers, donor accession numbers and persistent identifiers creates opportunities for linking national records with other institutional and international information resources.

Documentation of plant genetic resources

A specific strength of the Bulgarian system is its capacity to document local plant genetic resources collected directly from traditional agricultural systems. Local varieties and landraces are frequently maintained by small-scale farmers and gardeners outside formal breeding programmes. Their documentation therefore requires information that goes beyond conventional passport descriptors. The expedition questionnaire developed within the methodological framework records not only the identity and geographical origin of the accession but also farmer-related information, cultivation practices, reasons for maintaining the material, production destinations, seed sources and traditional uses. This additional information increases the cultural, historical and practical value of the accession record. It can also support future research on the relationship between genetic resources, traditional knowledge, agricultural practices and local food systems. The inclusion of collecting-site information and geographic coordinates also creates opportunities for analysis. Geographic descriptors can be used to identify areas of concentration of particular genetic resources, support future collecting missions and contribute to analyses of adaptation and diversity.

In essence, the introduction activity of international free germplasm exchange, which is carried out by the genebank in Sadovo using SMTA (FAO, 2006), serves the crop improvement

programs of the breeding institutes in Bulgaria. Accessions are introduced upon special requests with diverse geographical origins for study in the conditions of the country and for use as donors of valuable traits as ecological plasticity, resistance to a given pathogen, high productivity, etc. The main partners of the National Genebank in the exchange are: GRIN (USA), ICARDA, NordGen, IPK (Germany), INRA (France), John Innes Center (Great Britain).

The genebank conserves seeds of Bulgarian advanced varieties and breeding lines, the result of crop improvement programs, for long-term storage, which are registered in the GeneBankSystem with data on pedigree, breeding institution and access level.

Integration of the National Inventory with EURISCO

The Bulgarian National Genebank is presented in EURISCO and performs a coordinating role in relation to the Bulgarian National Inventory. The National Inventory integrates passport information from collections maintained by different Bulgarian scientific institutions. The National Focal Point is responsible for collecting, validating, harmonizing and periodically submitting information to EURISCO Intranet. Thus, the documentation system functions not only as an institutional database but also as a national information infrastructure connecting different plant genetic resources collections. The national-to-European data transfer is represented on the Figure 1.

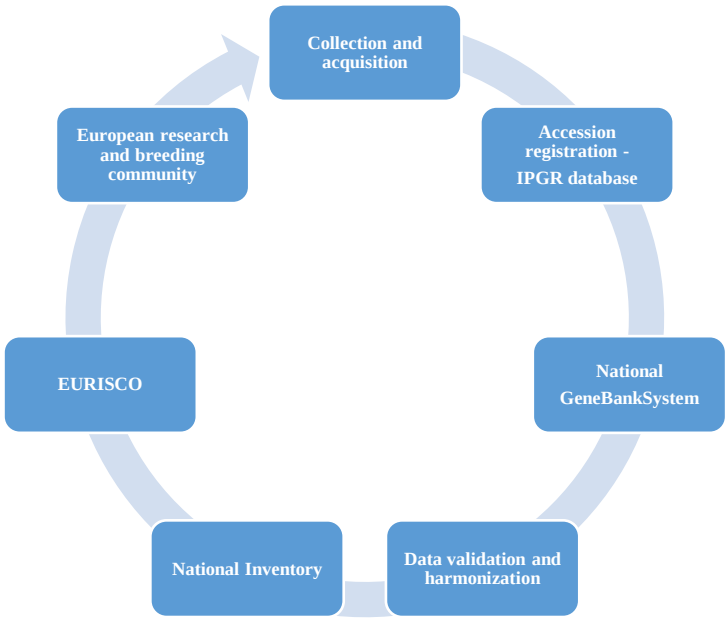

Figure 1.
Integration of the Bulgarian National Inventory with European plant genetic resources community system

Such interoperability increases the international visibility of Bulgarian plant genetic resources and facilitates their identification for scientific research, breeding and conservation activities. According to Mendel et al. (2026), improved data management and documentation contribute to the visibility and usability of genebank collections. The integration with EURISCO further strengthens this role by providing a standardized European environment for accessing passport information.

Open access and user-oriented information services

The transition from an internal database to a web-based information environment represents an important development in the Bulgarian GeneBankSystem. The public interface provides external users with access to accession information, while the protected component enables professional management of the collections.
Open access is available in both Bulgarian and English, and a mobile application has been developed to facilitate access by external users.
This approach is consistent with the broader development of digital infrastructures for genebank and responds to the increasing demand for accessible and interoperable information. Open access does not replace the physical conservation of germplasm; rather, it increases the visibility of conserved material and enables potential users to identify resources before requesting biological material.
The availability of standardized passport information is particularly important for breeders and researchers because it allows them to search collections according to crop, taxonomic identity, geographical origin, biological status and other characteristics.
Data security and quality management
The implementation of data backup and controlled access is another important element of the system. Information is maintained in electronic registers and backed up on primary and secondary servers, reducing the risk of data loss and supporting continuity of genebank operations. Data quality is further supported by defined responsibilities among documentation and conservation specialists and collection curators. Information may be corrected or supplemented when new evidence becomes available. This is particularly important for historical accessions, for which passport information may initially be incomplete. The system therefore follows a dynamic model of documentation in which accession records are considered continuously improvable rather than static records created only at the time of acquisition.
Current status and development potential
The current documentation framework provides an integrated digital environment for managing accession information in the Bulgarian National Genebank. Its main achievements include standardized passport documentation, unique accession identification, expedition documentation, integration of storage and regeneration information, evaluation and characterization records, public access and interoperability with EURISCO.
According to ECPGR (2023) and Velcheva et al. (2026) the system provides a foundation for further digital development. The GeneBankSystem explicitly defines the documentation framework as a dynamic structure that is expanded and updated with innovative techniques by IS-PGR-SADOVO public financed project. Future development is focus on increasing the interoperability of phenotypic datasets, improving geospatial functionality, strengthening links between passport and characterization data, expanding and implementing additional mechanisms for data validation and quality control. An important future direction is also the integration of more detailed characterization and evaluation datasets. While passport data provide the identity and origin of accessions, characterization and evaluation data provide the information needed to assess their actual value for breeding, research and sustainable agriculture.

CONCLUSIONS

The Bulgarian GeneBankSystem represents an integrated digital framework for the management of information associated with the national germplasm collections maintained at the National Genebank of IPGR-Sadovo.
The system combines accession registration, standardized passport documentation, collecting and expedition information, geographical data, biological status, storage and regeneration records, characterization and evaluation information, and distribution data. The use of

FAO/Bioversity Multi-Crop Passport Descriptors and alignment with EURISCO provide an internationally compatible structure for data exchange and interoperability.
A major achievement is the introduction of a unique and traceable accession identification system that maintains the connection between the physical genetic resource and its digital record throughout the accession conservation process. The expedition module enables the documentation of local varieties and landraces together with information on their traditional cultivation and utilization.
The integration of the Bulgarian documentation system with the National Inventory and EURISCO increases the visibility of Bulgarian plant genetic resources and facilitates their discovery and potential use by researchers, breeders and other stakeholders. The public web interface and mobile access further support the open-access principle.
The system provides mechanisms for data quality control, updating, backup and controlled access, which are essential for the long-term reliability of genebank documentation.
Overall, the Bulgarian GeneBankSystem demonstrates that digital documentation is an essential component of modern germplasm management. By connecting physical conservation with standardized, interoperable and accessible information, the system strengthens the capacity of the Bulgarian National Genebank to conserve, document, study and promote the sustainable use of plant genetic resources. Its modular and dynamic structure provides a basis for further integration of new data types, innovative technologies and European and international information infrastructures.

ACKNOWLEDGEMENTS

The research work was carried out under the project IS-PGR-SADOVO “Intelligent system for managing Bulgarian plant gene pool, conserved in the genebank of IPGR-Sadovo” with the financial support of the Ministry of Education and Science, Contract number KP-06-H86/9/09.12.2024 of Bulgarian National Science Fund.

ABSTRACT

The GeneBankSystem was developed to enhance transparency, collaboration, and innovation in plant genetic resources management. Coordinated by the Institute of plant genetic resources – Sadovo, the initiative aims to provide open and structured access to seed collections and research data. The platform integrates passport data, phenotypic and agronomic evaluations, and documentation of conserved germplasm, ensuring long-term preservation and accessibility. The creation of a database for phenotypic evaluation of seeds from different plant species is of a key importance for the management, scientific value, and sustainability of the genebank. The MARViN VisionLine measuring equipment is a high-tech analysis system that uses computer vision to precisely measure color, shape, size, and other visual parameters of seeds. It detects color anomalies and creates color-calibrated images for documentation. The results are characterized by high accuracy, precision, flexibility, and the ability to integrate into other information systems. A collection of common bean (*Phaseolus vulgaris L.*) with diverse geographical origin was analysed. The new data complement the passport, evaluation, and characterization records of the accessions. By promoting open science principles, the digital platform supports plant breeders, researchers, farmers, and policymakers in developing resilient and sustainable crop varieties. A key result is the digitization and systematization of national plant genetic resources collections, aligned with international standards for biodiversity conservation. The platform also strengthens knowledge transfer between science and practice, fostering innovation in agriculture under changing climate conditions. Overall, the GeneBankSystem contributes to the conservation of agrobiodiversity while advancing open access to scientific knowledge at national and international levels.

Keywords: Common bean, Genebank collection, Phenotyping, Conservation, Digitalization.

INTRODUCTION

Plant genetic resources for food and agriculture constitute an essential foundation for crop improvement, food security, adaptation to climate change, and sustainable agricultural development. Genebanks play a central role in conserving this diversity *ex situ* and in ensuring that valuable genetic material remains available for research, breeding, education, and future generations. However, the increasing size and complexity of genebank collections require advanced information systems capable not only of storing passport information but also of integrating characterization, evaluation, spatial, experimental, and monitoring data (Weise et al., 2020).

The National Genebank at the Institute of Plant Genetic Resources (IPGR) – Sadovo maintains *ex situ* plant gene pool of Bulgaria. The scale of the collection creates significant requirements for efficient registration, monitoring, documentation, storage, evaluation, and retrieval of

information (Desheva et al., 2026). The IS-PGR-SADOVO project, entitled "Intelligent system for managing Bulgarian plant gene pool, conserved in the genebank of IPGR-Sadovo", was designed to address these requirements through the development of intelligent components for the existing GeneBankSystem (Velcheva et al., 2025b).

A major objective of the project is to improve the management of processes associated with the conservation, research, and access to plant genetic resources. The system is being developed to support both specialized genebank personnel and external users, including researchers and other stakeholders with different levels of expertise. An important component is the development of a public information portal with intelligent access based on semantic models, allowing more complete and efficient access to information about conserved germplasm (Stoyanov et al., 2025).

The project combines several complementary technological approaches: an information system for genebank management, semantic modelling through GeneBankOntology, intelligent assistance for control germination testing, sensor-based monitoring of storage conditions, and integration of data generated by external seed-analysis equipment. These components create a digital environment in which biological material, scientific information, experimental results, and spatial data can be connected (Malinov et al., 2025).

Particular attention was given to phenotypic and biometric characterization. The establishment of a relational database for phenotypic evaluation is important for increasing the scientific value and long-term usability of genebank collections (Neshev & Velcheva, 2025). The acquisition of MARViN VisionLine and MARViN SmartLine systems enabled automated digital analysis of seed morphology and quality characteristics, generating standardized images and structured datasets that can subsequently be incorporated into the GeneBankSystem.

A new approach to the digital management of *ex situ* plant genetic resources has been developed at the Institute of Plant Genetic Resources "Konstantin Malkov" – Sadovo, Agricultural Academy. Particular emphasis is placed on the digitalization of characterization and evaluation data, which complement conventional passport information and increase the scientific value and usability of genebank collections. The establishment of a relational database for phenotypic evaluation of different plant species provides an important basis for systematic management, long-term preservation, scientific analysis, and future integration of genebank data into international information platforms. Such an approach facilitates information exchange among genebanks and provides wider access to genetic resources and associated scientific knowledge (Velcheva et al., 2025a).

The present paper summarizes the main results achieved during the first stage of the IS-PGR-SADOVO project, with particular emphasis on digital access to plant genetic resources, semantic information management, phenotyping, and the integration of scientific data into the genebank conservation system.

The aim of the study analyze the implementation of digital technologies for precise phenotypic analysis of seeds in the genebank as a tool for sustainable conservation, characterization, and evaluation of plant genetic resources.

MATERIAL AND METHOD

GeneBankSystem and digital documentation

The research activities were carried out using the information infrastructure of the National Genebank at IPGR-Sadovo and the GeneBankSystem. The system was developed to support the registration, storage, regeneration, monitoring, characterization, and evaluation of plant genetic resources.

During the first stage of the IS-PGR-SADOVO project, the existing system was analysed and expanded with additional functionalities for reproduction management and geremination

testing. According to the data check 31.08.2026, 53,970 accessions are registered in the GeneBankSystem by passport data. A significant amount of work was devoted to integrating reproduction records that had previously not been completely available in the old documentation Phyto 2000 database.

Scripts were developed for importing reproduction data, followed by manual verification and clarification of temporary reproduction numbers and their corresponding accessions. At the reported stage, more than 50,000 reproduction records existed, of which approximately 9,500 had been entered into the database together with associated geremination control-tests information. This data integration provides a basis for more reliable management of the collection.

Intelligent management of geremination control-tests

The GeneBankSystem was expanded with functionalities supporting the management of geremination control-tests. These include transferring seeds between storage collections, filtering accessions and reproduction records according to selected characteristics, exporting data in Excel format, and generating QR codes for individual storage records.

The QR-code functionality provides direct access to information concerning a specific reproduction and its geremination control-tests. A laboratory dashboard was designed to support the monitoring of recently processed reproductions and those requiring subsequent geremination control-tests (Figure 1).

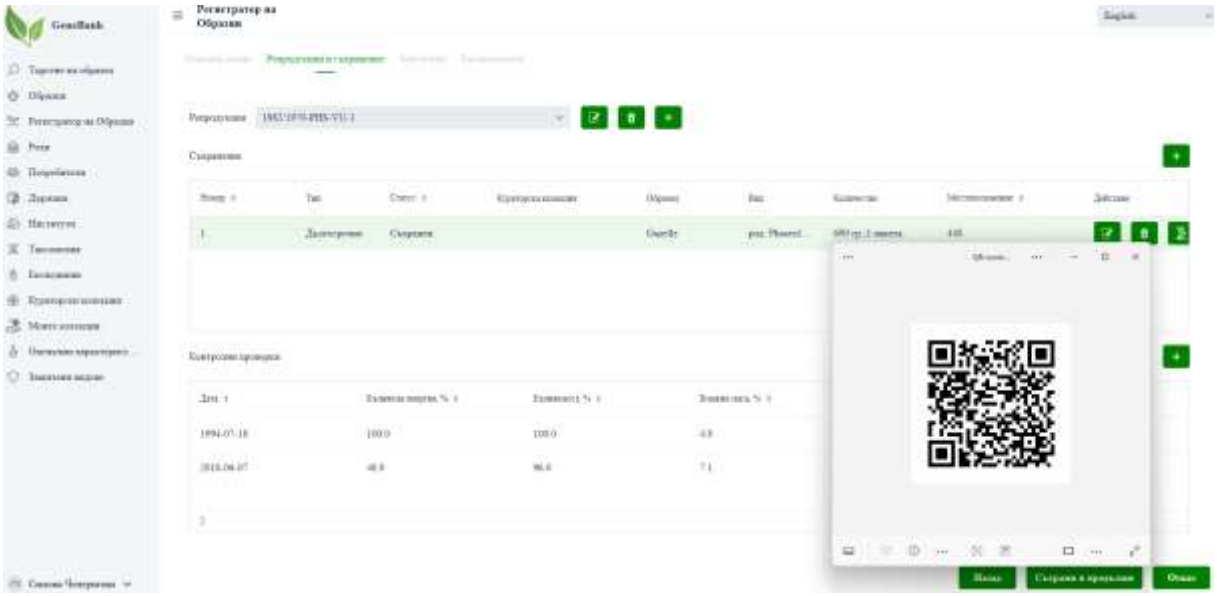

Figure 1. Generating a QR code for a seed reproduction of a common bean accession

Semantic modelling and external access

The GeneBankOntology was developed as a semantic representation of knowledge concerning plant genetic resources conserved in the National Genebank. Passport information was structured in accordance with EURISCO requirements and the FAO/Bioversity Multi-Crop Passport Descriptors (2017). The ontological model links accession identifiers with taxonomic information, collection sites, geographic coordinates, altitude, and other passport descriptors. Evaluation characteristics are also associated with individual accessions.

EURISCO uses standardized passport descriptors and also provides access to phenotypic information, supporting data discovery and exchange among genebanks and users. This approach follows the international documents towards interoperable documentation of plant

genetic resources for food and agriculture (Maggioni et al., 2014; FAO, 2021) and the Operational Guide for the Bulgarian Genebank (ECPGR, 2023).

Monitoring of seed-storage conditions

A sensor network was designed and implemented to monitor temperature and relative humidity in the seed-storage facilities. The network covers the active collection and designated laboratory areas. The sensors provide continuous measurements and transmit data to server infrastructure. The system supports real-time visualization, threshold-based notifications, and storage of historical measurements. Central information displays were installed, while measurements are also logged on servers for subsequent analysis (Figure 2).

Figure 2. Screenshot of temperature and humidity data from the genebank storage facilities

Continuous monitoring of storage conditions provides an additional protection for the biological material and complements the digital documentation system.

Digital phenotyping and seed analysis

The digitalization of characterization and evaluation data is one of the components of the project. To support this activity, two high-tech seed-analysis systems, MARViN VisionLine and MARViN SmartLine (Figure 3), were acquired (MARViTECH, 2026).

Figure 3. Measuring system for digital seed analysis - MARViN SmartLine and MARViN VisionLine

The systems use computer vision, cameras, and dedicated software to measure seed colour, shape, size, and other visual parameters. They can detect colour anomalies and generate colour-calibrated images suitable for documentation and scientific analysis. Their main advantages include high accuracy, precision, flexibility, and the potential for integration with other information systems.

MARViN VisionLine generates images and structured analytical data, including seed length, width, area, perimeter, shape, colour characteristics, weight, percentage of damaged seeds, automatically determined quality class, and information on the date of analysis. The resulting data can be exported in CSV, XLS, XLSX, and other tabular formats.

MARViN SmartLine provides automated counting, measurement, and classification of seeds based on digital image processing. The system generates seed images, analytical reports, and statistical information, including number of seeds, size, shape, area, colour characteristics, damaged seed percentage, and quality indicators.

The data generated by the two systems are intended for integration into the GeneBankSystem, where they can be linked to accession identifiers and other passport, characterization, and evaluation information. This creates a basis for the development of a database for phenotypic and biometric information.

Experimental evaluation of the common bean collection

A collection of 80 common bean (*Phaseolus vulgaris* L.) accessions with diverse geographical origins was studied within the framework of a PhD thesis study conducted at the Department of Plant Genetic Resources of IPGR-Sadovo. During 2024-2026, the accessions were evaluated through field observations and biometric measurements using international descriptors. Biological, morphological, and quality-related characteristics were assessed in two replications. In 2025, the seed material of the investigated collection was additionally analysed using the MARViN VisionLine system. This allowed conventional field-based characterization to be complemented by digital seed phenotyping and standardized image-based measurements. This approach enabled the integration of biological, morphological, visual, and spatial information into a unified digital documentation environment.

RESULTS AND DISCUSSION

Development of an integrated digital platform

The first stage of the IS-PGR-SADOVO project resulted in significant expansion of the GeneBankSystem towards an integrated digital platform for the management and utilization of plant genetic resources. The system now incorporates functionalities for passport data, reproduction management, germination control-tests, data filtering, Excel export and QR-code identification. These functions improve the traceability of conserved material and reduce the dependence on manual searching and fragmented documentation.

The integration of reproduction information was particularly important because a large number of reproduction records were not initially linked to the corresponding accessions in the database. Their gradual integration creates a more complete digital representation of the physical collection.

The platform therefore moves beyond the role of a conventional accession database. It increasingly functions as an integrated knowledge environment in which biological material is connected with scientific, technical, and environmental information.

Digitalization of characterization and evaluation information

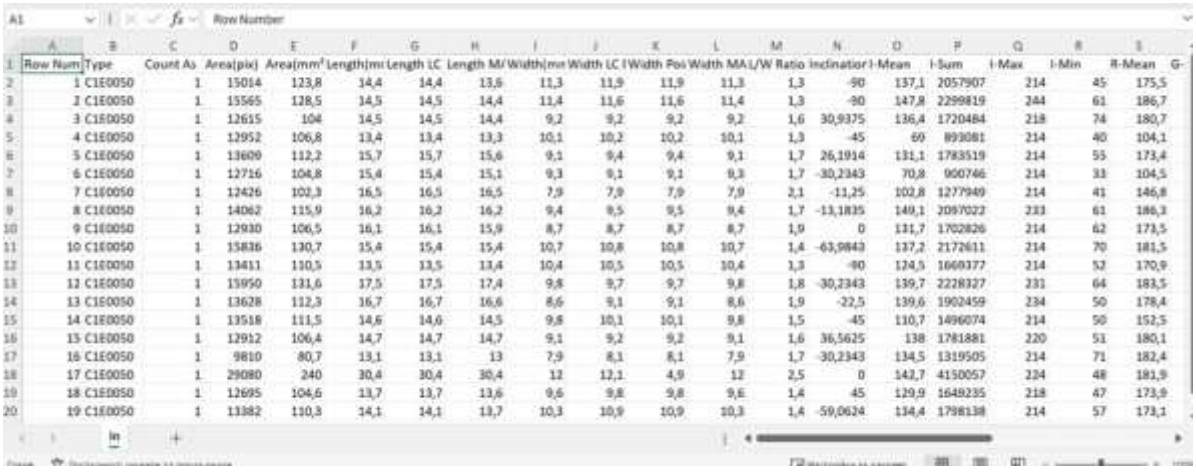
One of the important results of the project is the establishment of a technological basis for digitalizing characterization and evaluation information from *ex situ* collections. The creation of a database for phenotypic information provides a structured environment in which

measurements generated from different experiments and plant species can be stored, linked to accession identifiers, analysed, and subsequently shared. This is particularly important because phenotypic information may retain scientific value long after the completion of the original experiment.

The international development of EURISCO demonstrates the importance of this approach. EURISCO currently contains extensive phenotypic information in addition to passport data, and recent developments have focused on improving the standardization and FAIRness of phenotypic datasets.

The approach implemented at IPGR-Sadovo therefore corresponds to the broader development of genebank information systems from simple passport-data repositories towards integrated platforms supporting characterization, evaluation, visualization, and utilization of germplasm.

Digital phenotyping using MARViN systems



The introduction of MARViN VisionLine and SmartLine significantly increased the capacity of IPGR-Sadovo for standardized digital analysis of seed material. The systems generate both images and quantitative data, allowing seed characteristics to be documented in a reproducible digital format. This is particularly valuable for morphological traits such as seed length, width, area, perimeter, shape, colour, and damaged seed percentage.

The generated digital images provide a permanent visual record of the analysed accessions. In combination with structured measurements, they can be used for comparative analyses, statistical evaluation, and subsequent identification of accessions with desirable characteristics. The integration of these data into the GeneBankSystem will further increase their value by linking individual measurements to accession identity, passport information, evaluation data, and geographic origin.

Characterization and valorization of the common bean collection

The common bean collection provided a practical case study for the application of the new digital approach (Figure 4). The combination of field observations and computer-vision-based seed analysis enabled the creation of a more comprehensive accession profile. Instead of representing an accession only by its passport data, the digital record can include its geographical origin, phenological characteristics, biometric measurements, seed morphology, colour characteristics, digital images, and other quality-related parameters.

The analysis of the data from the Marvin seed analyzer was carried out on the average values of the traits, including: morphological parameters (length, width, area, perimeter) and intensity of the color indicators.

The analysis grouped the accessions into 5 groups, with the traits that influence their grouping being the perimeter of the seeds (perimeter mm) and the color of the seeds. The largest group unites all accessions with white seed color (40 accessions), the data are compared with the qualitative visual assessment of the trait – seed color according to the evaluation descriptors list. The other accessions are distributed in groups with a predominant brown color in several shades and black with small seeds. The collection is dominated by accession with kidney-shaped seeds (comparison was made with a qualitative assessment of the trait – seed shape).

Figure 5. Digital imagines of common bean seeds – output from the MARViN VisionLine

Accessions demonstrated promising agronomic characteristics and potential value for plant breeding programmes. These observations highlight the importance of curator collections maintained in genebanks as sources of potentially valuable variation for crop improvement.

The results demonstrate that the role of a genebank extends beyond long-term conservation. Conserved accessions can represent a reservoir of traits that may be used in breeding programmes aimed at improving productivity, quality, adaptation, and resilience under changing environmental conditions.

Local common bean populations as valuable genetic resources

The local common bean populations collected through expeditions represent an important component of Bulgarian agricultural biodiversity. Their value is associated not only with their genetic diversity but also with their adaptation to specific local environmental conditions and traditional agricultural practices.

The digital documentation of these populations makes it possible to preserve information that might otherwise be lost, including the location of origin, altitude, geographic coordinates, morphological characteristics, and visual features of the seed.

The spatial visualization developed within the project provides an accessible way of exploring the geographic distribution of local accessions. The combination of maps, passport information, morphological data, and seed images creates a more complete picture of the conserved genetic diversity.

This integrated approach may support future studies of relationships between geographical origin, environmental conditions, and phenotypic variation. It can also facilitate the identification of accessions for further evaluation and breeding.

Open access and knowledge transfer

A central principle of the developed platform is to increase access to information associated with conserved genetic resources. The digitalization of *ex situ* collections makes it possible to provide structured information to a wider range of users and to improve the connection between conservation and utilization.

Local common bean populations should not only be collected and conserved but also characterized, documented, and made visible to the scientific and agricultural community. Their

potential value can only be fully realized when researchers and breeders are able to identify relevant accessions and obtain sufficient information to assess their suitability for further use.
The GeneBankSystem provides a technological basis for this process by connecting passport information with phenotypic, biometric, visual, geographic, and evaluation data. The development of filter search further improves the accessibility and interpretability of the information.
Open access to information should be understood in the context of applicable rules governing access to genetic resources and associated benefit-sharing requirements. International systems such as EURISCO demonstrate the importance of making standardized information discoverable and reusable while respecting the rights and conditions associated with the underlying genetic material.
The proposed approach supports knowledge transfer between genebanks, research institutions, breeding programmes, farmers, and other stakeholders in the agri-food chain. It can therefore contribute to a transition from passive conservation towards active conservation and sustainable utilization of plant genetic resources (Westengen et al., 2018).
Contribution to breeding and climate-resilient agriculture
The combination of digital phenotyping and genebank documentation provides opportunities for identifying genetic resources with characteristics potentially useful for crop improvement. The common bean case study demonstrates how traditional local material can be evaluated using modern technologies and transformed into structured digital information. The value of these datasets is not limited to current research. Properly documented phenotypic data can be reused for future analyses, comparative studies, modelling, and breeding applications. This is particularly important under global climate change, when genetic diversity adapted to different environmental conditions may become increasingly valuable.
Digital documentation also reduces the risk that valuable knowledge associated with conserved accessions will be lost. By linking the seed material with its characterization history, images, measurements, and geographic origin, the system preserves both the biological resource and the knowledge generated about it.

CONCLUSIONS

The IS-PGR-SADOVO project has established an important technological basis for improving access to seeds and scientific knowledge associated with Bulgarian plant genetic resources conserved at the National Genebank of IPGR-Sadovo.
The main achievement is the development of an integrated digital environment that connects accession documentation, reproduction and germination testing information, semantic knowledge, phenotypic data, digital seed images, geographic information, and environmental monitoring.
The establishment of a database for characterization and evaluation data is a particularly important step towards the digitalization of *ex situ* collections. It creates opportunities for systematic storage, analysis, exchange, and future reuse of phenotypic information and provides a foundation for integration with national and international information platforms.
The acquisition and application of MARViN VisionLine and MARViN SmartLine introduced computer-vision-based digital phenotyping into the characterization of the genebank collections. The systems provide standardized measurements and digital images of seed morphology and quality characteristics and create opportunities for linking these data with accession passport information.
The evaluation of 80 *Phaseolus vulgaris* L. accessions of diverse geographical origin demonstrated the practical value of combining field observations, biometric measurements, international descriptors, and digital seed analysis. Promising accessions with potentially

valuable agronomic characteristics were identified, emphasizing the importance of curator collections as sources of material for future crop breeding programmes.

The development of GeneBankOntology and semantic search provides a further step towards intelligent and user-oriented access to genebank knowledge. By connecting taxonomic, passport, evaluation, and visual information, the system can make complex scientific information more accessible to different categories of users.

The project demonstrates that digitalization of *ex situ* collections should not be considered merely as a technical conversion of records into electronic format. It represents a strategic approach to increasing the visibility, scientific value, accessibility, and sustainable utilization of plant genetic resources.

The integration of seed material, scientific data, digital images, phenotypic information, and geographic origin creates a foundation for stronger cooperation between genebanks, researchers, crop breeders, farmers, and other stakeholders. The GeneBankSystem contributes not only to the conservation of Bulgarian agrobiodiversity but also to the transfer of scientific knowledge and the development of resilient and sustainable agriculture under changing climatic conditions.

ABSTRACT

Sheep farming plays an important role in the sustainability of rural economies and livestock production; however, the sector is increasingly affected by rising production costs as well as structural, technical, and institutional challenges. This study aims to examine the socioeconomic characteristics of sheep farming enterprises in Reşadiye district of Tokat Province, determine their production costs, and classify the major problems encountered by sheep farmers using factor analysis. The primary data were collected through face-to-face surveys with 117 sheep farming enterprises selected using stratified sampling. Descriptive statistics and exploratory factor analysis were employed to analyze the data. The average age of the farmers was 44.35 years, while their average experience in sheep farming was 19 years. In addition, 84.62% of the farmers were engaged in both crop and livestock production. The average total production cost was calculated as TRY 69,180.47 per enterprise. Variable costs accounted for 92.08% of total production costs, while fixed costs represented 7.92%. Among variable costs, concentrate and roughage feed costs constituted the largest cost component, with a combined share of 60.94%, followed by veterinary and animal health costs at 15.32%. The share of total feed costs in variable costs increased with farm size. The problems encountered by sheep farmers were grouped into four factors: structural, policy-related, and environmental problems; institutional support and production conditions; technical infrastructure and farm continuity; and production risks and resource constraints. These four factors explained 55.104% of the total variance. The findings indicate that the sustainability of sheep farming enterprises requires an integrated approach addressing not only production costs but also structural, institutional, technical, and production-related challenges. Accordingly, more efficient use of feed and pasture resources, strengthened support and agricultural extension services, measures to alleviate animal health and shepherd availability problems, and regional policies supporting the intergenerational continuity of sheep farming enterprises are recommended.

Keywords: Sheep farming, Production costs, Factor analysis, Farmers' problems

INTRODUCTION

Sheep farming is an important agricultural activity that enables the utilization of poor-quality pastures, fallow land, crop residues, and areas unsuitable for crop production by converting these resources into animal products such as meat, milk, wool, hair, and hides. In particular, sheep farming occupies an important place in the agricultural sector due to its role in the efficient utilization of natural resources, its contribution to rural income and employment, and its importance for the sustainability of livestock production. In addition to utilizing marginal and agriculturally disadvantaged areas, extensive sheep farming also plays an important role in

the provision of ecosystem services, the maintenance of rural populations, and the prevention of land abandonment (Bertolozzi-Caredio et al., 2021).

Rising production costs and inadequate producer prices in sheep and goat farming are among the main factors adversely affecting the economic sustainability of farms. Vouraki et al. (2020) reported that increasing production costs and inadequate farm-gate prices exert significant financial pressure on farms in the European small ruminant sector. This situation highlights the importance of jointly evaluating production costs and the economic challenges faced by sheep farms.

Sheep farming holds an important position in the global livestock sector. According to FAO (2023), there are approximately 1.2 billion sheep worldwide. Türkiye is also among the leading countries in the world in terms of its sheep population. According to 2024 data from the Turkish Statistical Institute (TURKSTAT), the sheep population in Türkiye increased by 4.8% compared with the previous year, reaching 44.081 million head (TURKSTAT, 2024). Sheep farming in Türkiye is generally characterized by the predominance of indigenous breeds and a feeding system largely based on pasture and grazing. In addition, the generally small scale of farms, difficulties in accessing production inputs, inadequacies in product marketing and utilization, and the limited share received by producers from product prices are among the major challenges facing the sector.

The distribution of the sheep population in Türkiye varies across regions and provinces. Tokat Province is one of the provinces where sheep farming is widely practiced due to its natural resources, rural structure, and livestock production activities. According to TURKSTAT (2024), Tokat Province has a total sheep population of 373,951 head, while Reşadiye District, which constitutes the study area, has a sheep population of 33,096 head. This situation underscores the importance of examining the existing structure and economic characteristics of sheep farming in Reşadiye District, as well as the problems faced by sheep farmers.

The economic sustainability of sheep farming is closely related not only to the income generated from production but also to the costs incurred during the production process. Bertolozzi-Caredio et al. (2021) stated that low profitability in sheep farming is associated with low selling prices and rising production costs, particularly increasing feed costs. Feed, labor, veterinary and animal health services, housing, energy, and other production inputs can significantly affect the cost structure and economic sustainability of sheep farms. Studies conducted in Türkiye have also demonstrated that factors such as feed, labor, pasture availability, access to shepherds, and marketing are important for the economic and structural sustainability of sheep farms (Çiçek et al., 2022; Gürer and Ulutaş, 2021; Mohamud and Çevrimli, 2023). Benoit et al. (2020) demonstrated that the economic performance of different sheep farming systems may be affected by technical and market-related risks and that farms develop different adaptation mechanisms in response to these risks.

However, the factors affecting the sustainability of sheep farming are not limited to production costs. Economic, structural, technical, and institutional challenges, including input prices, inadequate pasture and water resources, animal diseases, difficulties in finding shepherds, marketing opportunities, agricultural support policies, access to technical knowledge and extension services, and farm succession to future generations, may affect the continuity of production. Therefore, in addition to identifying the problems faced by sheep farmers, classifying these problems into their underlying dimensions is important for developing appropriate solutions and policies that address producers' needs.

The aim of this study is to determine the socioeconomic characteristics of sheep farms in Reşadiye District of Tokat Province, estimate production costs according to farm-size groups, and classify the main problems faced by sheep farmers using factor analysis. The findings are expected to contribute to the assessment of the economic and structural conditions of sheep

farming in the region and to the development of solutions aimed at enhancing the sustainability of sheep farms.

MATERIAL AND METHOD

Study Area and Data Collection

The primary material of the study consisted of primary data collected through face-to-face surveys from sheep farms in Reşadiye District of Tokat Province. Sheep farming is carried out in a total of 52 villages within the study area. The sheep population was taken into consideration in selecting the villages to be included in the study, and villages where sheep farming was concentrated were included in the research area. Accordingly, the survey was conducted in 10 villages, representing approximately 20% of the villages where sheep farming is practiced in the district.

At the farm level, data were collected on the socioeconomic characteristics of sheep farmers, farm structure, sheep production activities, production costs, and the problems faced by sheep farmers.

Sampling Method

Among the 52 villages where sheep farming is practiced in the study area, 10 villages were purposively selected based on the concentration of the sheep population. Sheep farms operating in the selected villages constituted the study population.

Prior to determining the sample size, the coefficient of variation was calculated based on the number of sheep owned by the farms constituting the population. The coefficient of variation is a measure used to determine whether the units within a population or sample exhibit a homogeneous or heterogeneous structure (Güneş & Arıkan, 1985; Şimşek, 2019). The calculated coefficient of variation was above 75%, indicating that the population had a heterogeneous structure. Therefore, the stratified sampling method was used to determine the sample size.

The farms were divided into three strata according to the number of sheep owned. The first stratum consisted of farms with 5–50 sheep, the second stratum of farms with 51–150 sheep, and the third stratum of farms with 151 sheep or more. The sample size was calculated at a 90% confidence level with a 1% deviation from the mean, and the number of farms to be surveyed was determined as 117. The proportional allocation method was used to distribute the sample among the strata (Çiçek & Erkan, 1996; Semerci, 2021). Accordingly, 33 farms from Stratum I, 39 farms from Stratum II, and 45 farms from Stratum III were included in the sample.

The following equation for the stratified sampling method was used to determine the sample size:

$$n = \frac{N.\sum N_h\,(S_h)^2}{N^2D^2 + \sum N_h\,(S_h)^2}$$

Where; n represents the sample size, N represents the total number of farms in the population, N_h represents the number of farms in the *h*th stratum, S_h represents the standard deviation of the *h*th stratum, and D represents the value associated with the allowable margin of error.

As a result of the sampling calculation, the number of farms to be surveyed within the scope of the study was determined as 117. The proportional allocation method was used to distribute the determined sample size among the strata (Çiçek & Erkan, 1996; Semerci, 2021). Accordingly, 33 farms from Stratum I, 39 farms from Stratum II, and 45 farms from Stratum III were included in the sample.

Table 1. Distribution of farms in the population by strata and number of farms selected for the sample

Stratum	Farm Size (head)	Mean (head)	Number of Farms (N_h)	Standard Deviation	Number of Farms in the Sample
I	5-50	27	72	14.23	33
ll	51-150	98	86	26.49	39
lll	151+	318	99	189.80	45
TOPLAM		163	257	173.05	117

The distribution of the 117 farms among the villages was based on the sheep population of the 10 villages included in the study. These villages had a total sheep population of 27,089 head, and the number of surveys to be conducted in each village was determined proportionally according to each village's share of the total sheep population. The following equation was used to calculate the sample size for each village:

$$n_i = \frac{N_i}{\sum_{i=1}^{10} N_i} * 117$$

Where:
n_i: number of surveys to be conducted in the *i*th village
N_i: sheep population of the *i*th village
$\sum_{i=1}^{10} N_i$: total sheep population of the 10 villages included in the study (27,089 head)
117: total sample size
The calculated values were rounded to the nearest whole number to determine the distribution of the sample size across the villages.

Table 2. Sheep population of the villages included in the study and proportional distribution of the sampled farms

Village	Sheep Population (head)	Share of Total (%)	Number of Sampled Farms
Çamlıkaya	4.392	16.21	19
Bereketli	3.722	13.74	16
Baydarlı	3.568	13.17	15
Cimitekke	3.292	12.15	14
Bereketli-Çakraz	2.525	9.32	11
Kuyucak	2.488	9.18	11
Bozçalı	2.256	8.33	10
Çınarcık	1.635	6.04	7
Nebişeyh	1.615	5.96	7
Cimitekke-Keteniği	1.596	5.89	7
Total	27.089	100.00	117

Data Analysis

Descriptive statistics were used to evaluate the data obtained from the study. Variables related to the socioeconomic characteristics of sheep farmers and farm structure were evaluated using frequencies, percentages, and mean values. Production costs associated with sheep farming were calculated by considering variable and fixed costs, and the shares of individual cost items in total production costs were determined.

Exploratory factor analysis was applied to classify the main problems faced by sheep farmers into a smaller number of meaningful dimensions. Factor analysis is a multivariate statistical method that enables a large number of interrelated variables to be grouped into a smaller number of meaningful factors (Aksoy & Özdemir, 2026; Küley Ağır et al., 2025).

Production costs associated with sheep farming were calculated by considering variable and fixed costs. Variable costs included animal material, concentrate and roughage feed, veterinary and animal health expenses, labor, water, electricity and heating, livestock insurance, guard dog, shearing, and marketing expenses. General administrative expenses were calculated as 3% of total variable costs excluding general administrative expenses. Fixed costs included depreciation of sheep housing capital, maintenance and repair expenses for sheep housing, and depreciation of machinery capital. The shares of individual cost items in variable and fixed costs, as well as the proportions of variable and fixed costs in total production costs, were also calculated.

The suitability of the dataset for factor analysis was assessed using the Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy and Bartlett's Test of Sphericity. A KMO value of 0.50 or above was considered acceptable, while a statistically significant Bartlett's Test of Sphericity was regarded as an indication that the correlation structure among the variables was suitable for factor analysis (Aksoy & Özdemir, 2026; Küley Ağır et al., 2025). Cronbach's Alpha coefficient was used to assess the internal consistency of the scale.

The analysis yielded a KMO value of 0.514 and a Cronbach's Alpha coefficient of 0.807, while Bartlett's Test of Sphericity was statistically significant ($p < 0.001$). Factors with eigenvalues greater than 1 were retained, and the Varimax rotation method was applied to improve factor interpretability (Küley Ağır et al., 2025). Variables with factor loadings of 0.40 or higher were considered in the interpretation of the factors. As a result of the analysis, four factors were identified, explaining 55.10% of the total variance.

RESULTS AND DISCUSSION

Socioeconomic Characteristics of Sheep Farmers

The overall mean age of the sheep farmers included in the study was 44.35 years. By farm-size group, the mean age was 43.43 years in Group I, 45.91 years in Group II, and 43.41 years in Group III. The similarity of the mean ages indicates that there was no marked difference in age among the farm-size groups. These results indicate that sheep farming in Reşadiye District is predominantly carried out by middle-aged farmers.

The professional experience of the farmers in sheep farming averaged 19.00 years. The mean professional experience was 13.42 years in Group I, 21.61 years in Group II, and 19.13 years in Group III, indicating that farmers in Group II had the highest average level of professional experience. Overall, the fact that the farmers had been engaged in sheep farming for a relatively long period indicates that they had accumulated considerable knowledge and experience in the sector.

The findings regarding the age of the farmers are similar to those reported in previous studies on sheep farmers in Türkiye. Çiçek et al. (2022) reported a mean age of 45.9 years for sheep farmers across Türkiye, while Gürer and Ulutaş (2021) reported a mean age of 45.15 years for farmers in Niğde and Aksaray provinces. Similarly, Köseman et al. (2022) found that 63.1% of sheep farmers in Malatya Province were in the 31–50 age group. When evaluated together with

these studies, the mean age of 44.35 years determined in Reşadiye is largely consistent with the findings in the literature and suggests that sheep farming is predominantly carried out by middle-aged farmers in different regions.

In terms of professional experience, the mean of 19 years determined in Reşadiye was lower than the averages of 27.5 years reported by Çiçek et al. (2022) for Türkiye as a whole and 23.65 years reported by Gürer and Ulutaş (2021). In contrast, Tweldebirhan et al. (2025) reported an average farming experience of approximately 20 years among farmers in Ethiopia, which is close to the result obtained in Reşadiye. These results indicate that although sheep farmers in Reşadiye have less professional experience than those examined in some studies conducted in Türkiye, they nevertheless have considerable production experience in sheep farming.

Table 3. Some characteristics of sheep farmers regarding age and professional experience

Characteristics	Group I	Group II	Group III	Overall
Age (years)	43.43	45.91	43.41	44.35
Professional experience (years)	13.42	21.61	19.13	19.00

The educational status of the sheep farmers was examined, and middle school graduates had the highest share in the overall distribution at 29.06%, followed by primary school graduates at 26.50% and high school graduates at 22.22%. The proportions of associate degree and bachelor's degree graduates were 11.97% and 7.69%, respectively, while 2.56% of the farmers were illiterate. When farmers with a middle school education or higher were considered together, their share in the total was 70.94%. This finding indicates that the educational status of the sheep farmers included in the study was not concentrated solely at the basic education level.

When evaluated by farm-size group, middle school graduates ranked first in Group I with 30.30%, followed by associate degree graduates with 24.24% and high school graduates with 21.21%. In Group II, primary school graduates had the highest share at 33.33%, while the proportion of middle school graduates was 20.51%. In Group III, middle school graduates ranked first with 35.56%, while primary school and high school graduates each accounted for 28.89%. Although the distributions differed descriptively among the groups, no statistical significance test was conducted to examine the relationship between education level and farm size; therefore, these differences should be interpreted at the descriptive level.

The educational structure identified in Reşadiye differs from that reported in some sheep farming studies conducted in different regions of Türkiye. Çiçek et al. (2022) found that 51.3% of sheep farmers across Türkiye were primary school graduates, 18.7% were middle school graduates, and 13.3% were high school graduates, while university graduates accounted for only 6.0%. In the same study, the proportions of primary school, middle school, and high school graduates in the Black Sea Region were reported as 40.0%, 26.7%, and 20.0%, respectively. Similarly, Mohamud and Çevrimli (2023) reported that 51.6% of farmers in Selçuklu District of Konya Province were primary school graduates, 21.0% were middle school graduates, and 16.1% were high school graduates. In a study conducted in Malatya by Köseman et al. (2022), 70.2% of the farmers were primary school graduates, while middle school–high school graduates and college–university graduates accounted for 25.3% and 4.5%, respectively.

Compared with these studies, the educational status of sheep farmers in Reşadiye was not concentrated at the primary school level and was more evenly distributed across middle school, high school, and higher education levels. In particular, the combined share of associate and bachelor's degree graduates was 19.66%. The relatively high level of education may provide

farms with a potential advantage in accessing and evaluating information on new production techniques, animal health practices, support programs, and farm management.
Indeed, Gürer and Ulutaş (2021) found that an increase in farmers' education level had a positive and statistically significant effect on the likelihood of continuing sheep farming, with an odds ratio of 1.513 for the education variable. This result indicates that education level is one of the socioeconomic characteristics that should be considered in relation to the sustainability of sheep farms.

Table 4. Distribution of sheep farmers by educational status

Educational status	Group I		Group II		Group III		Overall	
	F	%	F	%	F	%	F	%
Illiterate	1	3.03	2	5.13	0	0.00	3	2.56
Primary school	5	15.15	13	33.33	13	28.89	31	26.50
Middle school	10	30.30	8	20.51	16	35.56	34	29.06
High school	7	21.21	6	15.38	13	28.89	26	22.22
Associate degree	8	24.24	5	12.82	1	2.22	14	11.97
Bachelor's degree	2	6.06	5	12.82	2	4.44	9	7.69
Total	33	100.00	39	100.00	45	100.00	117	100.00

When the income sources of the sheep farmers were examined, the combination of crop and livestock production was found to be the most common production structure, accounting for 84.62%. The proportion of farmers engaged exclusively in livestock production was 15.38%, while 3.42% considered livestock production as a supplementary source of income. In addition, 46.15% of the farmers received retirement income, and 55.56% had household members earning non-agricultural income. These findings indicate that sheep farming in Reşadiye is largely carried out in combination with other agricultural activities and that the income structure of farm households is not based solely on livestock production.
Similar issues concerning income diversification have also been addressed in sheep farming studies conducted in different regions. Gürer and Ulutaş (2021) reported that the proportions of sheep farms with non-agricultural income in Niğde and Aksaray were 3% and 26%, respectively. In Reşadiye, however, 55.56% of the farmers had household members earning non-agricultural income, indicating that income sources outside agricultural activities also played an important role in the households included in the study. Nevertheless, caution should be exercised when directly comparing these proportions because the studies differ in how non-agricultural income was defined.
Köseman et al. (2022) reported that 73.2% of sheep farmers in Malatya were not engaged in any other commercial activity apart from sheep farming. In Reşadiye, however, 84.62% of the farmers carried out crop and livestock production together, while retirement income and non-agricultural income earned by household members were also common. This indicates that sheep farming is an agricultural activity sustained alongside different sources of household income. This structure suggests that income sources should be considered together when evaluating the role of sheep farming within the household economy in Reşadiye.

Table 5. Some characteristics of sheep farmers regarding production and income structure

Income and production characteristic	F	%
Crop and livestock production	99	84.62
Livestock production only	18	15.38
Livestock production as a supplementary source of income	4	3.42
Retirement income	54	46.15
Household members with non-agricultural income	65	55.56

Note: The first two categories indicate the structure of production activities and are mutually exclusive. Since the remaining variables allow multiple responses, the sum of all percentages in the table exceeds 100%.

Production Costs in Sheep Farming Enterprises

When production costs in sheep farming enterprises were examined according to farm-size groups, total cost per farm was determined as TRY 13,619.66 in Group I, TRY 34,125.36 in Group II, and TRY 104,411.87 in Group III, while the overall average total cost was calculated as TRY 69,180.47. Total production costs increased markedly from Group I to Group III. This indicates that as farm size increases, the amount of inputs used in production and the associated total costs also increase.

An examination of the structure of variable costs showed that feed expenses constituted the most important cost item across all farms. The average concentrate feed cost per farm was TRY 28,316.00, accounting for 44.45% of variable costs, while roughage cost amounted to TRY 10,508.00 and accounted for 16.49%. When concentrate and roughage were considered together, total feed costs reached TRY 38,824.00 and represented 60.94% of variable costs. Feed costs were followed by veterinary and animal health expenses at 15.32% and labor costs at 6.24%. These findings indicate that production costs in the sheep farms examined were largely concentrated around feed expenses.

By farm-size group, the share of feed costs in variable costs increased with farm size. When concentrate and roughage costs were considered together, the share of total feed costs was calculated as 37.37% in Group I, 57.00% in Group II, and 64.60% in Group III. In contrast, the share of veterinary and animal health expenses declined from 25.58% in Group I to 15.42% in Group II and 12.97% in Group III. The share of labor costs was 6.60%, 6.83%, and 6.33% in Groups I, II, and III, respectively, showing a relatively similar distribution across farm sizes. These results indicate that feed costs become increasingly dominant within the variable cost structure, particularly in larger farms.

An examination of fixed costs showed that depreciation of sheep housing capital was the most important fixed cost item in all farm-size groups. Its share in fixed costs was 80.66% in Group I, 75.26% in Group II, and 65.38% in Group III, while the overall share was 69.69%. In contrast, the share of sheep housing maintenance and repair costs increased from 18.62% to 25.61% with increasing farm size, while the share of machinery capital depreciation increased from 0.71% to 9.01%. This distribution indicates that the internal structure of fixed costs also changes as farm size increases.

When the cost structure identified in Reşadiye is evaluated together with the findings of sheep farming studies conducted in different regions of Türkiye, similarities are observed particularly regarding the importance of feed costs. Çiçek et al. (2022) reported that feed costs accounted for 47.55% of total costs and labor costs for 30.12% in sheep farms across Türkiye. Similarly, Mohamud and Çevrimli (2023) determined that feed costs accounted for 46.1% of total production costs in sheep farms in Selçuklu District of Konya Province. In Reşadiye, feed costs also ranked first, accounting for 60.94% of variable costs, supporting the importance of feed expenses in the economic structure of sheep farms. However, caution should be exercised when directly comparing these ratios because the classification of cost items and the cost totals used to calculate percentages may differ among studies.

The international literature also emphasizes the importance of feed costs for the economic performance of sheep farms. Bertolozzi-Caredio et al. (2021) reported that feed expenses constituted a substantial proportion of total costs in extensive sheep farms in the Aragón region of Spain and that feed costs were a key determinant of the economic sustainability of farms. Theodoridis et al. (2022) demonstrated that increasing on-farm feed production is important for reducing dependence on purchased feed and controlling production costs. Similarly, Papadopoulou et al. (2021) emphasized the importance of utilizing pasture resources for the economic sustainability of small ruminant farms.

Overall, feed expenses constitute the main cost component in the cost structure of sheep farms in Reşadiye, and their relative share in variable costs increases as farm size increases. This result indicates that, particularly for larger farms, improving on-farm feed production, increasing the availability of high-quality roughage resources, and ensuring the efficient use of existing pasture resources are important for controlling production costs.

Table 6. Distribution of production costs in sheep farming enterprises

Cost items	Group I (TRY)	%	Group II (TRY)	%	Group III (TRY)	%	Overall (TRY)	%
Animal material cost	1,753.57	16.53	1,795.80	6.06	1,817.00	1.86	1,803.00	2.83
Concentrate feed	3,428.57	32.32	12,919.35	43.61	45,763.00	46.87	28,316.00	44.45
Roughage	535.71	5.05	3,967.74	13.39	17,314.00	17.73	10,508.00	16.49
Veterinary and animal health	2,714.28	25.58	4,567.73	15.42	12,661.00	12.97	9,757.00	15.32
Labor costs	700.00	6.60	2,022.58	6.83	6,181.00	6.33	3,973.00	6.24
Water	46.42	0.44	237.09	0.80	408.00	0.42	289.00	0.45
Electricity and heating	267.85	2.52	427.41	1.44	766.00	0.78	621.00	0.97
Livestock insurance	0.00	0.00	361.29	1.22	2,811.00	2.88	1,874.00	2.94
Guard dog expenses	353.57	3.33	1,151.61	3.89	3,758.00	3.85	2,522.00	3.96
Shearing costs	471.42	4.44	1,016.12	3.43	2,520.00	2.58	1,706.00	2.68
Marketing costs	28.57	0.27	295.16	1.00	790.00	0.81	480.00	0.75
General administrative expenses (3%)	309.00	2.91	862.86	2.91	2,843.67	2.91	1,855.47	2.91
Total variable costs	10,608.96	100.00	29,624.74	100.00	97,632.67	100.00	63,704.47	100.00
Depreciation of sheep housing capital	2,428.57	80.66	3,387.09	75.26	4,432.20	65.38	3,816.00	69.69
Sheep housing maintenance and repair costs	560.71	18.62	936.12	20.80	1,736.00	25.61	1,291.00	23.58
Depreciation of machinery capital	21.42	0.71	177.41	3.94	611.00	9.01	369.00	6.73
Total fixed costs	3,010.70	100.00	4,500.62	100.00	6,779.20	100.00	5,476.00	100.00
Grand total costs	13,619.66	–	34,125.36	–	104,411.87	–	69,180.47	–

Note: General administrative expenses were calculated as 3% of total variable costs excluding general administrative expenses. Percentage values represent the shares of variable cost items in total variable costs and the shares of fixed cost items in total fixed costs.

When the total production costs of sheep farms were evaluated in terms of variable and fixed costs, variable costs accounted for a higher share of total costs in all farm-size groups. In Group

I, variable costs constituted 77.89% of total costs, while fixed costs accounted for 22.11%. In Group II, the share of variable costs increased to 86.81%, whereas the share of fixed costs was 13.19%. In Group III, the share of variable costs reached the highest level at 93.51%, while the share of fixed costs declined to 6.49%. Across all farms, variable costs accounted for 92.08% of total production costs, whereas fixed costs represented 7.92%.

Across the farm-size groups, the share of variable costs in total production costs increased from Group I to Group III, whereas the relative share of fixed costs decreased. The absolute value of fixed costs increased from TRY 3,010.70 in Group I to TRY 4,500.62 in Group II and TRY 6,779.20 in Group III. Nevertheless, the decline in the share of fixed costs in total production costs from 22.11% to 6.49% indicates that, as farm size increased, the increase in variable costs was greater than the increase in fixed costs. Indeed, variable costs increased from TRY 10,608.96 in Group I to TRY 97,632.67 in Group III.

This structure becomes clearer when evaluated together with the cost composition presented in Table 6. As farm size increased, the relative importance of feed costs within variable costs also increased. The combined share of concentrate and roughage costs was 37.37% in Group I, increasing to 57.00% in Group II and 64.60% in Group III. Therefore, as farm size increased, total production costs not only increased in absolute terms, but the cost structure also became increasingly concentrated in variable costs, particularly feed expenses.

The variable and fixed cost structure identified in Reşadiye is generally consistent with findings reported in the literature. Mohamud and Çevrimli (2023) found that variable costs accounted for 95% of total production costs and fixed costs for 5% in sheep farms in Selçuklu District of Konya Province. In Reşadiye, variable costs accounted for 92.08% of total production costs, while fixed costs represented 7.92%, indicating that production costs in sheep farms consist predominantly of variable costs. However, because the classification of cost items and, in particular, the way components such as labor are included in cost calculations may differ among studies, the cost calculation methods used should be considered when comparing these ratios.

Table 7. Distribution of variable and fixed costs by farm-size groups

Cost structure	Group I	Group II	Group III	Overall
Variable costs (TRY)	10,608.96	29,624.74	97,632.67	63,704.47
Share of variable costs (%)	77.89	86.81	93.51	92.08
Fixed costs (TRY)	3,010.70	4,500.62	6,779.20	5,476.00
Share of fixed costs (%)	22.11	13.19	6.49	7.92
Total costs (TRY)	13,619.66	34,125.36	104,411.87	69,180.47
Total (%)	100.00	100.00	100.00	100.00

Note: Percentage values represent the shares of variable and fixed costs in total production costs.

Classification of the Main Problems in Sheep Farming Using Factor Analysis

Exploratory factor analysis was applied to classify the main problems faced by sheep farmers into a smaller number of meaningful dimensions. The Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy and Bartlett's Test of Sphericity were used to assess the suitability of the dataset for factor analysis. The KMO value was calculated as 0.514, indicating that sampling adequacy was at the minimum acceptable level for factor analysis. Bartlett's Test of Sphericity was statistically significant ($\chi^2 = 957.597$; $df = 153$; $p < 0.001$). This result indicates that the correlation matrix was not an identity matrix and that sufficient relationships existed among the variables to allow factor analysis to be applied. The Cronbach's Alpha coefficient, calculated to assess the internal consistency of the scale, was 0.807, indicating a good level of internal consistency among the variables used.

As a result of the factor analysis, the problems faced by sheep farmers were grouped under four main factors, which together explained 55.10% of the total variance. This result indicates that the problems encountered by sheep farmers cannot be grouped under a single dimension and that different problem areas need to be considered together. The contents and naming of the factors are evaluated in detail in the following tables.

Similar methods have been used in studies analyzing the multidimensional structure of small ruminant farms. Siasiou et al. (2021) examined 551 sheep and goat farms in Greece using multivariate analysis methods and identified five factors through principal component analysis, explaining 61.22% of the total variance. The KMO value in their study was calculated as 0.571, and Bartlett's Test of Sphericity was statistically significant ($p < 0.001$). Although the KMO value of 0.514 and the total explained variance of 55.10% obtained in the Reşadiye study were lower than those reported by Siasiou et al. (2021), both studies demonstrate that a large number of variables can be classified under a smaller number of factors. These findings support the use of factor analysis as a method for classifying multidimensional characteristics and problem areas related to small ruminant farms.

Table 8. Tests of suitability for factor analysis

Test / Statistic	Value
Kaiser-Meyer-Olkin (KMO)	0.514
Bartlett's Approx. Chi-Square	957.597
Degrees of freedom (df)	153
Significance (p)	<0.001
Cronbach's Alpha	0.807

As a result of the factor analysis, four factors with eigenvalues greater than 1 were obtained, explaining 55.104% of the total variance. After Varimax rotation, the eigenvalue of the first factor was 3.003, explaining 16.686% of the total variance. The eigenvalue of the second factor was 2.955, accounting for 16.415% of the variance; the eigenvalue of the third factor was 2.217, accounting for 12.319%; and the eigenvalue of the fourth factor was 1.743, accounting for 9.685% of the variance.

After rotation, the contributions of the first and second factors to the total variance were quite similar. Together, these two factors explained 33.101% of the total variance. With the addition of the third factor, the cumulative explained variance increased to 45.420%, and with the inclusion of the fourth factor, it reached 55.104%. This distribution indicates that no single factor dominated the explanation of the problems faced by sheep farmers and that the total variance was distributed across different dimensions of the problems.

Table 9. Variance explained by the factors

Factor	Eigenvalue after rotation	Explained variance (%)	Cumulative variance (%)
1	3.003	16.686	16.686
2	2.955	16.415	33.101
3	2.217	12.319	45.420
4	1.743	9.685	55.104

An examination of the rotated factor loadings showed that the first factor consisted of constantly changing policies (0.813), problems related to guard dogs (0.718), problems arising from sheep housing (0.663), difficulties in obtaining grants (0.663), and wild animal attacks (0.518). Since

variables related to policy, farm structure, and environmental conditions were grouped together under this factor, this dimension was named "Structural, Policy, and Environmental Problems." The highest loading within the factor was associated with constantly changing policies (0.813), indicating that problems related to policy implementation were the most prominent component of this dimension.

In the second factor, insufficient support (0.807) and the limited number of informational seminars (0.788) had the highest factor loadings. These variables were followed by water shortages (0.595), marketing problems (0.585), and difficulties in finding shepherds (0.549). Since institutional support and information services were grouped together with basic conditions essential for sustaining production, this dimension was named "Institutional Support and Production Conditions." This structure indicates that farmers' problems are not limited to financial support but also include information and extension services, marketing, water availability, and labor supply.

The third factor consisted of problems in forage production (0.803), lack of modern technical facilities (0.642), and the lack of a successor to take over the farm (0.504). Since problems related to the technical structure of production and the transfer of the farm to future generations were grouped under the same factor, this dimension was named "Technical Infrastructure and Farm Continuity." This factor indicates that, in addition to existing technical conditions, the ability of sheep farms to continue operating in the future constitutes an important area of concern for their sustainability.

In the fourth factor, animal diseases had the highest factor loading at 0.881. Insufficient education (0.519), inadequate or unavailable pasture (0.506), and high feed prices (0.444) were also included in this factor. Since animal health risks were grouped together with production resources such as farmers' knowledge level, pasture availability, and feed costs, this dimension was named "Production Risks and Resource Constraints." The particularly high factor loading of animal diseases indicates that health-related risks were the most prominent component of this dimension.

Overall, the factor analysis results indicate that the problems faced by sheep farmers in Reşadiye District are not solely economic in nature; rather, they are grouped into four main dimensions encompassing structural and policy conditions, environmental risks, institutional support, production conditions, technical infrastructure, farm continuity, and constraints related to production resources.

Findings in the literature also support the multidimensional nature of the problems encountered in sheep farming. Nyam et al. (2022) classified the problems faced by small-scale sheep farmers in South Africa into four main components using principal component analysis and identified marketing, diseases and parasites, high feed costs, inadequate capital, professional knowledge, housing, labor, water, and pasture conditions as important problem areas. These results indicate that the problems identified in Reşadiye may also emerge in different production systems in economic, technical, structural, and production-resource dimensions.

The findings regarding farm continuity are also consistent with the literature. Siasiou et al. (2021) evaluated variables related to the current status and future of farms under a separate factor and demonstrated that farm succession and the tendency to continue production are important for the future of farms. Bertolozzi-Caredio et al. (2021) identified rural depopulation, labor shortages, and weak generational renewal among the factors threatening the continuity of extensive sheep farming. These findings support the inclusion of the lack of a successor to take over the farm within the farm continuity dimension identified in Reşadiye.

Similar results have also been reported regarding institutional support and production conditions. Gürer and Ulutaş (2021) found that an increase in the share of small ruminant support payments in the value of production positively affected farmers' likelihood of continuing sheep farming. The same study also reported that difficulties in finding shepherds

negatively affected the decision to continue production. These results support the inclusion of insufficient support and difficulties in finding shepherds within the same problem dimension in Reşadiye.

In terms of production risks and resource constraints, Mohamud and Çevrimli (2023) identified inadequate pasture, animal diseases, increasing costs, marketing, and difficulties in finding shepherds among the major problems faced by sheep farms. Çiçek et al. (2022) also reported that pasture availability and productivity, family labor, shepherd availability, product prices, and marketing opportunities are important for the structure and sustainability of sheep farms. These findings support the production risks and resource constraints dimension identified in Reşadiye.

Overall, the factor analysis results show that the problems faced by sheep farmers in Reşadiye emerge across different structural, institutional, technical, and production-related dimensions. Therefore, measures aimed at ensuring the sustainability of sheep farming should not focus solely on production costs; they should also consider support and extension services, technical infrastructure, pasture and feed resources, animal health, labor supply, and the intergenerational continuity of farms together.

Table 10. Classification of the main problems faced by sheep farmers according to factors

Factor / Dimension	Variable	Factor loading
Factor 1: Structural, policy, and environmental problems	Constantly changing policies	0.813
	Problems related to guard dogs	0.718
	Problems arising from sheep housing	0.663
	Difficulties in obtaining grants	0.663
	Wild animal attacks	0.518
Factor 2: Institutional support and production conditions	Insufficient support	0.807
	Limited number of informational seminars	0.788
	Water shortages	0.595
	Marketing problems	0.585
	Difficulties in finding shepherds	0.549
Factor 3: Technical infrastructure and farm continuity	Problems in forage production	0.803
	Lack of modern technical facilities	0.642
	Lack of a successor to take over the farm	0.504
Factor 4: Production risks and resource constraints	Animal diseases	0.881
	Insufficient education	0.519
	Inadequate or unavailable pasture	0.506
	High feed prices	0.444

CONCLUSIONS AND RECOMMENDATIONS

This study examined the socioeconomic characteristics and production costs of sheep farms in Reşadiye District of Tokat Province and classified the main problems faced by sheep farmers using factor analysis. The results showed that the mean age of the farmers was 44.35 years and their average professional experience in sheep farming was 19 years. The fact that 84.62% of the farmers were engaged in both crop and livestock production indicates that sheep farming in the study area is carried out in an integrated manner with other agricultural activities. In addition, the prevalence of retirement income and non-agricultural income sources within the household indicates a diversified income structure among farm households.

In terms of production costs, the overall average total cost per farm was calculated as TRY 69,180.47. When concentrate and roughage costs were considered together, total feed costs

accounted for 60.94% of variable costs, making feed the most important component of the cost structure. Feed costs were followed by veterinary and animal health expenses at 15.32% and labor costs at 6.24%. Variable costs accounted for 92.08% of total production costs, while fixed costs accounted for 7.92%. Across farm-size groups, the share of variable costs in total costs increased from 77.89% to 93.51%, whereas the share of fixed costs decreased from 22.11% to 6.49%. Furthermore, total feed costs accounted for 37.37% of variable costs in Group I, 57.00% in Group II, and 64.60% in Group III, indicating that the relative importance of feed costs increased with farm size. These findings demonstrate that production costs in sheep farms consist predominantly of variable costs and that the cost structure differs across farm-size groups.

The factor analysis grouped the problems faced by sheep farmers into four main dimensions: "Structural, Policy, and Environmental Problems," "Institutional Support and Production Conditions," "Technical Infrastructure and Farm Continuity," and "Production Risks and Resource Constraints." Together, these factors explained 55.104% of the total variance. Constantly changing policies, insufficient support, problems in forage production, and animal diseases had the highest factor loadings within their respective factors. These results demonstrate that the problems encountered in sheep farming are not limited to economic and cost-related issues but have a multidimensional structure encompassing structural, policy, institutional, technical, and production-related risks.

Based on the findings of the study, priority should be given to measures aimed at reducing feed costs, which constitute a major component of the cost structure of sheep farms. Improving farms' capacity to produce high-quality roughage, encouraging forage crop production, and protecting and efficiently utilizing existing pasture resources may contribute to reducing dependence on purchased feed and the associated cost burden. In particular, the increasing relative importance of feed costs as farm size increases highlights the importance of measures related to feed production and procurement for larger farms.

Based on the factor analysis results, it is recommended that access to support and grant programs be facilitated, predictability in agricultural support policies be improved, and training, information, extension, and advisory services for sheep farmers be strengthened. In addition, marketing opportunities should be improved and the effectiveness of producer organizations should be enhanced. Measures that take regional conditions into account should also be developed to address problems that directly affect the production process, including shepherd availability, water and housing conditions, animal diseases, inadequate pasture, and wild animal attacks.

The inclusion of the lack of a successor to take over the farm within the "Technical Infrastructure and Farm Continuity" dimension indicates that intergenerational continuity should also be considered in relation to the long-term sustainability of sheep farming. Therefore, developing measures that encourage young people to remain in or enter sheep farming is important for facilitating the transfer of farms to future generations.

In conclusion, the sustainability of sheep farming in Reşadiye District is shaped by several interrelated factors, including production costs, feed and pasture resources, institutional support, technical infrastructure, animal health, labor availability, marketing opportunities, and the intergenerational continuity of farms. Therefore, policies aimed at ensuring the continuity of sheep farming in the region should be developed through a comprehensive approach that takes regional conditions into account.

A REVIEW OF THE MECHANICAL BEHAVIOR OF AUXETIC TPMS-BASED FUNCTIONALLY GRADED STRUCTURES

TOLGA SOLAR[1], CANER SOLAR[2], PINAR AYDAN DEMİRHAN[3]

[1]Arel University, Engineering Faculty, Turkey
[2,3]Trakya University, Engineering Faculty, Turkey

ABSTRACT

Functionally graded materials (FGMs) enable spatial tailoring of mechanical properties by gradually varying material composition or structural characteristics, thereby reducing abrupt transitions commonly encountered in conventional composite systems. In recent years, triply periodic minimal surface (TPMS) architectures and auxetic structures with negative Poisson's ratio have attracted increasing attention because of their potential for lightweight design, deformation control, energy absorption, and impact resistance. TPMS architectures such as Gyroid, Primitive, Diamond, and I-WP provide smooth and continuous geometries, while auxetic behavior offers distinctive transverse deformation mechanisms. Their combination with functional grading provides a promising framework for tailoring the static, vibration, buckling, and dynamic responses of advanced lightweight structures. This review critically and comparatively examines recent developments in auxetic TPMS-based and functionally graded structures, with emphasis on geometrical design strategies, additive manufacturing, experimental characterization, mechanical behavior, and engineering applications. Particular attention is given to the relationships among topology, auxetic mechanism, grading strategy, manufacturing fidelity, and structural response. Current research limitations and future directions toward manufacturable, experimentally validated, and application-oriented auxetic TPMS systems are also discussed.

Key words: Auxetic structures, triply periodic minimal surfaces (TPMS), functionally graded materials (FGMs), sandwich structures, mechanical behavior.

INTRODUCTION

Mechanical metamaterials derive their macroscopic properties primarily from engineered architecture rather than solely from constituent materials. Among them, auxetic structures are particularly attractive because their negative Poisson's ratio can provide favorable deformation characteristics together with enhanced energy absorption, indentation resistance, and impact performance. These properties have motivated their investigation in protective systems, biomedical devices, automotive components, and lightweight engineering structures (Daynes, 2025; Novak et al., 2026). In parallel, functionally graded porous sandwich structures have been investigated as lightweight structural systems in which spatial variations in material properties and porosity can be used to tailor stiffness and static response (Solar and Demirhan, 2025).

Triply periodic minimal surface (TPMS) architectures have emerged as promising alternatives to conventional strut-based lattices because of their smooth and continuous geometries, high connectivity, and favorable mechanical efficiency. Primitive, Gyroid, Diamond, and I-WP are among the most frequently investigated TPMS topologies, although their responses vary considerably with topology, relative density, material properties, and loading conditions

(Chen and Wang, 2026; Engel et al., 2026). The integration of TPMS architectures into functionally graded porous sandwich structures has also been investigated for improving and tailoring their static structural response (Solar et al., 2025).

An important development has been the deliberate modification of TPMS architectures to generate auxetic behavior. Since conventional TPMS geometries are not universally auxetic, several geometrical strategies have been proposed, including buckling-induced deformation, coordinate transformation, unit-cell rotation, dual-period mapping, and shape-function optimization. Zheng et al. (2021) introduced a buckling-induced TPMS-derived auxetic metamaterial, while Wang et al. (2023) transformed a Gyroid architecture into a continuous auxetic tubular configuration. Liu et al. (2023) and Kim et al. (2024) subsequently demonstrated controllable auxeticity and deformation-dependent stiffness using modified Primitive-based architectures.

More recent research has shifted from simply achieving a negative Poisson's ratio toward simultaneously controlling auxeticity, stiffness, isotropy, deformation stability, and energy absorption. Daynes (2025) demonstrated TPMS-based configurations with positive, zero, and negative Poisson's ratios while addressing elastic isotropy, whereas Novak et al. (2026) showed that functional grading can stabilize auxetic deformation by suppressing localization and out-of-plane instability. Accordingly, this review examines the relationships among TPMS topology, auxetic mechanisms, functional grading, additive manufacturing, and mechanical response, with particular emphasis on compression, energy absorption, vibration, buckling, engineering applications, current challenges, and future research needs.

Table 1. Classification of the reviewed studies according to the integration strategy of auxeticity, TPMS and functional grading

Study	Main architecture	Design approach	Main contribution
Zheng et al. (2021)	Modified TPMS	Buckling-induced auxeticity	Introduced a mathematically defined 3D auxetic TPMS-derived structure
Wang et al. (2023)	Gyroid tubular TPMS	Coordinate transformation	Developed seamless auxetic tubular TPMS structures
Liu et al. (2023)	Primitive TPMS	Dual-period deformation	Enabled controllable NPR through geometric parameters
Kim et al. (2024)	Rotated Primitive TPMS	Unit-cell rotation	Achieved auxeticity with deformation-dependent stiffness
Daynes (2025)	Primitive TPMS	Shape-function mapping	Combined tunable Poisson's ratio with elastic isotropy
Novak et al. (2026)	Graded re-entrant AUXTPMS	Porosity grading	Improved deformation stability and sustained auxetic response

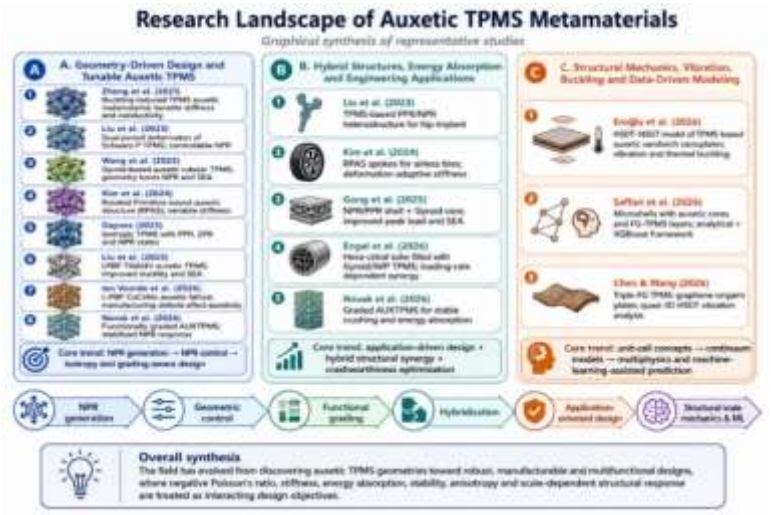

Fig. 1: Research landscape of auxetic TPMS metamaterials.

Design Strategies and Functional Grading of Auxetic TPMS Structures

Auxetic behavior in TPMS-based structures is generally achieved through deliberate geometric modification rather than being an inherent characteristic of conventional TPMS topologies. Recent design strategies therefore focus on activating rotational, bending, and buckling mechanisms while simultaneously controlling stiffness, anisotropy, deformation stability, and manufacturability (Kim et al., 2024; Novak et al., 2026). The evolution of these approaches is illustrated in Fig. 2.

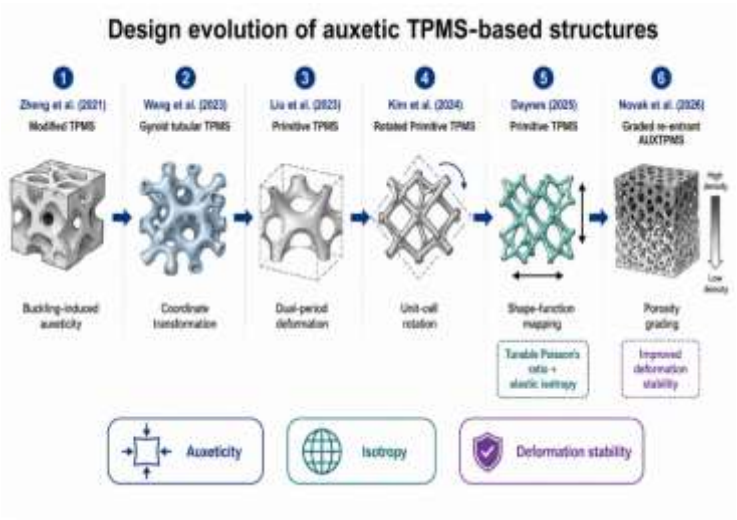

Fig. 2: Design evolution of auxetic TPMS-based structures. Original schematic synthesized from Zheng et al. (2021), Wang et al. (2023), Liu et al. (2023), Kim et al. (2024), Daynes (2025), and Novak et al. (2026).

Geometrical strategies for inducing auxetic behavior

Several geometrical approaches have been proposed to generate negative Poisson's ratio behavior in TPMS-derived structures. A modified TPMS architecture based on buckling-

induced deformation was among the early three-dimensional approaches, demonstrating that structural instability could be intentionally used to produce an auxetic response (Zheng et al., 2021). A different strategy transformed a Gyroid-type TPMS from Cartesian to cylindrical coordinates, producing a continuous tubular auxetic architecture suitable for additive manufacturing (Wang et al., 2023).

Primitive TPMS has subsequently become an important basis for controllable auxetic design. Dual-period deformation functions and Bézier-based transformations were applied to the P-surface to obtain tunable three-dimensional negative Poisson's ratio behavior (Liu et al., 2023). Unit-cell rotation was also used to generate oblique connections and deformation-dependent stiffness in rotated Primitive structures, providing a direct route toward application-oriented designs such as airless tires (Kim et al., 2024).

More recently, shape-function mapping and level-set optimization have enabled simultaneous control of Poisson's ratio and elastic isotropy. At a relative density of 20%, Poisson's ratios ranging approximately from +0.29 to −0.38 were demonstrated, including positive, zero, and auxetic configurations (Daynes, 2025). These developments indicate a transition from simply generating auxeticity toward programming several mechanical properties within the same TPMS-based architecture.

Functional grading of auxetic TPMS architectures

Functional grading introduces an additional design variable by allowing porosity, relative density, wall thickness, or other geometrical parameters to vary spatially. Unlike conventional FGMs, where grading is commonly associated with changes in material composition, TPMS-based structures can also achieve spatial property variation through geometry alone.

Current evidence shows that grading does not necessarily increase all mechanical properties simultaneously. Thickness-graded auxetic TPMS lattices exhibited altered deformation characteristics but did not consistently outperform homogeneous configurations in peak mechanical performance (ten Voorde et al., 2026). In contrast, porosity grading in re-entrant AUXTPMS structures promoted sequential crushing, reduced deformation localization, and suppressed out-of-plane instability, thereby maintaining the auxetic response over a wider strain range (Novak et al., 2026).

These findings suggest that one of the principal benefits of functional grading is deformation control rather than universal strength enhancement. Grading can therefore be used to regulate where deformation initiates, how collapse propagates, and how long the auxetic mechanism remains active.

Emerging multi-parameter and hybrid grading concepts

Recent studies have extended functional grading beyond a single geometrical parameter. A Triple-FG TPMS–graphene-origami system was proposed in which TPMS architecture, origami folding degree, and reinforcement content were graded independently, enabling multi-parameter control of dynamic response (Chen and Wang, 2026).

Hybrid concepts have also combined different architected mechanisms within separate structural components. For example, butterfly-shaped auxetic cores have been integrated with FG-TPMS face layers and graphene platelet reinforcement, demonstrating a multi-level design approach in which auxetic and TPMS functions are combined without necessarily being incorporated into the same unit cell (Saffari et al., 2026).

Overall, current design strategies are evolving from isolated auxetic unit cells toward graded, hybrid, and multi-parameter architected systems in which geometry, material distribution, and deformation mechanisms are tailored simultaneously.

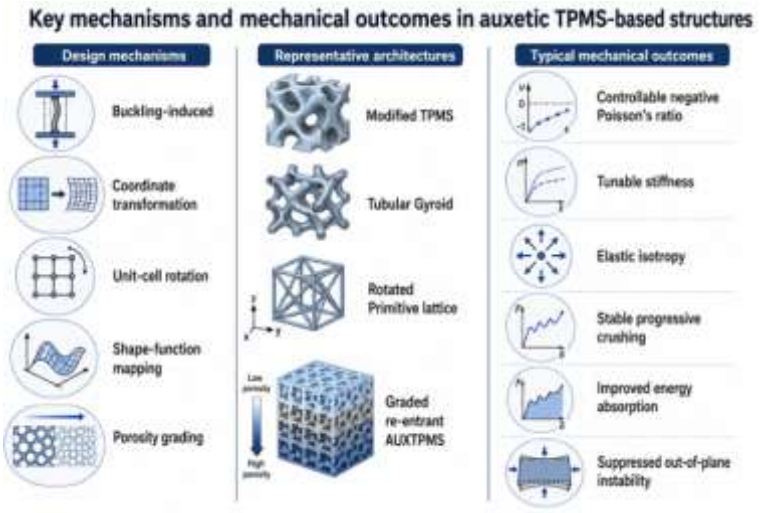

Fig. 3: Principal design mechanisms, representative architectures and typical mechanical outcomes of auxetic TPMS-based structures. Original schematic synthesized from the reviewed literature.

Mechanical Behavior of Auxetic TPMS-Based Structures

The mechanical response of auxetic TPMS-based structures is governed by the combined effects of topology, relative density, grading strategy, deformation mechanism, parent material, and loading condition. Most experimental studies focus on compression and energy absorption, whereas recent analytical investigations have extended the field toward vibration, buckling, and multifunctional structural behavior.

Compression behavior and energy absorption

Compression remains the most extensively investigated loading condition because it directly reveals auxetic deformation, collapse mechanisms, and energy-absorption capability. Recent studies indicate that achieving a stronger negative Poisson's ratio does not necessarily lead to simultaneous improvements in stiffness, strength, and energy absorption.

Homogeneous CoCrMo auxetic TPMS lattices fabricated by L-PBF exhibited apparent Poisson's ratios as low as approximately −0.1443, energy absorption up to 37.93 J/cm³, and compressive strength up to 231.44 MPa. However, the thickness-graded configuration did not consistently outperform the homogeneous structures in peak mechanical properties (ten Voorde et al., 2026).

High auxetic deformation has also been demonstrated in Ti6Al4V TPMS-based tubular metamaterials. An optimized configuration achieved an effective auxetic strain of 17.173% and a specific energy absorption (SEA) of 16.6 J/g, illustrating the possibility of combining pronounced auxeticity with high energy absorption while retaining an inherent trade-off with structural strength (Liu et al., 2025).

Functional grading can provide additional benefits by controlling the collapse sequence rather than simply increasing peak strength. Porosity-graded re-entrant AUXTPMS structures maintained negative Poisson's ratio behavior over a wider strain range and suppressed out-of-plane instability. Metallic specimens exhibited SEA values of 2.63 J/g for aluminium and 5.05 J/g for stainless steel (Novak et al., 2026).

Hybridization provides another route for improving compressive performance. The integration of a Gyroid core into NPR cylindrical shells increased both peak load and SEA by approximately 47% in selected configurations (Gong et al., 2025). However, such improvements can be loading-rate dependent. TPMS-filled hexa-chiral tubes showed increases of up to 104% in mass-specific energy absorption under quasi-static loading, whereas comparable benefits were not maintained under dynamic loading because of changes in the deformation behavior of the base material (Engel et al., 2026).
Overall, these findings demonstrate that auxeticity alone does not determine compressive performance. Topology, grading, hybrid interaction, material behavior, and loading rate must be considered simultaneously.

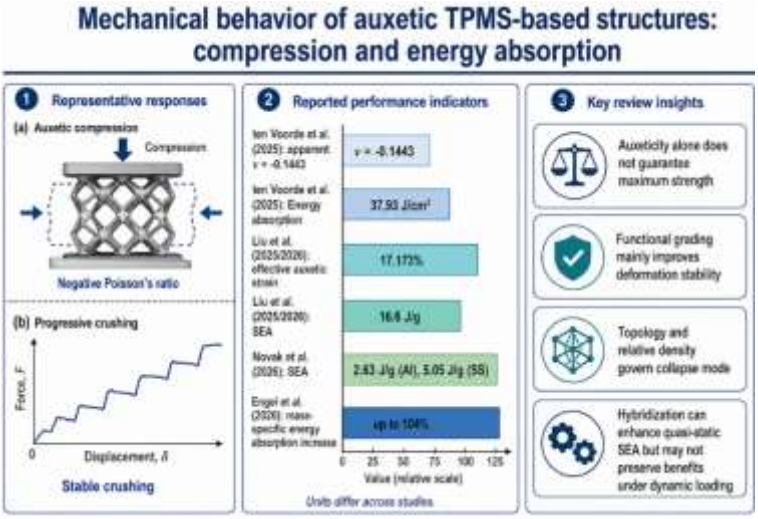

Fig. 4: Summary of representative compression responses, reported performance indicators and main review insights for auxetic TPMS-based structures. Original review figure synthesized from the reviewed literature.

Vibration and dynamic response

Compared with compression, vibration studies remain relatively limited. Nevertheless, recent investigations demonstrate that TPMS topology and functional grading can also be used to tailor the dynamic behavior of lightweight auxetic structures.
In Triple-FG TPMS–graphene-origami plates, natural frequencies were strongly affected by TPMS topology, grading pattern, and reinforcement distribution. Among the investigated configurations, P-type TPMS produced the highest natural frequencies, while increasing porosity generally reduced the fundamental frequency. The combined FGV-X/FGP-O grading configuration provided the highest response among the examined pattern combinations (Chen and Wang, 2026).
Machine-learning-assisted approaches have also been introduced for rapid prediction of vibration characteristics. For cylindrical microshells incorporating butterfly-shaped auxetic cores and FG-TPMS face layers, XGBoost models achieved coefficients of determination ranging from 98.84% to 99.91%, demonstrating the potential of data-driven methods for efficient performance prediction (Saffari et al., 2026).
These studies indicate a transition from geometry-based vibration analysis toward multi-parameter structural models combining functional grading, reinforcement distribution, foundation effects, and data-driven prediction.

Buckling and structural stability

Structural stability is becoming increasingly important as auxetic TPMS concepts are extended from cellular compression specimens to sandwich plates and other load-bearing systems. Functional grading has been shown to suppress out-of-plane instability and promote more stable progressive deformation in re-entrant AUXTPMS architectures (Novak et al., 2026).

At smaller structural scales, coupled vibration and buckling behavior has been investigated for sandwich nanoplates containing TPMS-based auxetic cores. Porosity, TPMS topology, nonlocal effects, strain-gradient effects, temperature, and external electric and magnetic fields were shown to modify both natural frequency and stability. Increasing porosity and nonlocal effects generally reduced effective stiffness, whereas strain-gradient effects increased structural rigidity (Eroğlu et al., 2026).

These results demonstrate that stability in auxetic TPMS structures is governed not only by geometry, but also by scale-dependent effects, environmental conditions, and multiphysics interactions. Buckling can therefore be considered both a failure mechanism and a controllable design parameter.

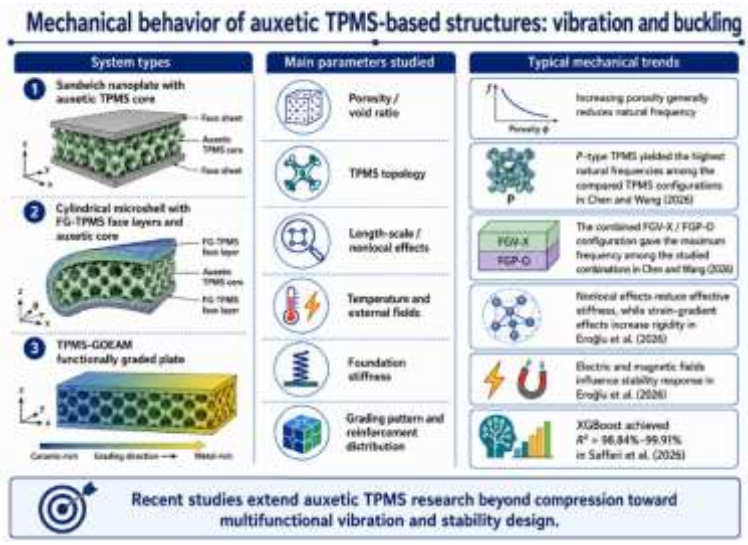

Fig. 5: Summary of system types, governing parameters and main mechanical trends reported in vibration and buckling studies of auxetic TPMS-based structures. Original review figure synthesized from the reviewed literature.

Comparative discussion

Overall, three trends emerge from the reviewed mechanical studies. First, auxetic TPMS architectures can provide favorable energy absorption and progressive deformation, although stronger auxeticity does not automatically correspond to higher strength or stiffness. Second, functional grading appears particularly useful for controlling deformation localization and structural stability. Third, recent analytical studies are extending auxetic TPMS research beyond compression toward vibration, buckling, multiphysics coupling, and data-driven structural design.

Table 2. Summary of the main mechanical findings in the reviewed studies

Study	Mechanical focus	Main reported result	Review interpretation
ten Voorde et al. (2026)	Compression / auxeticity / energy absorption	Apparent \(\nu \approx -0.1443\); energy absorption = 37.93 J/cm³; compressive strength up to 231.44 MPa	Strong performance, but grading does not automatically improve all peak properties.
Liu et al. (2025)	Compression / auxetic strain / SEA	Effective auxetic strain = 17.173%; SEA = 16.6 J/g	Strong auxeticity can coexist with good energy absorption, but trade-offs remain.
Novak et al. (2026)	Graded compression / stability / SEA	SEA = 2.63 J/g (Al), 5.05 J/g (SS); grading stabilizes collapse and prolongs NPR behavior	Functional grading is most valuable as a stability-control mechanism.
Gong et al. (2025)	Hybrid compression / peak load / SEA	Gyroid core improved compressive performance, with increases around 47% in some NPR-shell cases	Shell–core interaction can significantly improve compressive behavior.
Engel et al. (2026)	Quasi-static and dynamic crushing	Mass-specific energy absorption increase up to 104% under quasi-static loading	Hybridization can be beneficial, but the advantage may diminish under dynamic loading.
Chen and Wang (2026)	Free vibration / graded auxetic plate	P-type TPMS produced the highest frequencies; increasing porosity reduced frequency; FGV-X/FGP-O gave the highest response	TPMS topology and grading pattern strongly govern dynamic behavior.
Saffari et al. (2026)	Free vibration / ML-assisted prediction	XGBoost R^2 = 98.84–99.91%	Data-driven prediction is becoming relevant in architected TPMS systems.
Eroğlu et al. (2026)	Vibration / buckling / stability	Porosity reduces frequency; nonlocal effects soften the structure; strain-gradient effects increase rigidity; external fields affect stability	Buckling and vibration depend on topology, scale effects and coupled physical fields.

Additive Manufacturing and Experimental Characterization

Additive manufacturing (AM) is a key enabling technology for auxetic TPMS-based structures because their continuous curvature, internal cavities, and spatially varying geometries are difficult to realize using conventional manufacturing methods. The reviewed studies employ different AM routes depending on the parent material, structural scale, and intended mechanical response. Metallic structures are predominantly fabricated using laser powder bed fusion (LPBF), whereas polymeric and elastomeric architectures have been produced using material extrusion, selective laser sintering (SLS), direct ink writing (DIW), and digital light processing (DLP) (Wang et al., 2023; Daynes, 2025; Novak et al., 2026; Engel et al., 2026).

Additive manufacturing routes

Metal-based AM has enabled the fabrication of complex TPMS-derived auxetic structures with relatively high load-carrying capacity. Gyroid-derived tubular architectures were successfully produced using LPBF, demonstrating the feasibility of manufacturing continuous auxetic geometries without assembling separate cellular components (Wang et al., 2023). CoCrMo auxetic TPMS lattices were also fabricated by L-PBF, although process resolution imposed limitations on the smallest manufacturable features (ten Voorde et al., 2026). Similarly, Ti6Al4V structures produced by LPBF showed measurable differences between numerical and experimental stiffness because of manufacturing imperfections such as unmelted particles and lack-of-fusion defects (Liu et al., 2025).

Polymer-based AM provides greater flexibility for investigating large and recoverable auxetic deformation. TPU-95A structures with positive, zero, and negative Poisson's ratios were manufactured by material extrusion and tested under compression (Daynes, 2025). Rubber-based rotated Primitive structures were produced using a customized DIW process combined with photocuring and thermal vulcanization, demonstrating the manufacturability of flexible auxetic TPMS concepts for airless-tire applications (Kim et al., 2024).

Other AM routes have also been successfully applied. Graded AUXTPMS structures were fabricated from PA2200 using SLS, while selected configurations were additionally produced from stainless steel and aluminium alloys for material comparison (Novak et al., 2026). DLP was used to manufacture photopolymer hexa-chiral/TPMS hybrid structures for quasi-static and dynamic testing (Engel et al., 2026), whereas FFF with PLA enabled experimental investigation of concave cylindrical shells, Gyroid cores, and their hybrid configurations (Gong et al., 2025). Post-processing can also introduce additional functionality; electroless nickel coating substantially increased the stiffness and conductivity of a flexible TPMS-derived auxetic metamaterial while retaining its auxetic mechanism (Zheng et al., 2021).

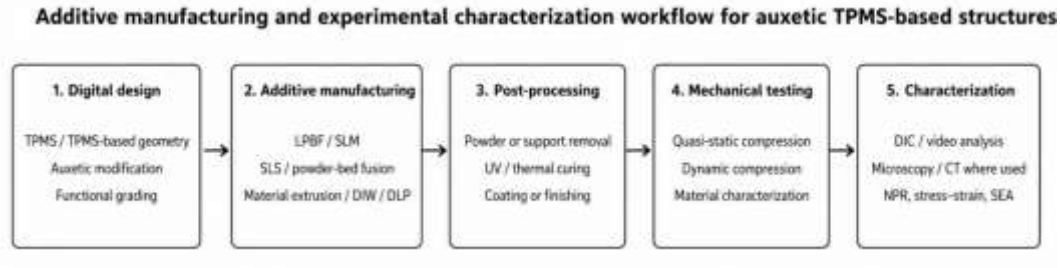

Fig. 6: Additive manufacturing and experimental characterization workflow

Experimental characterization

Quasi-static compression is the dominant experimental method in the reviewed literature because it simultaneously provides information on stress–strain response, collapse mechanisms, energy absorption, and negative Poisson's ratio behavior. However, the measurement techniques vary substantially among studies.

Digital image correlation (DIC) and related optical techniques are particularly valuable because auxetic deformation cannot always be adequately characterized using global force–displacement measurements alone. Three-dimensional deformation fields measured during compression showed generally good agreement with numerical predictions and enabled direct evaluation of negative Poisson's ratio behavior (Liu et al., 2023). Video image analysis combined with DIC was similarly used to compare uniform and graded AUXTPMS structures and to quantify longitudinal and transverse deformation during progressive collapse (Novak et al., 2026).

Experimental characterization has also been used to evaluate anisotropy. TPMS-based PPR, ZPR, and NPR specimens were tested in three loading orientations, allowing predicted elastic isotropy and Poisson's ratio behavior to be assessed experimentally (Daynes, 2025).

Dynamic testing remains comparatively limited. Quasi-static and dynamic compression tests on TPMS-filled hexa-chiral structures showed that mechanical benefits observed under slow loading may diminish at higher loading rates (Engel et al., 2026). This highlights the need to extend experimental validation toward impact, fatigue, vibration, and buckling conditions.

Table 3. Additive manufacturing and experimental characterization in representative reviewed studies

Study	Material	Manufacturing route	Experimental characterization	Main manufacturing/experimental insight
Zheng et al. (2021)	Flexible printed material + Ni coating	3D printing + electroless plating	Compression, mechanical and conductivity measurements	Ni coating substantially increased stiffness and conductivity while retaining auxetic behavior.
Wang et al. (2023)	Metallic system	LPBF	Compression + numerical validation	AM enabled seamless Gyroid-derived auxetic tubular structures.
Liu et al. (2023)	Flexible resin	3D printing	Compression + DIC	DIC confirmed 3D NPR deformation and generally good numerical–experimental agreement.
Kim et al. (2024)	Rubber-based ink	DIW + UV-assisted curing + vulcanization	Compression / tire deformation	Demonstrated manufacturability of flexible TPMS-based auxetic tire structures.
Daynes (2025)	TPU-95A	Material extrusion	Multi-direction compression, LVDT, transverse measurements	Enabled experimental validation of tunable Poisson's ratio and elastic isotropy.
Liu et al. (2025)	Ti6Al4V	LPBF	Compression + FEA comparison	Manufacturing defects produced measurable deviations from ideal numerical predictions.
Gong et al. (2025)	PLA	FFF	Tensile material tests + quasi-static compression	Provided direct comparison of shell, Gyroid core and hybrid deformation/failure modes.

ten Voorde et al. (2026)	CoCrMo	L-PBF	Compression + microscopy	Process resolution constrained minimum feature size; experiments confirmed strong NPR and energy absorption.
Novak et al. (2026)	PA2200; selected SS316L and AlSi10Mg	SLS / powder-bed fusion	ISO compression + VIA + DIC	Grading stabilized the auxetic deformation; different parent materials changed SEA.
Engel et al. (2026)	Photopolymer resin	DLP	Quasi-static + dynamic compression	Demonstrated that quasi-static benefits of hybridization are loading-rate dependent.

Review synthesis

The reviewed studies demonstrate that additive manufacturing is not merely a fabrication step but an integral part of the process–structure–property relationship in auxetic TPMS systems. Polymer-based AM facilitates large and recoverable deformation, whereas metallic LPBF offers higher strength but introduces greater sensitivity to geometric resolution and process defects. Full-field optical techniques such as DIC are increasingly important for characterizing local auxetic deformation, while experimental research remains strongly concentrated on quasi-static compression. Broader validation under dynamic, fatigue, vibration, and buckling conditions therefore remains necessary.

Fig. 7: Typical workflow for the design, additive manufacturing, post-processing and experimental characterization of auxetic TPMS-based structures. Original review schematic synthesized from the reviewed literature.

Engineering Applications of Auxetic TPMS-Based Structures

Auxetic TPMS-based structures are increasingly being considered for engineering applications requiring lightweight design, deformation control, energy absorption, and structural adaptability. The reviewed literature mainly identifies four application areas: biomedical implants, automotive and crashworthiness components, aerospace and protective systems, and vibration-control or multifunctional structures.

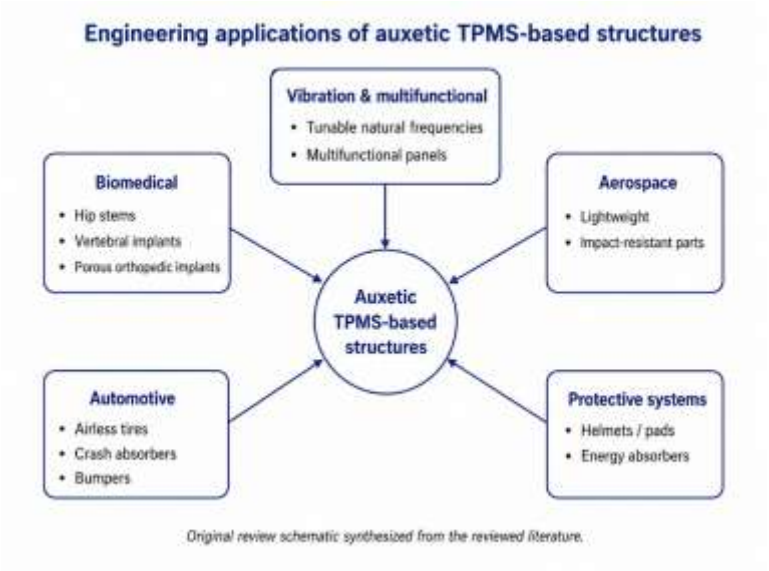

Fig. 8: Representative engineering application areas of auxetic TPMS-based structures. Original review schematic synthesized from the reviewed literature.

Biomedical applications

Controlled porosity, tunable stiffness, and negative Poisson's ratio behavior make auxetic TPMS architectures attractive for load-bearing biomedical applications. A TPMS-based heterostructure combining positive- and negative-Poisson's-ratio regions was proposed for hip stems to improve mechanical interaction at the bone–implant interface. The opposing transverse deformation of the two regions increased the contact area between the implant and surrounding bone during loading (Liu et al., 2023).
Ti6Al4V auxetic TPMS structures have also been proposed as candidates for artificial vertebral body implants because of their high ductility, tunable auxetic response, and energy-absorption capability (Liu et al., 2025). These studies indicate that biomedical applications require a balance among auxeticity, stiffness matching, porosity, strength, and long-term durability.

Automotive and crashworthiness applications

Automotive applications primarily exploit the energy absorption and deformation-dependent stiffness of auxetic TPMS structures. Rotated Primitive-based architectures were incorporated into airless tire spokes, where increasing stiffness with deformation improved shock absorption and limited excessive local deformation compared with conventional spoke concepts (Kim et al., 2024).
Gyroid-derived auxetic tubular architectures have also been proposed for crash absorbers, bumpers, and other protective tubular components because of their continuous geometry and controllable deformation (Wang et al., 2023). Hybrid NPR-shell/Gyroid-core structures

further demonstrated improved peak load and energy absorption through interaction between the outer shell and internal TPMS core (Gong et al., 2025).

Aerospace and protective systems

The high specific properties and energy-dissipation capability of auxetic TPMS structures also make them promising for aerospace and protective applications. Ti6Al4V TPMS-based auxetic metamaterials have been suggested for lightweight aerospace components requiring enhanced deformation capacity and energy absorption (Liu et al., 2025). Gyroid-derived tubular structures have similarly been associated with impact-resistant aerospace and protective components (Wang et al., 2023).
Hybrid NPR-shell/Gyroid-core architectures have been proposed for aerospace buffer structures, anti-collision systems, and personal protective equipment (Gong et al., 2025). However, most available experimental evidence remains based on quasi-static compression, and validation under impact, repeated loading, and fatigue conditions is still limited.

Vibration control and multifunctional applications

Recent studies extend the application scope beyond compression and crashworthiness. Multi-parameter grading of TPMS–auxetic composite plates enables natural frequencies to be tailored through changes in topology, porosity, and reinforcement distribution, indicating potential for lightweight vibration-control and multifunctional structural panels (Chen and Wang, 2026).
These developments suggest that auxetic TPMS architectures may progressively evolve from passive energy-absorbing systems toward multifunctional structures integrating load carrying, vibration control, sensing, and adaptive mechanical response.

Table 4. Representative engineering applications of auxetic TPMS-based structures

Application area	Representative study	Architecture	Functional advantage	Application potential
Hip implant	Liu et al. (2023)	P-TPMS NPR + G-TPMS PPR heterostructure	Improved bone–implant contact and tunable stiffness	Hip stems and porous orthopedic implants
Vertebral implant	Liu et al. (2025)	Ti6Al4V auxetic TPMS tubular structure	High ductility, NPR and energy absorption	Artificial vertebral body implants
Airless tire	Kim et al. (2024)	Rotated Primitive TPMS	Variable stiffness and shock absorption	Non-pneumatic tire spokes
Crashworthiness	Wang et al. (2023)	Gyroid-derived auxetic tube	Lightweight energy absorption and controllable deformation	Vehicle crash absorbers and tubular protectors
Protective structures	Gong et al. (2025)	NPR shell + Gyroid core	Improved peak load and SEA	Aerospace buffers, anti-collision and personal protection
Vibration control	Chen and Wang (2026)	Triple-FG TPMS–auxetic plate	Tunable natural frequencies	Lightweight vibration-controlled panels

Review synthesis

The reviewed applications show a transition from material-level auxetic demonstrations toward application-oriented structural design. Biomedical applications emphasize interface mechanics and stiffness compatibility, automotive and protective systems focus on energy absorption and progressive collapse, while recent analytical studies extend the concept toward vibration and multifunctional behavior. Consequently, practical design should target a

balanced combination of auxeticity, stiffness, strength, stability, energy absorption, and manufacturability rather than maximizing the negative Poisson's ratio alone.

Current Challenges and Future Research Directions

Despite the rapid development of auxetic TPMS-based structures, several challenges continue to limit their transition from conceptual designs to reliable engineering systems. The main limitations identified in the reviewed literature concern direct integration of functional grading with auxetic TPMS architectures, inconsistent performance metrics, limited experimental validation, manufacturing fidelity, multifunctional optimization, and application-level verification.

Limited direct integration of functional grading and auxetic TPMS

A major research gap is the limited number of studies in which auxeticity, TPMS architecture, and functional grading are directly integrated within the same structure. Most available studies focus either on modified auxetic TPMS architectures or on hybrid systems in which auxetic and TPMS mechanisms are located in separate structural components. Direct grading of an already auxetic TPMS architecture remains comparatively uncommon (ten Voorde et al., 2026; Novak et al., 2026).
Future studies should therefore investigate spatial variation of relative density, wall thickness, unit-cell geometry, and auxetic parameters within directly graded AUXTPMS architectures. Such designs could provide greater control over both local deformation and global structural response.

Lack of standardized comparison criteria

Direct comparison among published studies remains difficult because different materials, relative densities, unit-cell dimensions, loading conditions, and performance indicators are employed. Some studies characterize auxeticity through apparent Poisson's ratio, whereas others report effective auxetic strain, stiffness, peak load, SEA, or stability-related parameters. More consistent reporting of relative density, Poisson's ratio, mechanical properties, loading conditions, deformation range, and energy-absorption metrics would improve comparison between different architectures and facilitate the development of more general design guidelines.

Limited experimental validation

Experimental research remains strongly concentrated on quasi-static compression. Although this loading condition is appropriate for characterizing auxetic deformation and progressive collapse, many proposed applications are subjected to dynamic, cyclic, or stability-related loading conditions.
Differences between quasi-static and dynamic responses have already demonstrated that performance improvements observed at low loading rates may not necessarily remain under dynamic conditions (Engel et al., 2026). Furthermore, several advanced vibration and stability models remain primarily numerical or analytical and require broader experimental verification (Chen and Wang, 2026; Eroğlu et al., 2026).
Future experimental studies should therefore place greater emphasis on dynamic loading, impact, fatigue, vibration, buckling, post-buckling, and long-term cyclic behavior.

Manufacturing fidelity and as-built geometry

Additive manufacturing introduces deviations between ideal numerical geometries and fabricated structures. Thin walls, small connections, and graded features are particularly sensitive to manufacturing resolution, surface irregularities, and process-induced defects. Such imperfections may substantially alter stiffness and deformation behavior relative to idealized numerical predictions (Liu et al., 2025).
Process-resolution limitations have also been identified as an important constraint in metallic auxetic TPMS structures (ten Voorde et al., 2026). Consequently, future numerical models should increasingly incorporate measured as-built geometry and experimentally characterized defects rather than relying exclusively on ideal CAD models.

Limited multifunctional and multi-objective optimization

Recent studies have expanded auxetic TPMS research toward vibration, buckling, energy absorption, and multifunctional systems. However, most optimization strategies still focus on one or a limited number of performance indicators.
Practical structures generally require simultaneous consideration of auxeticity, stiffness, strength, stability, energy absorption, mass, and manufacturability. Future research should therefore employ multi-objective optimization strategies capable of identifying suitable compromises between competing mechanical requirements.

Application-level validation

Although promising concepts have been proposed for biomedical implants, airless tires, protective structures, and aerospace components, many remain at the proof-of-concept stage. Application-specific requirements are considerably more demanding than demonstrating negative Poisson’s ratio behavior under laboratory compression.
Biomedical structures, for example, require consideration of fatigue, stiffness compatibility, biocompatibility, and long-term implant–bone interaction. Automotive and protective systems require impact-rate sensitivity, repeated loading resistance, and reliable energy absorption under realistic service conditions.
Future research should therefore progress from generic mechanical characterization toward service-condition-based and application-specific validation.

Table 5. Summary of the main research gaps, current limitations, their significance, and corresponding future research needs in auxetic TPMS-based structures.

Research gap	Current limitation	Why it matters	Future need
Direct FG auxetic TPMS studies are limited	Few studies combine auxeticity, TPMS and grading in the same architecture	Limits understanding of true structure–grading coupling	More direct graded auxetic TPMS designs
Lack of standardized metrics	Different studies report different parameters and test conditions	Difficult to compare performance across the literature	More consistent reporting of density, NPR, SEA, stiffness and loading conditions
Experimental validation is narrow	Most tests are quasi-static compression only	Real applications require broader validation	Dynamic, fatigue, vibration and buckling experiments
Manufacturing fidelity issues	As-built defects alter the designed behavior	Numerical results may overestimate actual performance	Stronger integration of AM process–geometry–property analysis
Multifunctional optimization is limited	Most studies optimize one response at a time	Practical structures require balanced performance	Multi-objective design frameworks
Application-level validation is incomplete	Many studies remain proof-of-concept	Engineering transfer remains limited	Service-condition-based validation

Section synthesis

The reviewed challenges show that the field is now moving from demonstrating auxetic TPMS concepts toward establishing reliable, manufacturable and application-ready structural systems. The main research need is no longer simply to create a TPMS-based structure with a negative Poisson's ratio, but to understand how topology, grading, manufacturing quality and loading environment interact to determine actual performance.
In this sense, the most important future direction is the development of integrated design approaches that connect: geometry + grading + manufacturing + experimental validation + application requirement within a unified framework.

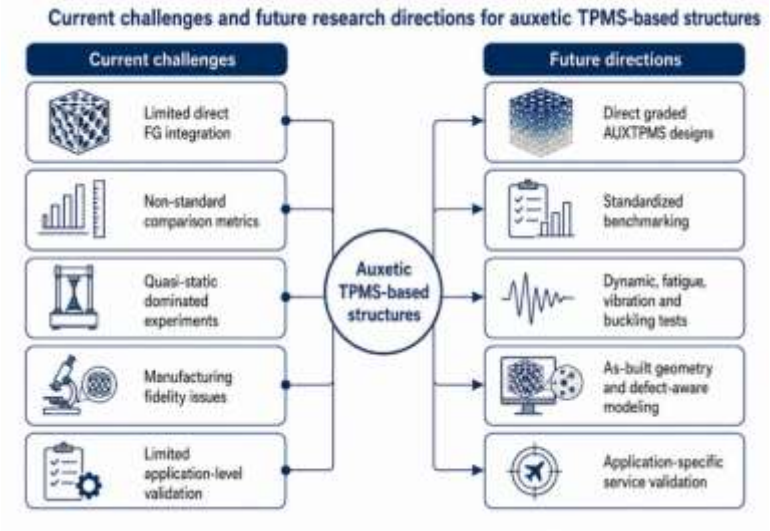

Fig. 9: Current challenges and future research directions for auxetic TPMS-based structures.

CONCLUSION

This review examined recent developments in auxetic TPMS-based and functionally graded structures with particular emphasis on geometrical design, functional grading, mechanical behavior, additive manufacturing, and engineering applications. The reviewed literature demonstrates that conventional TPMS architectures are not universally auxetic, and negative Poisson's ratio behavior generally requires deliberate geometrical modification through mechanisms such as rotation, buckling, coordinate transformation, or shape-function-based design.

Functional grading provides an additional means of tailoring structural response; however, its contribution should not be interpreted solely in terms of increased stiffness or strength. The available studies indicate that grading can be particularly effective in controlling deformation localization, progressive collapse, and the stability of the auxetic response. Mechanical performance therefore depends on the combined effects of topology, relative density, material properties, grading strategy, loading condition, and manufacturing quality.

Additive manufacturing has enabled increasingly complex metallic, polymeric, and elastomeric auxetic TPMS structures, but deviations between ideal and as-built geometries remain an important challenge. Experimental research is still dominated by quasi-static compression, whereas dynamic loading, fatigue, vibration, buckling, and long-term service behavior require substantially greater attention.

Overall, auxetic TPMS-based structures are evolving from geometry-driven metamaterial concepts toward graded, programmable, and multifunctional architected systems. Future progress will depend on the integrated optimization of auxeticity, stiffness, strength, stability, energy absorption, and manufacturability, together with experimentally validated designs under realistic service conditions. In particular, the limited number of studies directly combining functional grading with auxetic TPMS architectures represents a significant opportunity for future research.

ABSTRACT

The application of defoliants in modern agriculture plays an important role in facilitating mechanized harvesting, reducing labor costs, and increasing production efficiency. However, conventional defoliants often exhibit high chemical activity and may persist in soil and water environments for extended periods, resulting in environmental contamination and adverse effects on non-target organisms. Therefore, the development of environmentally safe defoliation technologies has become a significant challenge in sustainable agriculture and green chemistry.This study aims to develop an environmentally safe defoliation technology based on pH-sensitive defoliants and to investigate the possibility of controlling defoliant activity according to environmental pH conditions. The proposed concept is based on the assumption that pH-sensitive systems can selectively activate defoliants in the naturally acidic microenvironment of plant leaf surfaces while maintaining low activity in soil and aquatic environments. Such selective activation may reduce the chemical burden on the environment and improve the ecological safety of defoliation practices. The research was conducted using a modeling approach to evaluate the pH-dependent behavior of a pH-sensitive system. Three model environments representing acidic (pH ≈ 5), neutral (pH ≈ 7), and alkaline (pH ≈ 8) conditions were prepared. The activity of the model system was assessed through indicator-based observations under different pH conditions. The results demonstrated that the highest activity was observed in the acidic environment, while significantly lower activity was recorded

under neutral and alkaline conditions. These findings indicate a strong dependence of system activity on environmental pH. The obtained results confirm the feasibility of utilizing pH-sensitive systems for controlled defoliant activation. The proposed approach may contribute to reducing environmental pollution, protecting soil and water resources, and preserving beneficial microorganisms. Furthermore, it provides a scientific basis for the development of next-generation environmentally friendly defoliants and sustainable agricultural technologies. The study highlights the potential of pH-responsive systems as an effective strategy for improving the environmental safety and efficiency of defoliation processes.
Keywords: defoliants, pH-responsive defoliants, environmental safety, environment, controlled activity, sustainable agriculture.

INTRODUCTION

The use of defoliants in modern agriculture plays a significant role in facilitating mechanized harvesting, simplifying the picking process, and reducing labor costs. However, many conventional defoliants exhibit high biological activity and may persist in soil and aquatic environments for extended periods, thereby exerting adverse effects on environmental components. Consequently, ecological problems such as reduced soil fertility, inhibition of beneficial microbial activity, and contamination of water resources may arise.

In recent years, the growing demand for environmentally safe agricultural technologies based on the principles of green chemistry has become increasingly evident. In this context, controlling the activity of defoliants not by increasing their concentration but by adapting their performance to environmental conditions represents an important scientific challenge. In particular, utilizing the naturally acidic microenvironment of plant leaf surfaces to activate defoliants only at the required site and time may significantly enhance environmental safety.

This study is aimed at developing an environmentally safe defoliation technology based on pH-sensitive defoliants. The proposed approach is expected to reduce the chemical load associated with defoliation processes, contribute to environmental protection, and support the development of sustainable agricultural practices [1].

Research Objective. The objective of this study is to develop an environmentally safe defoliation technology based on pH-sensitive defoliants and to provide a scientific rationale for controlling the activity of defoliants as a function of environmental pH conditions [2,3].

Research Tasks:

1. To analyze the pH-dependent activity mechanisms of defoliants based on available scientific literature.
2. To develop an environmentally controlled model of defoliants using pH-responsive carrier systems such as coatings, gels, or adsorbents.
3. To model and compare the activity of defoliants under different pH conditions.
4. To establish criteria for evaluating the environmental safety of pH-sensitive defoliants.
5. To substantiate the practical applicability of the proposed technology [4].

Scientific Novelty:

1. A concept for controlling defoliant activity based on environmental pH rather than chemical concentration is proposed.

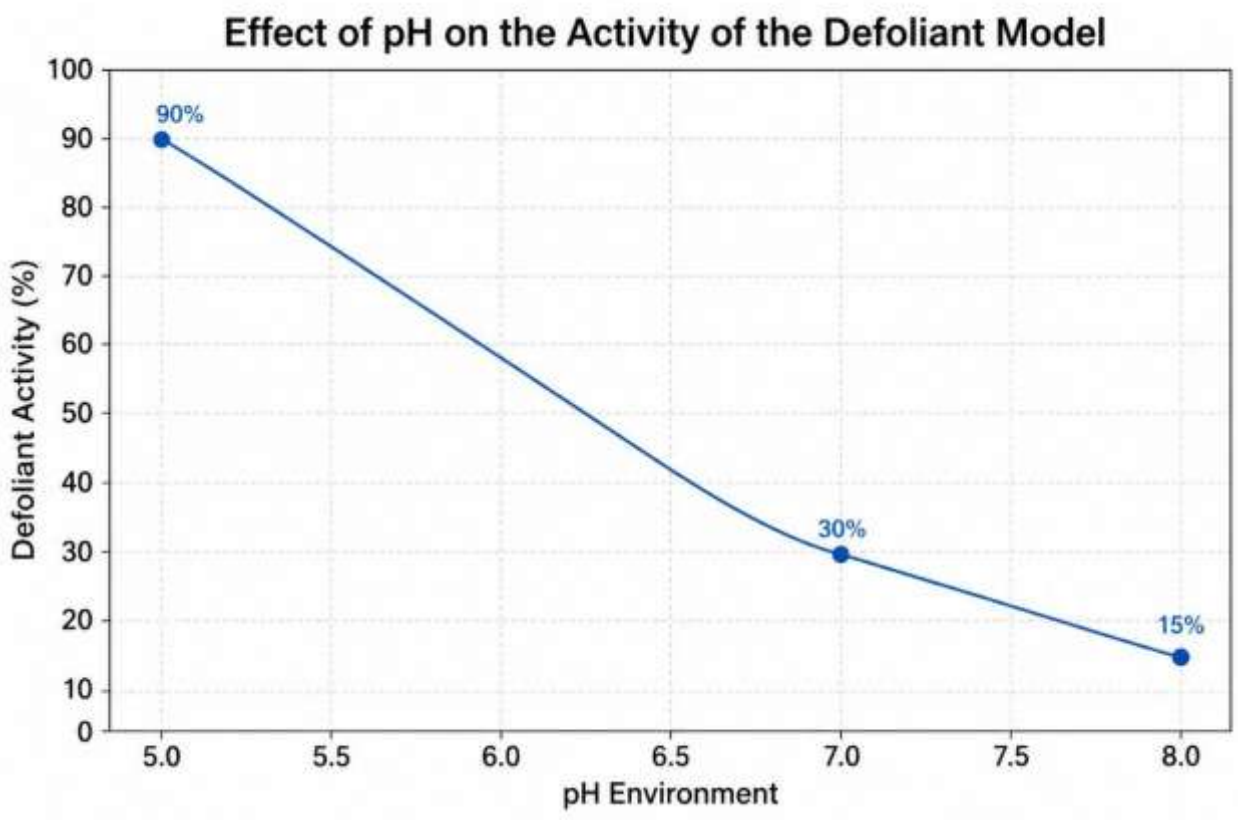
2. A model for transforming conventional defoliants into environmentally controlled systems through the use of pH-sensitive carrier materials has been developed.
3. A mechanism has been substantiated whereby defoliants remain active in the naturally acidic microenvironment of leaf surfaces while becoming passive in soil and aquatic environments.
4. A novel conceptual approach for ensuring environmentally safe defoliation processes has been developed [5].

RESEARCH OBJECT AND METHODOLOGY

The object of this study is the defoliation process and the defoliants used therein. The subject of the research is the activity of defoliants modified with pH-sensitive carrier systems and the mechanisms ensuring their environmental safety [6,7].
The following research methods were employed during the implementation of the project [8]:
- Analysis and synthesis of scientific literature;
- Modeling method (development of the operating mechanism of pH-sensitive defoliants);
- Comparative analysis (comparison of defoliant activity under different pH conditions);
- Observation method;
- Analysis and interpretation of results using graphical and tabular representations.

Practical Part:
The research was carried out through modeling the pH-dependent activity of defoliants. Rather than synthesizing an actual defoliant, a model system representing the operating mechanism of pH-sensitive defoliants was employed [9].
Stage 1. Preparation of pH Environments.
Three model environments with different pH values were prepared for the experiments:
- pH ≈ 5 (model of the acidic microenvironment of leaf surfaces);
- pH ≈ 7 (neutral environment model);
- pH ≈ 8 (model approximating soil conditions).

Stage 2. Modeling of the pH-Sensitive System.
A pH-responsive indicator-based model system was selected. This system was used as a simulation tool to mimic the pH-dependent activity of defoliants.
Stage 3. Evaluation of Activity.
An equal amount of the model system was introduced into each pH environment. Changes in color and the manifestation of activity indicators were subsequently observed. The appearance of color was considered an indicator of the active state of the defoliant, whereas the absence or disappearance of color was interpreted as a passive state.
Stage 4. Recording and Analysis of Results.
The experimental observations were recorded in tabular form. The activity levels were compared according to pH values, and the obtained results were presented graphically to illustrate the relationship between environmental pH and defoliant activity.



RESULTS

During the study, the activity of the pH-sensitive model system was observed in environments with different pH values. The results showed that the model system exhibited high activity in an acidic environment (pH ≈ 5), while its activity decreased significantly in a neutral environment (pH ≈ 7). In an alkaline environment (pH ≈ 8), the activity was minimal.

Table 1. Activity of the Defoliant Model Depending on pH Value

pH Value	**Environment Description**	**Observed Condition**	**Activity Level (%)**
5	Leaf surface model (acidic)	Strong color change	90%
7	Neutral environment model	Weak color intensity	30 %
8	Soil environment model (alkaline)	Almost no color change	15%

Figure 1. Presents the graphical relationship between pH value and the activity of the defoliant model.

The obtained results indicate that the activity level of pH-sensitive systems is directly dependent on the pH value of the surrounding environment. This finding confirms that defoliants can remain active in the acidic microenvironment of leaf surfaces while becoming passive in soil and aquatic environments.

Expected Results:

- The dependence of defoliant activity on environmental pH will be scientifically substantiated using pH-sensitive systems.
- The mechanism by which defoliants remain active in the acidic microenvironment of leaf surfaces and passive in soil and water environments will be modeled.
- The potential of pH-sensitive defoliants to ensure an environmentally safe defoliation process will be demonstrated.
- The reduction of the chemical load released into the environment during the defoliation process will be scientifically justified.

Practical Significance of the Research*:* The results of this study provide an opportunity to organize the defoliation process in agriculture in an environmentally safe manner. The technology developed on the basis of pH-sensitive defoliants can contribute to reducing soil and water contamination, preserving the activity of beneficial microorganisms, and promoting sustainable agricultural development. Furthermore, the findings of this research may be applied in the future improvement of defoliant production technologies.

Research Limitations: No experiments were conducted using actual defoliants in this study. The experiments were performed using an indicator-based model system representing the pH-dependent activity of defoliants. Therefore, the obtained results are conceptual and modeling-based in nature.

CONCLUSION

The development of an environmentally safe defoliation technology based on pH-sensitive defoliants can reduce the negative environmental impact of the defoliation process. The concept of controlling defoliant activity according to environmental pH conditions enables the defoliation process to become more environmentally safe and controllable. The obtained results confirm the scientific validity of the proposed approach.

ABSTRACT

Sunflower (*Helianthus annuus* L.) which is the most important oil crops grows mainly drylands in the world. Therefore, environmental conditions mostly influence severely sunflower yields especially in some seasons. In addition to biotic stresses such downy mildew, broomrape parasite, weeds, some other diseases, etc. biotic stress such as drought is the most limiting factor of sunflower production in different parts of the world. Due to global warming, sunflower will affect more these conditions so new developing hybrids need to drought tolerant. The study was conducted to determine their drought tolerance performances and to evaluate their drought indices of some sunflower candidate hybrids in conducted yield trials in Tekirdag and Edirne existing in Trakya Region which is European part of Turkey which has more than 40 % of Turkish sunflower production. Based on the study results, some candidate hybrids had higher drought tolerant indices such as total chlorophyll content, hairiness, dry root weight at stem than control hybrids in the study.

Keywords: Sunflower, Sustainable production, Drought tolerance, Hybrid, Yield traits, Yield performance,

INTRODUCTION

Sunflower grows widely in not only in Turkey both also in Blacksea region countries which has over 60% of the world sunflower planted areas as well as other parts of the world due to higher adaption capability, higher mechanization use, easy marketing (Kaya, 2016, 2020). Hybrids are preferred and used totally in sunflower production both in Turkey and also in other producer countries in the world due to higher yielding, homogeneity and adaption capability (Arslan and Kaya, 2019).

Biotic stresses such as downy mildew and broomrape parasite are the most limiting factors reducing seed and oil yield in sunflower production areas (Sezer et al., 2014, Jocic et al., 2015). However, abiotic stress such as drought, higher temperatures in lower fertility soils especially during grain filling period because as a summer crop sunflower grows mostly in rainfeed areas (Ahmed et al., 2009; Ghaffari et al., 2012; et al., 2012; Pekcan et al., 2012; Andrade et al., 2013). Total chlorophyll measurement which is a novel and easy technique and widely used to measure the plant's response to drought stresses (Cicek et al., 2019; Arslan et al., 2020). Therefore, these changeable environmental conditions with increasing global warming recently lead that sunflower breeders should consider more and develop drought tolerant hybrids to solve these problems and to produce enough for humanity in the future (Rauf, 2008; Jocic et al., 2015; Kaya and Beser, 2020).

The study was conducted to determine their drought tolerance performances and to evaluate their drought indices of some sunflower candidate hybrids in conducted yield trials in the most planted provinces as Tekirdag and Edirne existing in Trakya Region in 2017.

MATERIAL AND METHOD

The yield trials were conducted in Edirne and Tekirdag location in 2017 to determine yield performances of candidate sunflower hybrids. There were 23 hybrids including 4 controls from commercial hybrids (ITALICA, SY GIBRALTAR, P 64 LL 62, LG 5582) in the market. The experimental design was a Randomized Complete Block Design with four replicates. The four rows plots were 7,50-m long with the 70 x 35 cm plant spacing. Total plot area at planting was 7,5*2,8 as 21 m^2. The middle two rows were harvested and the border rows were discarded, and plot size was 9.66 m^2 at harvest. The compose fertilizers (20-20-0, Zn) were applied 200 kg/ha dose at planting. Statistical analysis was performed with JMP statistical program.

Tekirdag location was conducted in Beyazkoy village fields, Saray County and the trials were planted by hand in 15 April 2017. Emergence date of sunflower plants was in 22 April 2017 and left only one plant each as mentioned plant density above. The trials were harvested by hand in 25 August 2017 as middle two rows except one plant at the beginning of the middle rows. Edirne location was conducted in Sarayakpinar village fields and the trials were planted by hand in 28 April 2017. Emergence date of sunflower plants was in 5 May 2017 and the trials were harvested by hand in 5 September 2017. The plant height and head diameter of hybrids were measured from 3 plants at mid rows of the plots in each replication at PM stage. Oil content of the hybrids were determined utilizing Nuclear Magnetic Resonance (NMR) analysis.

Some sunflower hybrids both from classical and IMI types were planted in the pots to measure responses to drought conditions with measuring of dry and wet root weight as well as total chlorophyll content as the most known drought indices in sunflower drought tests (Figure 1, 2 and 3). The ratio of Chlorophyll content of sunflower hybrids was recorded by Portable Florescence Device (HandyPEA, Hansatech Ltd.) at R5-1 vegetative stages (Figure 4). Furthermore, plant height, plant number per area, leaf number per plant, leaf area, anthocyanin existence, head inclination, hairiness at stem, total chlorophyll content, leaf width and leaf length were measured at the yield trials conducted in the field to determine their responses to drought stress.

RESULTS AND DISCUSSION

Based on the study results, the classical sunflower hybrids exhibited higher performance both for seed and oil yield as SY GIBRALTAR control sunflower hybrid, the candidate hybrid

1628, control hybrid P 64 LL 62 and 9718x RHA64 DMR in Edirne location in the research. On the other hand, in Tekirdag location, the highest seed yield was obtained from 1623 candidate hybrid followed by LG5582 and SY GIBRALTAR sunflower commercial hybrids and the highest oil yield obtained from SY GIBRALTAR, P 64 LL 62 and LG5582 sunflower commercial hybrid. Based on the average results in the study, we could include 1624 candidate hybrid in addition to above ones. In the IMI type hybrids, DT5234 CLP, NS--H-7801, LG5565CL, P-LC108 and IMIO44AXIMI-NI hybrids seems promising ones for seed and oil yield in the study.

Based on study results at the pot study; In IMI herbicide resistant hybrids, Surimi CL hybrid had highest wet and dry root weight as 30,33 g and 6,66 g. LG5565 CL hybrid followed that hybrid and the lowest values were obtained from PUNTASOL CL and SUNFLORA hybrids (Table 1). In classical hybrids, LG5582 had the highest performance had 26,3 g wet and 5,4 g dry root weight respectively. P64LL62 had the lowest value among these hybrids in the study (Figure5 and 6).

The total chlorophyll contents of sunflower hybrids were changed between 7,4 and 15,7 in classical hybrids in Edirne location (Table 2) and between 8,7-15,4 in IMI hybrids in Edirne location (Table 3). The total chlorophyll contents of sunflower hybrids were changed between 6,4 and 12,9 in classical hybrids in Tekirdag location (Table 4) and between 7,8-15,2 in IMI hybrids in Tekirdag location (Table 5). For drought tolerance in sunflower hybrids, larger leaves ones have more photosynthesis capacity and preferable ones. For larger leaf areas, 1624 1625, LG5565CL SUNFLORA, NS--H-7850, 163, 1619, 1624, 1625, 1434 and 1462 sunflower hybrids seem promising ones (Table 6, 7, 8 and 9). Similarly, hairiness in the stem also preferable ones for drought tolerances. Among hybrids, NS--H-7812 and IMIO44A X IMI-NI in IMI types and 1522 candidate hybrid in classical ones seems having higher values.

CONCLUSIONS

Based on the study, some hybrids exhibit different performances on measured drought indices. Some of the hybrids seems promising ones for drought tolerance. However, there is no specific and concrete results on evaluated data mainly could be used to determine for drought tolerance connected with seed and oil yield together. Maybe the study was not performed in controlled environments or it could need to conduct longer years or many trials in different locations studies.

ABSTRACT

The COVID-19 pandemic created an urgent need for experimental platforms that could support the safe and efficient study of SARS-CoV-2 entry, neutralization, and antiviral inhibition under more accessible laboratory conditions. In this context, spike-pseudotyped viral systems emerged as powerful alternatives to assays based on authentic SARS-CoV-2 because they reproduce the viral entry step while lacking full replication competence. This feature enabled their broad use in biosafety level 2 (BSL-2) laboratories and expanded research capacity beyond highly specialized high-containment facilities. Over time, SARS-CoV-2 pseudovirus systems evolved from emergency-response tools into versatile experimental platforms for neutralization assays, entry inhibitor screening, variant comparison, vaccine evaluation, and mechanistic studies of spike biology. Their increasing value has been driven by two major developments: first, biosafety-oriented improvements in vector architecture and packaging design, including multi-plasmid strategies, self-inactivating transfer systems, and refined lentiviral backbones; and second, technical advances that improve production efficiency, assay sensitivity, and biological relevance, such as optimized spike constructs, reporter-based readouts, host-cell engineering, and variant-adapted assay conditions. Recent studies have further demonstrated that these systems are scalable, applicable in resource-limited laboratory settings, and useful not only for neutralization analysis but also for investigating spike biogenesis and intracellular processing. Comparisons among HIV-1-, MLV-, and VSV-based backbones have also shown that platform choice can directly influence yield, workflow, and experimental interpretation. In addition to the broader literature, thesis-based laboratory implementation and chapter-based conceptual work from our group support the practical and methodological relevance of these platforms in SARS-CoV-2-related experimental design. Overall, the available evidence indicates that SARS-CoV-2 spike pseudovirus technology has become a mature, flexible, and indispensable framework for viral entry research, translational virology, and early-stage antiviral discovery.

Keywords: SARS-CoV-2, pseudovirus, spike protein, biosafety, lentiviral vector, VSV, neutralization assay

INTRODUCTION

The emergence of SARS-CoV-2 created an immediate need for systems capable of rapidly evaluating viral entry, antibody-mediated neutralization, and potential antiviral candidates. However, work with authentic SARS-CoV-2 requires high-containment infrastructure, most commonly BSL-3 laboratories, which limited access for many research groups during the

pandemic and beyond (Millet et al., 2019; Chen & Zhang, 2021). In response to this challenge, pseudovirus systems became one of the most widely adopted surrogate models because they preserve the viral entry properties of the authentic virus while eliminating full replication capacity, thereby substantially reducing experimental risk (Li et al., 2018; Nie et al., 2020).

Among all SARS-CoV-2 structural proteins, the spike glycoprotein occupies a central position because it mediates receptor recognition and membrane fusion through interaction with angiotensin-converting enzyme 2 (ACE2) and host proteases such as TMPRSS2 and furin (Walls et al., 2020; Wang et al., 2020; Hoffmann et al., 2020). For that reason, most SARS-CoV-2 pseudovirus platforms are designed around spike-pseudotyped particles built on alternative viral backbones, allowing researchers to model the entry process in a tractable and safer way (Crawford et al., 2020; Johnson et al., 2020).

Initially, these systems were used mainly as substitutes for live-virus assays. Yet the field developed rapidly, and pseudovirus platforms soon became essential tools for variant comparison, neutralizing antibody assessment, vaccine evaluation, and screening of entry inhibitors (Nie et al., 2020; Schmidt et al., 2020; Xiang et al., 2022). More recent studies further demonstrated that these assays can be deployed in laboratories with limited infrastructure, making them relevant not only for advanced research centers but also for broader diagnostic and drug-screening applications (Manu et al., 2024). Manu et al. (2024) strengthened this practical dimension by showing that a lentiviral assay based on p8.91, the luciferase reporter plasmid pCSFLW, and spike-expression constructs could be used in ACE2-expressing HEK293 cells for both compound screening and plasma neutralization analysis. In addition to the broader literature, a thesis from our group on pseudovirus production for SARS-CoV-2 neutralization antibody testing and a complementary book chapter on lentiviral vector design further support the methodological relevance of these platforms (Köseoğlu, 2023; Köseoğlu & Cing Yıldırım, 2023).

Biosafety framework of SARS-CoV-2 pseudovirus systems

The major biosafety advantage of pseudovirus systems lies in their replication-defective architecture. These particles are generally engineered for single-round infection, meaning they can enter susceptible cells and express a reporter signal but cannot complete a productive replication cycle or generate infectious progeny. This design markedly reduces biological risk compared with authentic SARS-CoV-2 and explains why such systems can be used under BSL-2 conditions in many settings (Millet et al., 2019; Nie et al., 2020; Chen & Zhang, 2021).

Nevertheless, the biosafety of pseudoviruses does not depend solely on the absence of replication. It is also determined by the organization of the vector system itself. In lentiviral platforms, for example, safety has progressively improved through the separation of viral functions into multiple plasmids, removal of unnecessary accessory elements, and use of self-inactivating transfer constructs (Dull et al., 1998; Maetzig et al., 2011; Tareen et al., 2013). These design principles reduce the theoretical possibility of recombination and increase control over the production system. Consequently, modern third-generation lentiviral systems are widely regarded as safer than earlier vector generations for laboratory applications involving pseudotyping (Dull et al., 1998; Chen & Zhang, 2021). This perspective is also consistent with our chapter-based work, which emphasizes third-generation lentiviral systems, SIN vectors, and chimeric 5′LTR designs as key biosafety layers in pseudovirus production (Köseoğlu & Cing Yıldırım, 2023).

Another important issue is the choice of viral backbone. SARS-CoV-2 spike pseudoviruses are most commonly generated using HIV-1-based lentiviral particles, murine leukemia virus (MLV)-based retroviral particles, or vesicular stomatitis virus (VSV)-based systems (Li et al., 2018; Chen & Zhang, 2021; Trischitta et al., 2024). Each system has advantages and limitations. Lentiviral systems are highly versatile and widely used in neutralization assays. MLV-based

systems are also useful for entry studies, whereas VSV-based systems often provide strong signal intensity and high infectious yield. This diversity indicates that biosafety is best understood not as a simple yes-or-no category, but as a combination of vector design, laboratory workflow, and experimental purpose. Trischitta et al. (2024) additionally noted that HIV-1- and MLV-based systems are generally easier and less time-consuming than VSV-based workflows, whereas VSV systems often provide higher particle yields; they also emphasized that VSV and MLV platforms may be considered safer than HIV systems in some methodological contexts.

Operational biosafety remains essential even when replication-defective systems are used. Appropriate institutional approval, personnel training, controlled workflow, physical containment practices, personal protective equipment, and validated decontamination measures are still required. Dahiya et al. (2023), for instance, explicitly noted that their pseudovirus work was conducted under institutional biosafety approval. This point is particularly important in a scientific meeting context because the use of a lower-risk surrogate does not eliminate the need for rigorous biosafety governance.

Technical advances in pseudovirus preparation

One of the main reasons pseudovirus systems remain highly relevant is the steady refinement of their technical design. Early studies largely aimed to generate functional particles for proof-of-concept assays, whereas more recent work has focused on reproducibility, yield optimization, host-cell susceptibility, variant-adapted calibration, and assay scalability.

A critical determinant of assay performance is the biological readiness of the target cell. Since spike-mediated entry depends on ACE2 binding and proteolytic activation, cells that express ACE2 together with TMPRSS2 or furin often provide improved sensitivity and more robust readouts (Hoffmann et al., 2020). Condor Capcha et al. (2021) demonstrated that viral entry signals could be enhanced when ACE2 was co-expressed with one or more activating proteases, emphasizing that pseudovirus assay quality depends not only on the particles produced but also on the receptor–protease context of the recipient cells. This work also illustrated how assay design can be streamlined into a relatively rapid workflow suitable for entry and neutralization studies.

Reporter selection constitutes another major technical variable. Fluorescent reporters such as GFP are valuable for visual confirmation, imaging, and qualitative assessment of infection, whereas luciferase-based systems generally provide greater sensitivity and wider dynamic range for quantitative neutralization and inhibitor screening (Crawford et al., 2020; Nie et al., 2020). Consequently, the choice of reporter should not be treated as a trivial technical detail; rather, it should reflect the intended analytical purpose of the study, whether that is visualization, quantification, or high-throughput screening.

Production efficiency has also emerged as a key focus of recent studies. Johnson et al. (2020) emphasized that spike-pseudotyping efficiency can vary markedly depending on construct design and packaging conditions. Extending this line of work, Fujioka et al. (2022) showed that conventional transient-expression VSV pseudotyping may produce a large proportion of particles lacking spike on their surface. According to their findings, excessive spike expression in producer cells may interfere with parental VSV infection and thereby reduce the yield of properly pseudotyped virions. To overcome this limitation, they developed a strategy using stable spike-expressing cell lines, which substantially improved the generation of spike-bearing VSV pseudoviruses with higher infectious yield. This contribution is particularly important because it shows that technical optimization is not limited to transfection efficiency, but also involves controlling spike expression biology in producer cells.

Another major advance is the growing recognition that optimization cannot be generalized across all SARS-CoV-2 variants. Sun et al. (2022) developed an HIV-1-based luciferase pseudovirus neutralization assay that included Alpha, Beta, Gamma, Kappa, and Omicron

variants and found that the optimal spike-plasmid-to-backbone ratio and collection time differed among variants. Notably, Omicron/BA.1 required a distinct optimal condition compared with earlier variants, demonstrating that pseudovirus systems must be recalibrated as spike evolution changes entry behavior and assay performance. This finding is highly relevant to current research because it underscores that pseudovirus platforms are dynamic systems that need continuous updating in response to viral evolution.

The expansion of pseudovirus technology into laboratories with limited infrastructure is another noteworthy development. Manu et al. (2024) established a lentiviral pseudovirus assay for both compound screening and neutralization analysis and emphasized that the system was scalable, practical, and suitable for medium- to high-throughput applications without requiring higher-level containment facilities. Their study is valuable not only methodologically but also strategically, because it demonstrates that pseudovirus-based assays can democratize access to SARS-CoV-2 functional studies across research settings with unequal resources. Their study also provides concrete methodological detail by using ACE2-HEK293 target cells and luciferase readout to quantify infection, and by defining a working titer threshold for assay use (Manu et al., 2024).

Our chapter-based review also describes transfer, envelope, and packaging plasmids as the core functional modules of lentiviral pseudovirus production and highlights HEK293T-based workflows as widely used experimental platforms (Köseoğlu & Cing Yıldırım, 2023). In parallel, the thesis work from our group supports the practical feasibility of producing pseudoviruses for SARS-CoV-2 neutralization-related applications within a modular lentiviral framework (Köseoğlu, 2023).

Applications in neutralization assays and variant assessment

SARS-CoV-2 spike pseudoviruses have become central tools for evaluating neutralizing antibodies, candidate vaccines, therapeutic monoclonal antibodies, and entry inhibitors (Crawford et al., 2020; Nie et al., 2020; Schmidt et al., 2020). Because these systems directly model spike-dependent entry, they are especially useful for studying how changes in spike structure alter neutralization susceptibility.

This role became even more important with the emergence of variants of concern. Sun et al. (2022) showed that Omicron/BA.1 exhibited marked resistance to some monoclonal antibodies and substantial immune evasion against convalescent plasma, whereas other antibodies retained activity with reduced potency. These findings highlight the importance of pseudovirus systems in rapidly identifying neutralization escape phenotypes before such data can be extensively generated with authentic virus. Similarly, other pseudovirus-based analyses have shown that neutralizing responses may differ substantially among variants, reinforcing the need for continuous variant-aware assay interpretation (Xiang et al., 2022; Trischitta et al., 2024).

In addition to antibody studies, pseudovirus systems have become valuable in early-stage compound screening. Because they can be used safely, rapidly, and at scale, they serve as effective prescreening platforms before authentic-virus confirmation. Manu et al. (2024) directly demonstrated this utility by identifying compounds that altered pseudovirus infectivity and by validating neutralizing activity in convalescent plasma. Thus, pseudovirus assays now occupy an important translational position between basic virology and applied antiviral discovery.

From entry assays to mechanistic studies of spike biology

A particularly important conceptual development in the field is the use of pseudovirus systems not only as entry readouts but also as tools to investigate spike biogenesis, processing, and intracellular trafficking. Dahiya et al. (2023) contributed to this direction by using lentivirus-based SARS-CoV-2 spike pseudoviruses in HEK293T cells expressing virus-specific

intrabodies targeting the polybasic cleavage site of spike. Their approach allowed the simultaneous evaluation of pseudovirus output and the intracellular fate of spike protein, showing that pseudovirus platforms can also serve as mechanistic systems for understanding how spike is processed and assembled.

This shift expands the scientific role of pseudovirus technology. The field is no longer limited to asking whether spike-bearing particles can enter cells or whether antibodies can block them. It is increasingly equipped to explore how spike is synthesized, trafficked, cleaved, stabilized, and incorporated into particles. Such studies suggest that future optimization may involve not only changing plasmid ratios or reporter types but also deliberately engineering intracellular spike handling in producer cells.

Limitations and future perspectives

Despite their strengths, pseudovirus systems have inherent limitations. Most importantly, they primarily model the entry phase of infection and therefore cannot fully reproduce the complete replication cycle, accessory protein functions, host responses, or pathogenic complexity of authentic SARS-CoV-2 (Chen & Zhang, 2021; Xiang et al., 2022). For this reason, pseudovirus data should ideally be interpreted alongside authentic-virus studies when possible.

In addition, the chosen viral backbone may influence particle morphology, spike density, and entry behavior. HIV-1-, MLV-, and VSV-based systems are highly useful, but none can be regarded as a perfect structural surrogate for native SARS-CoV-2 (Li et al., 2018; Trischitta et al., 2024). Assay outputs can also vary according to target cell line, reporter system, packaging design, spike construct, harvest timing, and titration strategy. These sources of variability create ongoing standardization challenges across laboratories. In this regard, Trischitta et al. (2024) emphasized that yield, safety, and operational complexity differ among HIV-1, MLV, and VSV backbones, reinforcing the idea that platform choice directly influences assay interpretation and standardization.

Looking ahead, three needs stand out. First, stronger inter-laboratory standardization is required in terms of producer cells, target cells, plasmid architecture, and readout methods. Second, continuing viral evolution demands variant-specific optimization rather than static protocol transferability. Third, the field is likely to move further toward biologically informed engineering strategies, including stable producer cell lines, regulated spike expression, and intracellular modulation of spike processing. Together, these directions suggest that pseudovirus technology is maturing from an emergency substitute into a robust, flexible, and enduring platform for viral entry research and antiviral development.

CONCLUSION

SARS-CoV-2 spike pseudovirus systems have developed into mature and highly adaptable platforms that combine biosafety, analytical flexibility, and practical scalability. Their value lies not only in enabling lower-risk studies of viral entry, but also in their continual methodological refinement through improved vector design, host-cell engineering, reporter selection, and variant-responsive optimization. Recent studies further show that these systems can support scalable neutralization and compound-screening workflows, can be adapted to resource-limited laboratories, and can even be repurposed for mechanistic studies of spike biogenesis and intracellular regulation. Taken together, the literature, our thesis-based work, and our chapter-based synthesis indicate that pseudovirus technology is no longer simply a provisional response to the COVID-19 crisis. Rather, it has become a durable experimental framework for studying viral entry, neutralization escape, and early-stage antiviral discovery.

ABSTRACT

Human skin is a complex ecosystem that is home to millions of microorganisms known as the skin microbiome. These microorganisms play a vital role in regulating the immune system and protecting against pathogens. However, the media represents a significant discrepancy between scientific reality and how the skin is portrayed. Digital and traditional platforms consistently promote biologically unrealistic, sterile beauty standards that misrepresent normal microbial variation and trigger severe social stigmatization. Using a qualitative, multi-case study methodology, this paper examines the discrepancy between biological facts and media-driven aesthetic myths. We examined three distinct narratives: a ten-year autoethnographic experience of *Acne vulgaris*; the systemic aesthetic bullying of participant Stelina Kurila on Big Brother VIP Albania 5; and the digital activism of skin-positivity advocate Maia. Our findings reveal that media channels systematically moralize and misidentify biological dysbiosis as a failure of personal hygiene. They utilize a divisive normalization mechanism that marginalizes affected individuals. In contrast, skin-positivity movements successfully challenge these unscientific standards of perfection. This study concludes that aligning cultural narratives with genomic reality by shifting public communication from media-induced fear to evidence-based scientific awareness is a critical psychosocial and public health intervention, necessary for the mental well-being and social integration of individuals living with visible dermatological conditions.

Keywords: Skin microbiome, *Acne vulgaris*, Mass media, Aesthetic bullying, Stigmatization

INTRODUCTION

The human skin, the body's largest and most exposed organ, covers an average surface area of approximately 1.8 m² and accounts for about 15% of an adult's body weight (Belkaid and Segre, 2014; McKenna et al., 2024; McGrath, 2025). Contemporary microbiology no longer classifies the skin as merely a physical barrier. Instead, the skin is conceptualized as a dynamic, complex ecosystem and meta-organism comprising the macroscopic host and vast communities of symbiotic bacteria, fungi, and viruses (Belkaid and Segre, 2014; Byrd et al., 2018). Advances in molecular biology have shifted the scientific view of the skin from a passive covering to an active "immunological organ" (Grice and Segre, 2011; McGrath, 2025). The cutaneous microbiome is a "guardian of health" that regulates innate and adaptive immune responses, defends against invading pathogens, and supports critical physiological processes such as wound healing (Sanford and Gallo, 2013; Belkaid and Segre, 2014; Byrd et al., 2018). The healthy skin microbiome is taxonomically dominated by four primary bacterial phyla: Actinobacteria, Firmicutes, Proteobacteria, and Bacteroidetes (Grice et al., 2009). Beneficial

species, such as *Staphylococcus epidermidis*, act as primary defenders by producing antimicrobial peptides and other molecules that inhibit pathogen colonization and modulate host immunity (Sanford and Gallo, 2013; Belkaid and Segre, 2014; Nakatsuji et al., 2018). Conversely, *Cutibacterium acnes* is a lipophilic commensal, naturally dominates sebaceous units but is often unfairly associated with pathology. In reality, *C. acnes* usually contributes to inflammation only when the microbial balance is disrupted, a state of dysbiosis (Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013; Byrd et al., 2018).

However, the intersection of skin health and social perception is heavily influenced by the media, where physical appearance plays a significant role in shaping self-esteem and social integration, particularly among adolescents and young adults (Dalgard et al., 2015; Cohen et al., 2017; Yousaf et al., 2020). Dermatological conditions are more than just a cosmetic nuisance. They often cause significant psychological distress, including anxiety, depression, low self-esteem, and social isolation, similar to the distress experienced with chronic, disabling illnesses, such as arthritis or diabetes (Barankin and DeKoven, 2002; Dalgard et al., 2015; Germain et al., 2021; Christensen and Jafferany, 2023). Visible skin disorders often expose patients to stigmatization, teasing, and aesthetic cyberbullying (Luck-Sikorski et al., 2022; Chernyshov et al., 2024; Alfahaad et al., 2025). However, the media often oversimplifies this biological complexity. Digital platforms such as Instagram and TikTok promote heavily edited, filtered, and idealized images of perfect skin, establishing an unrealistic and sterile beauty standard by systematically removing natural pores and texture (Magin et al., 2011; Fardouly et al., 2015). This media construct consequently fosters a culture of fear regarding the skin's ecosystem, leading to an unnecessary obsession with aggressive disinfection and the overuse of cosmetic products (Basch et al., 2015). Recent studies on the skin-brain axis have revealed a possible link between certain bacterial species, including *Cutibacterium*, and positive psychological well-being, suggesting that a balanced microbiome is associated with reduced stress and improved mood (Luck-Sikorski et al., 2022; Tyson-Carr et al., 2025).

This article examines the significant contrast between the biological reality of the skin microbiome and media-driven aesthetic myths, analyzing how personal and digital media affect public perception. Through content analysis, we identify trends in dermatological representations, distinguishing media channels that foster pathophobia and misinformation (Vrenozi and Lugaj, 2025) from those that promote evidence-based health communication (Kite et al., 2023). This communication gap reflects broader public health dynamics in Albania, where inadequate scientific literacy fosters societal anxiety toward other medically significant taxa, allowing sensationalized fear to overshadow clinical reality (Vrenozi, 2025). Transitioning public discourse toward genomic realism, biological naturalism, and body diversity requires replacing media-induced panic with scientific awareness.

MATERIAL AND METHOD

This research uses a qualitative and analytical approach that combines media content analysis with case studies to examine the relationship between dermatological health and media narratives. The primary methodology involves systematically monitoring prominent Albanian media outlets, including Top Channel, TikTok, Instagram, JOQ Albania, Anabel Magazine, and Iliria News. These outlets were selected based on their significant public reach and influence on social discourse. Three case studies are analyzed to illustrate the tangible, real-world impact of these media narratives on psychological well-being and social integration.

1. A personal autoethnographic story: It involves the decade-long experience of one patient with *Acne vulgaris* from 2014 to 2024 (D. Myrtaj, personal communication). The story explores the tension between individual clinical reality and the “sterile” beauty standards promoted by the media.

2. Media representation of a reality show participant: This case study examined the public discourse surrounding Stelina Kurila during her time on the reality TV show Big Brother VIP Albania 5 in 2026. The case study examined public and digital responses, demonstrating how traditional and social media platforms can trigger intense public scrutiny and aesthetic judgment based on skin appearance. This case was chosen because of its high visibility, which sparked a national debate on skin appearance and health. Several media outlets documented the scandal, their editorial positions on natural beauty, and celebrities' reactions. A few examples are included here, such as Anabel Magazine (January 6, 2026) and Iliria News (January 5, 2026), as well as digital platforms such as Top Channel, JOQ Albania, TikTok, and Instagram.
3. Digital activism of a skin-positivity creator: This case study, taken from Maia's story in Changing Faces (March 7, 2023), examines the effect of digital activism in promoting skin positivity and challenging societal norms regarding beauty standards. It highlights narratives that challenge unrealistic beauty ideals and celebrate natural beauty.
By combining these three case studies, the manuscript aims to bridge the gap between contemporary biological science and the media's perception of the skin microbiome.

RESULTS AND DISCUSSIONS

Case Study 1. Autoethnographic Narrative of Acne vulgaris: Transitioning from media-induced fear to scientific awareness in acne management

The autoethnographic narrative highlights a profound discrepancy between the skin's biological reality and its hyper-sanitized media depiction (Magin et al., 2011), presenting a ten-year story of living with *Acne vulgaris* (D. Myrtaj, personal communication) (Figure 1). Although often dismissed as a minor cosmetic nuisance, the resulting psychological morbidity, including severe anxiety and depression, is clinically comparable in quality-of-life impairment to chronic, disabling conditions such as type 2 diabetes, heart disease, and severe arthritis (Barankin and DeKoven, 2002; Dalgard et al., 2015; Christensen and Jafferany, 2023). Throughout this decade, the patient was constantly exposed to unrealistic, sterile aesthetic standards on digital platforms like Instagram and TikTok, which filter out natural pores and texture to establish an unscientific baseline of perfection (Magin et al., 2011; Fardouly et al., 2015; tirananews, January 6, 2026).

Figure 1. The face images of the autoethnographic clinical progress: **A**- Started treatment 01.02.2024; **B**- After treatment 07.07.2026 ©danielamyrtaj

Because the human face represents the primary locus of the "social and relational self," the inability to meet this standard precipitated profound self-stigma and social anxiety (Barankin and DeKoven, 2002; Magin et al., 2011; Germain et al., 2021), compounded by "aesthetic bullying" from a public that moralizes cutaneous pathology as a failure of hygiene (Luck-

Sikorski et al., 2022; Chernyshov et al., 2024; Alfahaad et al., 2025). To achieve this ideal, the patient initially adopted aggressive, media-promoted "bacterial destruction" protocols (Basch et al., 2015). However, rather than providing relief, these sterilization methods damaged the outermost layer of the epidermis, stripping the vital extracellular lipid matrix and elevating the skin's naturally acidic pH, which ultimately exacerbated her acne severity (Grice and Segre, 2011; Sanford and Gallo, 2013; McGrath, 2025).

The decisive turning point in both the patient's clinical management and psychological well-being was reached through scientific literacy, reframing the skin not as an unhygienic surface to sterilize, but as a living meta-organism (Belkaid and Segre, 2014; Byrd et al., 2018). According to the hologenome theory, the human host and resident cutaneous microbiota coexist in a symbiotic relationship in which commensals actively calibrate local immunological networks (Belkaid and Segre, 2014; Byrd et al., 2018; Nakatsuji and Gallo, 2019). The patient successfully destigmatized her condition and transformed a decade of fear into a managed reality by transitioning her internal narrative from a moralizing language of "uncleanliness" and "failure" to biological homeostasis (Magin et al., 2011; Alfahaad et al., 2025). This shift repositioned *Cutibacterium acnes* as a vital lipophilic commensal that contributes to inflammation only in a state of dysbiosis (Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013; Byrd et al., 2018), and highlighted *Staphylococcus epidermidis* as an essential "guardian of health" that secretes antimicrobial peptides to defend the host and regulate immune responses (Sanford and Gallo, 2013; Belkaid and Segre, 2014; Nakatsuji and Gallo, 2019). This alignment of cultural perception with genomic reality significantly reduced her psychological burden, enabling her to abandon makeup as a "mask" and accept natural skin variation (Tyson-Carr et al., 2025).

The culture of mass media's perfection filters out the reality of the human meta-organism (Magin et al., 2011; Fardouly et al., 2015), leaving the public shocked by natural appearance and detached from its genomic reality (Belkaid and Segre, 2014; Byrd et al., 2018). The true scandal is not the presence of *C. acnes*, but our collective failure to recognize its evolutionary role as a protective symbiont (Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013). Replacing media myths with scientific education is critical for cutaneous immune homeostasis and psychological well-being (Tyson-Carr et al., 2025). In the Albanian context, addressing these public misconceptions requires a systematic shift in communication strategies. Regional surveys reveal significant public knowledge gaps and low preparedness regarding local biological exposures (Vrenozi, 2025). This educational shift is essential to destigmatize visible skin conditions and promote a broader biological naturalism (Changing Faces, March 7, 2023; Alfahaad et al., 2025).

Case Study 2. Public Perception of Cutaneous Health on Reality Television: "Aesthetic Bullying" and Hygiene Stigmatization

The 2026 season of Big Brother VIP Albania 5 provided a contemporary example of "aesthetic bullying" under constant 24/7 public surveillance (Anabel Magazine, January 6, 2026; Top Channel, 2026). One notable incident occurred when participant Stelina Kurila appeared on camera without makeup (Joker Albania, 2026; Iliria News, January 5, 2026) (Figure 2/A). Screenshots of her bare face quickly circulated across TikTok, Instagram, and Albanian portals like JOQ, Anabel, and Iliria News, triggering highly judgmental, offensive, and mocking commentary (Figure 2/A, B) (Anabel Magazine, January 6, 2026; Iliria News, January 5, 2026; Joker Albania, 2026; JOQ Albania, 2026; tirananews, January 6, 2026). This negative reaction to her visible *Acne vulgaris* highlights how the high visibility of facial lesions, particularly in central regions like the forehead and nose, attracts disproportionate public scrutiny, leading to

severe external stigmatization, anxiety, and negative social impressions (Barankin and DeKoven, 2002; Germain et al., 2021; McKenna et al., 2024; Alfahaad et al., 2025).

Figure 2. The face images: S. Kurrila: **A**- BBV appearance 05.01.2026 ©ilirianews.al; **B**-treatment 02.03.2026 ©ledaaesthetic; Maia's: **C** and **D**- Social media vs Reality 07.03.2023 ©changingfaces.org.uk

Anabel Magazine (January 6, 2026) pointed out the profound irony that, although the show is categorized as reality, viewers were shocked by it. This backlash demonstrates the public's shifting perception of healthy skin, replacing it with the computer-enhanced standard of perfection seen on Instagram. This shift has driven a divisive normalization mechanism that categorizes natural biological variations as other or abnormal (Magin et al., 2011; Alfahaad et al., 2025; Anabel Magazine, January 6, 2026). Social media commentators have relied on erroneous stereotypes that moralize skin conditions, characterizing Kurila's acne as a scandal, filth, or a personal failure of hygiene and self-care (Alfahaad et al., 2025; Anabel Magazine, January 6, 2026; Iliria News, January 5, 2026; JOQ Albania, 2026). These judgments ignore that acne is a complex biological process involving microbial dysbiosis, hormonal shifts, and inflammatory dynamics, rather than a lack of cleanliness. Individuals with acne often invest significant resources in high-quality skincare products and dermatological treatments (Magin et al., 2011; Alfahaad et al., 2025; Anabel Magazine, January 6, 2026; Ruci, March 2, 2026). The media's focus on Stelina's aesthetic deviation aligns with mass media's consistent promotion of the ideal of perfect skin, such as hyper-idealized celebrity accounts on Instagram (Cohen et al., 2017) (Table 1).

Table 1. Comparative analysis of media representation, public perception, and biological reality of skin microorganisms

Feature	Presentation in Media	Public Perception	Scientific Evidence	Gaps in Albanian Media	References
Cutaneous Microbiota	Portrayed as pathogens requiring complete eradication for hygiene	Pathophobia; associating natural bacterial presence with filth and infection	Symbiotic ecosystem essential for physical barrier homeostasis and immunity	Binary framing; omission of ecological complexity and host-microbe mutualism	(Grice and Segre, 2011; Belkaid and Segre, 2014; Byrd et al., 2018; JOQ Albania, 2026; Top Channel, 2026)

Feature	Presentation in Media	Public Perception	Scientific Evidence	Gaps in Albanian Media	References
Acne vulgaris	Portrayed as a superficial blemish or failure of personal hygiene	Triggers profound self-stigma, shame, and social isolation	Driven by genetic barriers, hormonal shifts, and follicular dysbiosis	Prioritizes commercial product marketing over microbiological explanations	Barankin and DeKoven, 2002; Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013; Alfahaad et al., 2025; Anabel Magazine, January 6, 2026; JOQ Albania, 2026; Top Channel, 2026
Aesthetic Standards (Perfect skin)	Digitally filtered, edited, and hyper-idealized images across media platforms	Induces unrealistic beauty expectations, self-stigma, and appearance dissatisfaction	The healthy epidermis has natural texture, variations, and vital symbiotic microbes	Prioritizes artificial cosmetic perfection over biological and genomic realism	Barankin and DeKoven, 2002; Magin et al., 2011; Fardouly et al., 2015; Byrd et al., 2018; Alfahaad et al., 2025; Joker Albania, January 5, 2026; tirananews, January 6, 2026
Cutaneous Interventions	Cosmetic products marketed as universal, over-the-counter therapeutic cures	Uncritical product trust, delaying medical care in favor of self-medication	Requires professional clinical diagnosis and personalized, evidence-based therapy	Prioritizes commercial product marketing over clinical and scientific facts	Basch et al., 2015; Yousaf et al., 2020; Alfahaad et al., 2025; Ruci, March 2, 2026; Top Channel, 2026
Social Media "Skin Care"	Unregulated, simplified cosmetic advice promoted by non-medical influencers	High susceptibility to health misinformation and hazardous, unverified skin practices	Most digital advice lacks clinical grounding, empirical evidence, or safety verification	Omission of scientific screening, peer verification, or medical oversight	Basch et al., 2015; Yousaf et al., 2020; Iliria News, January 5, 2026; Joker Albania, January 5, 2026; tirananews, January 6, 2026
Educational Media Role	Infrequent, isolated health campaigns or authentic patient narratives	Fosters public empathy, health literacy, and destigmatization	Strategic health communication reduces public stigma and builds support	Omission of systematic health campaigns; untapped educational capacity	Luck-Sikorski et al., 2022; Kite et al., 2023; Alfahaad et al., 2025; Vrenozi and Lugaj, 2025; Top Channel, 2026

In response, Albanian public figures, including O. Marashi, A. Musta, F. Haxhialiu, and L. Brati, criticized this hypocrisy. They noted that a public that demands naturalness is repulsed by its biological reality (Anabel Magazine, January 6, 2026). The resulting cyberbullying created a toxic social environment, inflicting severe psychological distress, including anxiety, social withdrawal, and diminished self-esteem, that can be as disabling as the clinical condition itself (Dalgard et al., 2015; Germain et al., 2021; Luck-Sikorski et al., 2022; Chernyshov et al., 2024; Alfahaad et al., 2025). To remediate this social "inflammation", mass media platforms must transition from spaces of aesthetic judgment and public panic to public health advocates that promote scientific awareness, eliminate misinformation, and destigmatize natural cutaneous variations (Basch et al., 2015; Kite et al., 2023; Vrenozi and Lugaj, 2025).

Case Study 3. Digital Activism and the Skin-Positivity Movement: The psychosocial transition from stigmatization to communication through acne positivity

Maia's longitudinal experience as a digital activist and content creator illustrates that having a visible facial dermatological condition during adolescence increases the risk of severe social discrimination and bullying (Barankin and DeKoven, 2002; Luck-Sikorski et al., 2022; Changing Faces, March 7, 2023). Her personal history of schoolyard harassment and derogatory online comments led to severe social anxiety and low self-worth. This aligns with clinical evidence showing that the psychological distress caused by visible facial lesions is comparable in severity to that caused by disabling systemic diseases (Barankin and DeKoven, 2002; Changing Faces, March 7, 2023; Alfahaad et al., 2025). Initially, she used heavy makeup as a defensive mask to conceal her skin and manage daily social interactions, a widely documented coping mechanism used to mitigate stigma (Barankin and DeKoven, 2002; Changing Faces, March 7, 2023).
Eventually, Maia repurposed her digital platforms to join the acne positivity movement, posting unedited, natural images of her face (Figure 2/C, D) to challenge the beauty industry's standard practice of using digital enhancement to project a flawless, "sterile" aesthetic (Magin et al., 2011; Cohen et al., 2017; Changing Faces, March 7, 2023). This shift highlights how a new model of health communication can treat digital networks as therapeutic environments and sources of social support (Basch et al., 2015; Yousaf et al., 2020; Kite et al., 2023). By reframing natural skin variation as a component of a living meta-organism rather than an aesthetic failure, such movements provide the empathy and inclusivity needed to remediate social dysbiosis and improve patients' quality of life (Belkaid and Segre, 2014; Byrd et al., 2018; Changing Faces, March 7, 2023; Alfahaad et al., 2025). If our social perception, or "social skin", is integral to health, then mass media must complement public health by eliminating misinformation and promoting a new aesthetic of genomic realism that aligns cultural narratives with biological reality (Barankin and DeKoven, 2002; Magin et al., 2011; Fitz-Gibbon et al., 2013; Basch et al., 2015; Kite et al., 2023; Tyson-Carr et al., 2025; Vrenozi and Lugaj, 2025). Aligning cultural narratives with genomic realities is essential to alleviating the psychological burden imposed by unscientific standards of cutaneous perfection (Magin et al., 2011; Fardouly et al., 2015; Tyson-Carr et al., 2025).

CONCLUSIONS

This study's analysis reveals a profound, systemic discrepancy between contemporary scientific understanding of the skin and its depiction in the media. While biological research conceptualises the skin as a dynamic 'meta-organism' and an active immunological organ, media platforms consistently project a reductive, 'sterile' version of the human body. This

computer-enhanced ideal, which systematically removes pores, texture, and natural variations, forces individuals to view healthy biological processes as 'aesthetic failures' or evidence of personal neglect. The case studies of Stelina Kurila and Maia, along with the personal autoethnographic story, highlight the severe psychosocial consequences of this media construct. Visible dermatological conditions are not merely cosmetic concerns; they can lead to psychological distress, including anxiety, depression, and social withdrawal, at levels comparable to those experienced with chronic disabling illnesses.

Transitioning public discourse from 'aesthetic bullying' towards inclusivity requires a fundamental shift in literacy. Ultimately, replacing media-driven myths with scientific facts about the skin microbiome is essential for destigmatisation. Understanding the role of biological homeostasis and the protective function of commensal microorganisms can help society move away from a 'culture of fear' and towards a more inclusive understanding of body diversity. Promoting scientific awareness is not just a clinical necessity but also a vital step in safeguarding the mental health and social integration of individuals living with visible skin conditions.

ABSTRACT

Urban air pollution is a growing environmental and public health challenge in Albania, driven by rapid urbanization and inadequate infrastructure. Elbasan, a major city with a strong industrial legacy, is particularly vulnerable. This study aims to evaluate urban air quality in Elbasan city using 2023 monitoring data, generated through measurements conducted by the National Environmental Agency (NEA) for key pollutants, including PM_{10}, NO_2, CO, O_3, SO_2, and C_6H_6. The analysis of the monitoring data shows that for some of the main pollutants (NO_2 and PM_{10}), the concentrations measured during 2023 exceeded or were very close to the limit values established by international air quality standards. The annual average NO_2 concentration (32.94µg/m³) remains below the EU limit of 40 µg/m³ but is approximately 3.5 times higher than the 2021 WHO guideline of 10 µg/m³. Regarding PM_{10}, the annual average concentration (47.85 µg/m³) slightly exceeds the EU limit (40 µg/m³) but is more than three times higher than the WHO guideline value (15 µg/m³). Additionally, daily PM_{10} concentrations frequently surpass both EU and WHO daily limits, indicating exceedances of both short-term and long-term air quality standards. Seasonal analysis shows that air quality is poorest during winter, when pollutants such as PM_{10}, NO_2, CO, and C_6H_6 reach their highest concentrations and most frequent exceedances. This pattern is driven by both winter meteorological conditions and increased human activities. These results also demonstrate that, especially during the colder months, residents of Elbasan are exposed to air pollution levels that may harm health, with children, older adults, and people with pre-existing health conditions being the most vulnerable.
Keywords: Urban air quality; Air pollution; Air quality monitoring; Elbasan

INTRODUCTION

Currently, air pollution is acknowledged as one of the foremost environmental hazards to global human health. In particular, the World Health Organization reported that exposure to air pollution is the cause of more than seven million premature deaths annually and it is associated with several health problems such as asthma, chronic bronchitis, lung cancer, and cardiovascular diseases (WHO, 2021). In addition to the negative impacts on human health, air pollution also has a significant impact on the environment, leading to loss of biodiversity, ecosystem deterioration and degradation of soil and water quality (EEA, 2022).

The major sources of urban air pollution are vehicular traffic, domestic heating, industry and inappropriate waste disposal. The relative importance of these sources varies depending on the

pollutant and the local context (EEA, 2022). In addition, meteorological parameters such as wind speed, wind direction, temperature and atmospheric stability play an important role in the dispersion, accumulation and concentration of air pollutants and thus have an impact on the urban air quality (EEA, 2022)

The National Environment Report (NEA, 2023) points out that air pollution in major Albanian cities has become a serious environmental and public health problem, driven by rapid urbanization, increasing traffic density and lack of sustainable infrastructure. In this context, accurate determination and ongoing monitoring of the air quality are key to the assessment of pollution levels, identification of pollution sources, and to support data-driven environmental policies to protect the public health and promote sustainable urban growth.

Elbasan is one of the major cities in Albania. In the last decades, it has experienced many urban and socioeconomic changes, which have resulted in increasing environmental problems, especially in terms of air quality and its impacts on public health. The city is situated in the central part of Albania, in the valley of the Shkumbin River at an average altitude of about 110m above sea level. It has a Mediterranean climate with moderate winters, hot summers, and seasonal rainfall patterns.

Since the 1990s, rapid urban growth and domestic migration have fueled the spread of residential zones, often haphazardly and at the expense of farmland. This demographic growth has added to the strain on metropolitan infrastructure and services, leading to more traffic, higher energy consumption and more generated waste. These and the continuous growth of the city has made air pollution one of the major environmental problems in the city.

Prior to the 1990s, Elbasan was a major industrial center in Albania and was known as one of the most polluted regions in the country. While industrial activity has declined, pollution of air, water and soil remains a serious environmental problem with pollutants often exceeding national and international standards.

Today, Elbasan is one of the most polluted cities in Albania regarding its air quality. Unregulated industrial discharges, absence of regular environmental monitoring, poor compliance with environmental regulations and limited emission reduction efforts have been blamed for the decreasing air quality, especially around industrial facilities. Surveillance of data shows high levels of particulate matter, nitrogen dioxide , and carbon monoxide (AKM 2026). Pollution levels are typically highest during the colder months, when residential heating with wood and fossil fuels increases emissions, while unfavorable meteorological conditions reduce atmospheric dispersion and promote the accumulation of pollutants.

The objective of this study is to give a detailed assessment of the existing air quality in Elbasan, based on the monitoring data of 2023 obtained from the measurements carried out by the National Environmental Agency (NEA) for significant pollutants such as PM_{10}, NO_2, CO, O_3, SO_2 and C_6H_6. It aims also to identify the main air pollutants, their temporal variations, and the main factors contributing to air pollution. The findings are expected to improve the understanding of the city's air quality status and provide important information for developing effective environmental governance and pollution control strategies.

MATERIAL AND METHOD

The data on air pollutants monitoring used in this study were collected from National Agency of Environment (NEA), the institution responsible for environmental monitoring in Albania. The measurements were performed in the city of Elbasan in the period January-December 2023. The automated instrument monitored continuously, logging the concentration of each contaminant each hour. The monitoring station is classified as an urban station and the sampling area is mainly residential.

The analysis is concentrated on six airborne pollutants: PM_{10}, NO_2, CO, SO_2, O_3, and C_6H_6. The data set includes continuous hourly measurements, from which monthly and annual averages were derived. This information provides a general overview of the seasonal variation of air quality and enables comparison with national standards, as well as international standards and guidelines set by the European Union and the World Health Organization (WHO). The monthly and annual averages obtained were used to analyze the air quality in Elbasan, to identify seasonal pollution patterns and to assess the influence of factors such as the weather conditions, traffic volume and economic activities. The collected monitoring data was processed and analyzed by Microsoft Excel 2016 for mathematical and statistic calculations.

A limitation of the study is the lack of data on the monitoring of $PM_{2.5}$ in 2023, considering that it is one of the most harmful air. In addition, technical problems with the monitoring equipment resulted in incomplete data sets for some pollutants, limiting the accuracy of assessing seasonal trends.

RESULTS AND DISCUSSION

Table 1 presents the average monthly and annual concentrations of sulfur dioxide (SO_2), ozone (O_3), carbon monoxide (CO), nitrogen dioxide (NO_2), particulate matter (PM_{10}), and benzene (C_6H_6) measured in the city of Elbasan during 2023.

Table 1. Average monthly and annual concentrations of the main air pollutants in the city of Elbasan during 2023

Parameter	**SO_2 µg/m³**	**O_3 µg/m³**	**CO mg/m³**	**NO_2 µg/m³**	**PM_{10} µg/m³**	**C_6H_6 µg/m³**
January	1.93	25.66	6.13	23.22	-	2.85
February	1.11	35.5	6.99	28.09	-	1.53
March	0.65	-	-	48.19	-	1.13
April	1.31	-	-	-	-	-
May	2.94	17.48	1.71	42.75	39.9	2.04
June	8.46	51.62	1.1	25.82	38.48	0.87
July	8.74	76.29	0.54	27.04	48.34	0.79
August	2.73	70.12	0.51	28.78	61.41	2.67
September	3.47	64.37	0.39	32.6	45.61	2.7
October	5.04	45.96	0.69	29.47	42.29	1.84
November	1.97	32.75	0.45	34.32	40.84	3.36
December	2.42	23.1	0.61	42.05	65.92	4.82
Annual average	3.40	44.29	1.91	32.94	47.85	2.24

Based on these data, graphical analyses, interpretation, and discussion are presented for each monitored air quality parameter.

Sulfur dioxide

Sulfur dioxide (SO_2) is a major air pollutant primarily emitted from industrial processes and the combustion of sulfur-containing fossil fuels. High SO_2 concentrations can irritate respiratory system, aggravate asthma and cause acid rain and environmental acidification (WHO, 2021). Figure 1 presents the monthly and annual means of SO_2 concentrations measured in Elbasan during 2023.

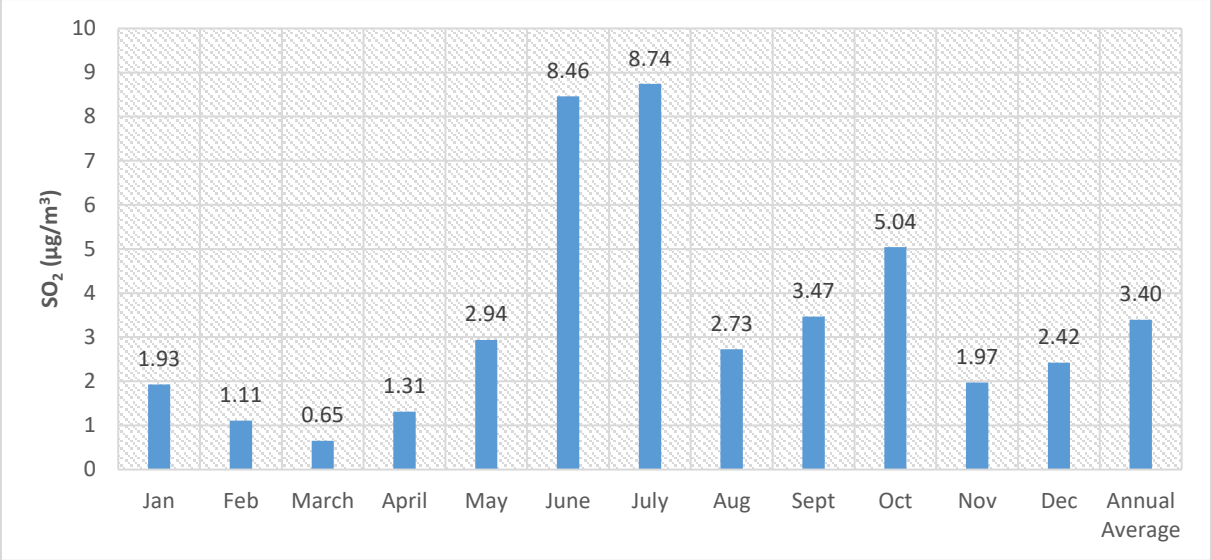

Figure 1. SO_2 concentration (µg/m^3) in the urban air of Elbasan during 2023

The annual average concentration of SO_2 as shown in Figure 1 was 3.4 µg/m³. Since the air quality standards for SO_2 are based on hourly and 24-hour concentrations, the monitoring data were compared with the corresponding guideline values. The average concentrations over 24 h ranged from 0.25 to 13.03 µg/m³, being below the limits of the European Union (125 µg/m³) and WHO (40 µg/m³), indicating that SO_2 pollution did not pose a significant air quality problem during the study period.

Maximum concentrations of SO_2 were found in June and July, and minimum in February and March. This seasonal pattern is different from that of some international studies where SO_2 levels are usually higher in winter and reach their lowest levels during summer (Lin et al., 2012; Wang et al., 2018). The relatively higher summer concentrations in Elbasan can be explained with the local meteorological conditions such as dry weather and low wind speeds that limits the dispersion of pollutants.

Ozone

Tropospheric ozone (O_3) is a secondary air pollutant formed by photochemical reactions of nitrogen oxides (NOx) and volatile organic compounds (VOCs) in the presence of sunlight. High concentrations of ozone can have a negative impact on the health of the respiratory system,

especially for children, elderly people and those who already suffer from respiratory diseases (WHO, 2021). Monthly and annual mean concentrations of O_3 measured in the city of Elbasan for 2023 are shown in figure 2.

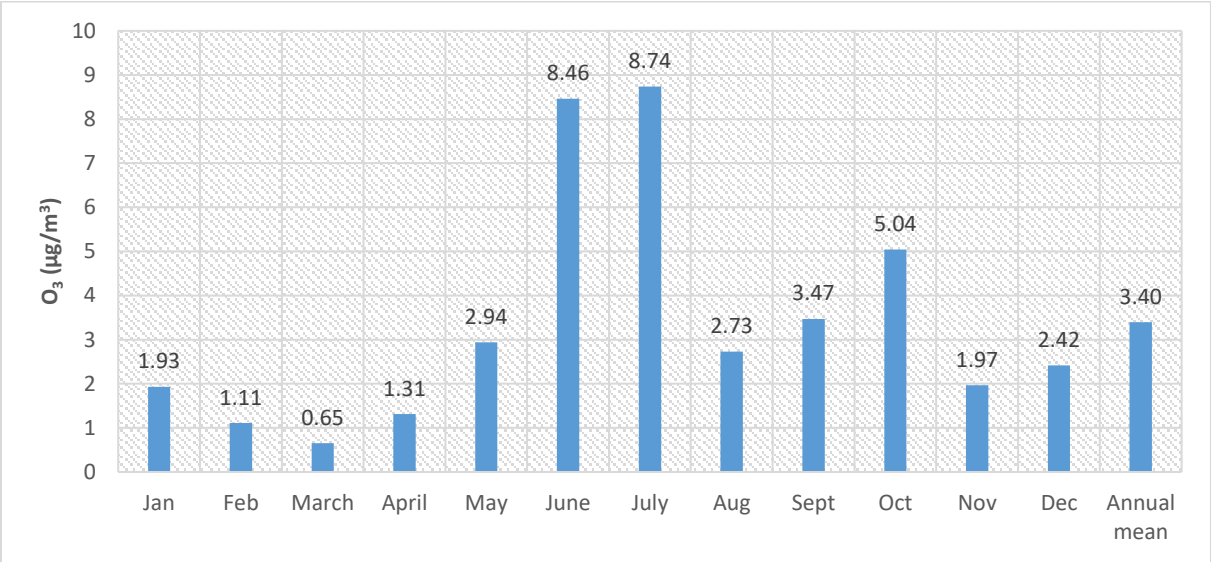

Figure 2. O_3 concentration (µg/m^3) in the urban air of Elbasan during 2023

The average annual concentration of O_3 was 44.29 µg/m^3. The ozone concentrations resulted to be higher in the warm season (June–September) than in the cold season (October–February). This trend is consistent with the typical seasonal pattern driven by stronger solar radiation and higher temperatures that enhance photochemical ozone formation. Hourly data analysis also indicated that ozone peaks around mid-day when solar radiation is the highest, consistent with the diurnal pattern of photochemical ozone formation (U.S. EPA, 2020) .

According to the European Union Air Quality Directive the maximum daily 8-hour average ozone (O_3) concentration should not exceed 120 µg/m³, whereas the WHO Air Quality Guidelines (2021) recommend a maximum daily 8-hour average of 100 µg/m³ and a peak-season average of 60 µg/m³. The analysis of the monitoring data of 2023 shows that the hourly O_3 concentrations in Elbasan exceeded the WHO peak-season guideline of 60 µg/m^3 in 21.4 % of the measurements, mainly in June-September, while 3.8 % of the measurements exceeded the 100 µg/m^3 guideline. However, the EU and Albanian limit value of 120 µg/m^3 was not exceeded. These results indicate that ozone pollution in summer may present a potential risk to public health and vegetation even when the current EU and national standards are met.

Nitrogen dioxide

Nitrogen dioxide (NO_2) is a major air pollutant produced mainly by the high-temperature combustion of fossil fuels from road traffic, industrial activities, and power generation. Exposure to elevated NO_2 levels is associated with adverse respiratory effects and contributes to the formation of ground-level ozone and secondary particulate matter, with negative impacts on both human health and ecosystems (WHO, 2021; EEA, 2024). Figure 3 presents the average monthly and annual NO_2 concentrations measured in the city of Elbasan during 2023.

As shown in this figure, the annual mean NO_2 concentration in Elbasan during 2023 was 32.94 µg/m³. This value is below the EU and Albanian annual limit of 40 µg/m³, but more than three times higher than the WHO Air Quality Guideline of 10 µg/m³, indicating a potential

health concern may arise from exposure to this pollutant (WHO, 2021; Directive 2008/50/EC). The highest monthly concentrations were recorded in March, May, and December, when average levels exceeded 40 µg/m³. Daily concentrations during these months were also frequently above the WHO recommended daily guideline.

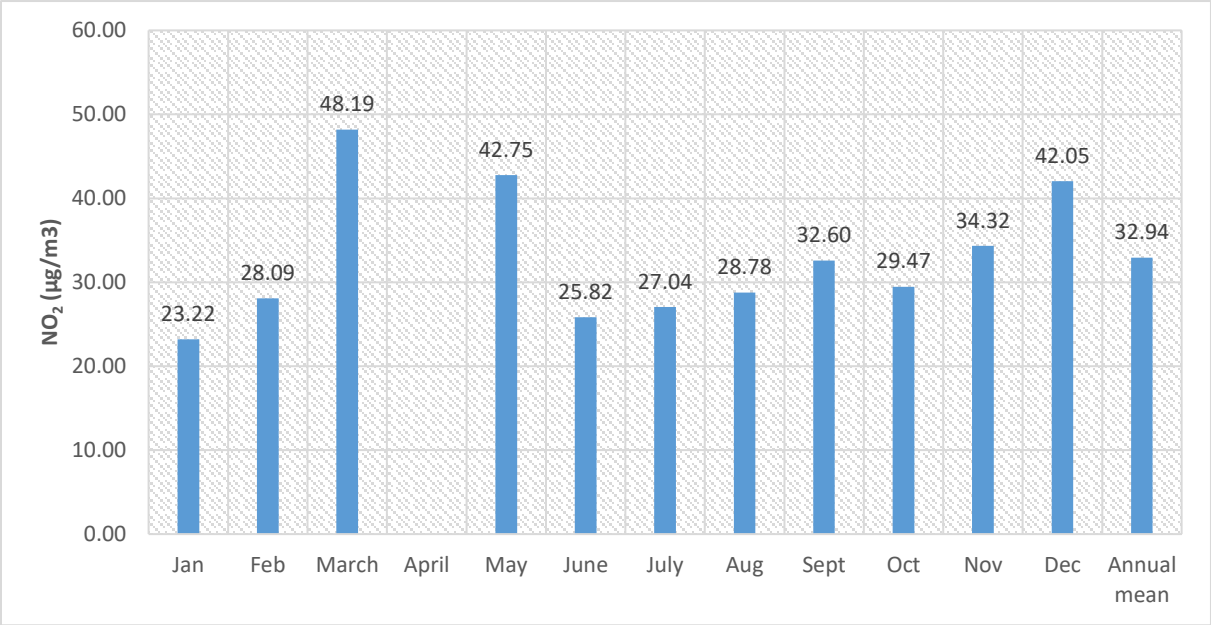

Figure 3. NO_2 concentration (µg/m^3) in the urban air of Elbasan during 2023

The observed seasonal variation generally follows the typical pattern reported in the literature, with higher NO_2 concentrations during the colder months due to increased fossil fuel combustion for residential heating (Guion et al., 2025), higher vehicle emissions, reduced atmospheric dispersion, and lower solar radiation (U.S. EPA, 2016). On a daily scale, NO_2 concentrations peaked during the morning and evening, corresponding to periods of increased traffic intensity, while daytime concentrations tend to decrease as atmospheric mixing and dilution increase (U.S. EPA, 2016;Voiculescu et al., 2020).

Carbon monoxide

Carbon monoxide (CO) is a toxic air pollutant produced mainly from the incomplete combustion of fossil fuels. Its main sources are emissions from vehicles, industry, residential heating with wood or coal and biomass burning, including forest fires. CO is especially harmful to human health as it binds with hemoglobin and decreases the blood's capacity to transport oxygen to organs and tissues, which may result in cardiovascular and respiratory effects at high exposure levels (WHO, 2021).

Figure 4 presents monthly and annual average concentrations of CO measured in the city of Elbasan during the year 2023. According to the monitoring data, the average annual concentration of CO in Elbasan in 2023 was 1.91 mg/m^3. The highest concentrations were observed in January and February, in accordance with the typical seasonal pattern of elevated CO concentrations during the colder months due to the increased combustion of fossil fuels for heating and poorer atmospheric dispersion (U.S. EPA, 1979; Gratsea et al., 2017). The highest daily CO concentrations were observed in the morning and evening, corresponding to hours of increased traffic and lower atmospheric mixing, while lower levels were observed during the midday hours.

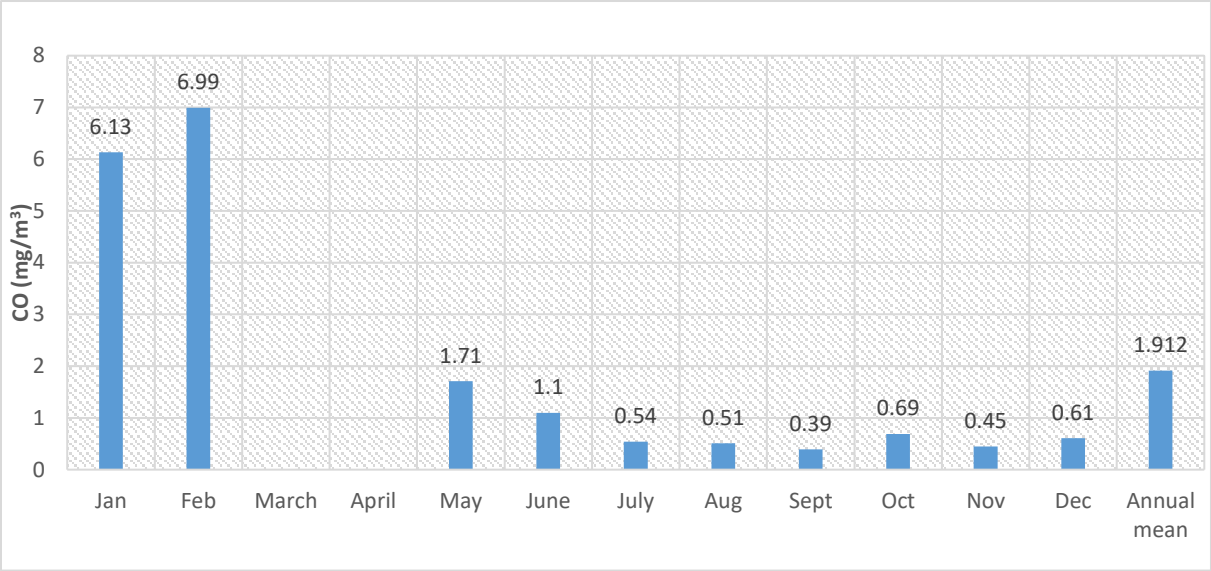

Figure 4. CO concentration (mg/m^3) in the urban air of Elbasan during 2023

When considering compliance with air quality standards note that the EU Air Quality Directive and national standards of Albania establish the maximum daily 8-hour average CO concentration at 10 mg/m^3. Monitoring data indicate that in 2023 the CO concentrations in Elbasan did not exceed this limit. However, according to the WHO Air Quality Guidelines (2021), the recommended 24-hour average should not exceed 4 mg/m³. The daily CO concentrations measured during the months January and February, consistently exceeded this guideline, suggesting that CO pollution may pose a potential health risk during the winter season despite compliance with current EU and national standards.

Particulate matter PM_{10}

Particulate matter with aerodynamic diameter ≤ 10 μm and ≤ 2.5 μm (PM_{10} and $PM_{2.5}$) are among the most important air pollutants of concern for human health. These particles are small enough to penetrate deep into the respiratory system. The high health hazard of $PM_{2.5}$ are related with their ability to cross the lung barrier and enter the bloodstream, contributing to cardiovascular and respiratory diseases, stroke and lung cancer (Abriha-Molnáret al., 2020). Short and long term exposure to particulate matter has been associated with increased morbidity and mortality (WHO, 2021; WHO, 2024).

The NEA's air quality monitoring data for Elbasan in 2023 are incomplete: $PM_{2.5}$ data are entirely unavailable, while PM_{10} data cover only May–December. The data gap impedes a reliable evaluation of the extent of these health-relevant pollutants and thus air pollution in the city.

The average concentration calculated from the available PM_{10} measurements is 47.85 μg/m^3, which is above the EU annual limit value of 40 μg/m^3 and more than three times the WHO guideline value of 15 μg/m^3. However, since the available measurements cover only May–December, this value should be interpreted as an average for the available monitoring period rather than as a fully representative calendar-year average.

The figure 5 presents monthly average for PM_{10} concentrations and calculated annual mean in Elbasan for 2023. The highest concentrations were observed in August and December, when the monthly averages greatly exceeded the applicable annual standard. During these months mean daily concentrations also exceeded the corresponding daily limit or guideline values, which are 50 μg/m^3 under the EU standard and 45 μg/m^3 under the WHO recommendation.

These results indicate that Elbasan was subject to PM_{10} pollution above the air quality standards for both short and long terms during the monitoring period.

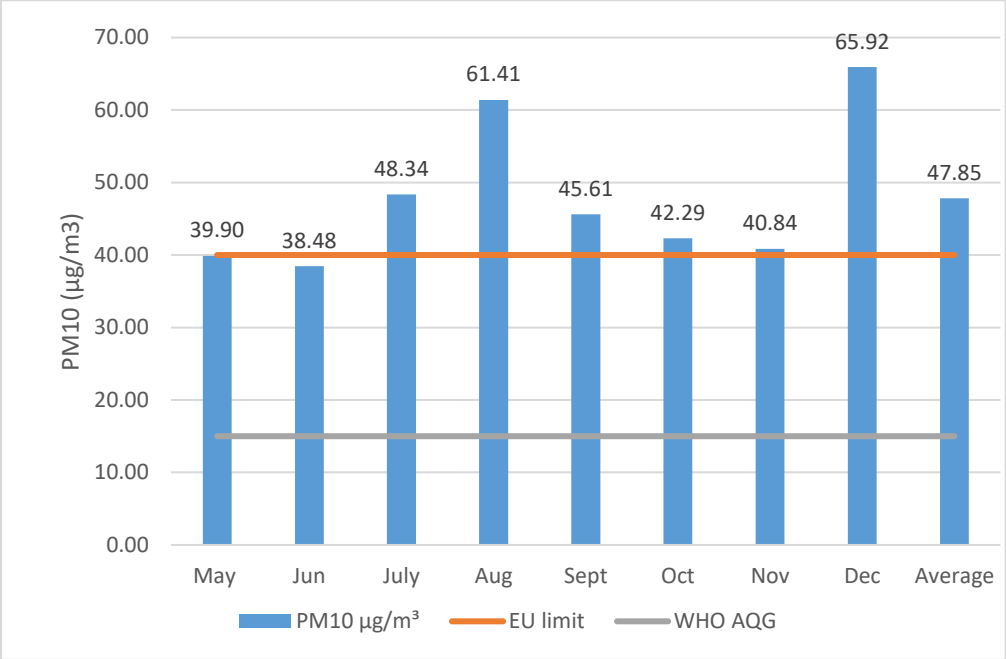

Figure 5. PM10 concentration (µg/m^3) in the urban air of Elbasan during 2023

Benzene C_6H_6

Benzene (C_6H_6) is a dangerous air pollutant that is emitted primarily from fuel combustion, vehicle exhaust, fuel evaporation, and industrial processes. Inhalation is the main way of exposure. Short-term exposure to high benzene levels can cause headache, dizziness, tiredness and irritation of the eyes and respiratory system, whereas long-term exposure may damage the bone marrow, decrease the white blood cells and is associated with an increased risk of leukaemia. International Agency for Research on Cancer (IARC) has classified benzene as carcinogenic to humans – Group 1 (IARC, 2018). It is also caracterized as a known human carcinogen by the US EPA (WHO, 2019; US EPA, 2003).

Figure 6 shows the monthly and annual mean concentrations of C_6H_6 in the city of Elbasan in 2023. As can be seen from the figure, the average annual concentration of benzene has resulted in 2.24 µg/m^3, with the highest concentrations being recorded in January, November and December. This trend matches usual seasonal variations in benzene concentrations which are generally higher in winter due to increased fuel combustion for heating, less atmospheric dispersion due to stable conditions and inversions, and less efficient photochemical breakdown (Baudic et al., 2025; Zhang et al., 2014).

The average annual concentration of benzene was below the EU limit of 5 µg/m^3 However, concentrations increased substantially during the colder months, approaching the EU limit value in December. From a public health perspective, these levels remain relevant because benzene is a known human carcinogen, and the WHO states that no safe level of exposure to airborne benzene can be recommended. The risk assessments of WHO show that even low levels of benzene are associated with an increased lifetime risk of leukemia (WHO, 2019; WHO, 2024).

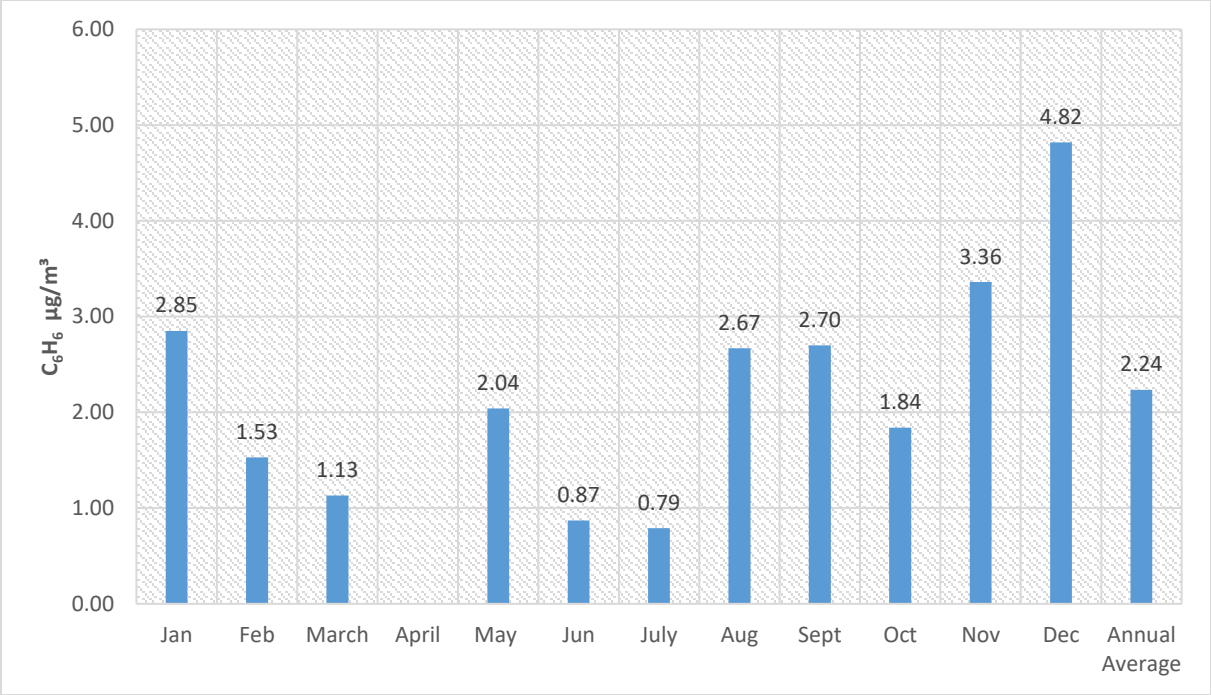

Figure 6. C_6H_6 concentration (µg/m^3) in the urban air of Elbasan during 2023

CONCLUSIONS

The analysis of the data obtained from the air quality monitoring in the city of Elbasan during the year 2023 is a useful basis for the evaluation of the urban air pollution of the city. The results indicate that air quality remains a concern, with several key pollutants exceeding or approaching national and EU limit values. Some pollutants that meet EU standards are still above WHO health-based guideline levels.

The seasonal analysis reveals that the air quality is generally worse in winter, with higher concentrations of PM10, NO_2, CO, and C_6H_6. This trend of pollution is mostly caused by increased burning of fuels for heating, lower temperatures and poor atmospheric dispersion due to temperature inversions.

Air pollution in Elbasan is influenced by multiple sources, particularly road traffic, industrial activities, residential heating, and the use of low-quality fuels. Open waste burning and agricultural activities may also contribute to pollutant levels. Effective control of these sources, together with strengthened air quality monitoring, would contribute to improving urban air quality and reducing potential adverse impacts on public health.

ABSTRACT

Calosoma sycophanta (Linnaeus, 1758), commonly known as the forest caterpillar hunter (FCH), is a large ground beetle that has long been recognized as an effective predatory species in the biological control of lepidopteran pests. In Türkiye, *C. sycophanta* is mass-reared in insect production facilities for the biological control of the pine processionary moth, *Thaumetopoea* spp. (Denis & Schiffermüller). However, despite being mass-produced through considerable effort and expense, *C. sycophanta* alone is insufficient to effectively suppress high-density infestations of the pine processionary moth. In addition, pathogenic viruses, bacteria, fungi, protists, and nematodes may cause chronic infections in predatory insects reared in laboratories for biological control. The use of healthy insects can significantly enhance the efficacy and overall success of biological control programs. This study investigated the current distribution of microsporidial and nematode infections in insect rearing laboratories used for biological control programs across Türkiye. From seven rearing laboratories in Türkiye (Antalya, Balıkesir, Bursa, Isparta, İzmir/Bergama, Manisa and Sakarya/Geyve) 447 dead adult specimens of *C. sycophanta* were procured. To find infected individuals, the beetles were dissected in Ringer's solution and examined under a light microscope at magnifications of 400–1000×. The study revealed that microsporidian infection was detected exclusively in samples obtained from the mass-rearing laboratory in Antalya province, whereas nematode infection was detected only in samples collected from the laboratory in Bursa province. The results showed that microsporidian infection was detected in samples collected from Antalya and Sakarya/Geyve, whereas nematode infection was detected exclusively in samples collected from Bursa. The prevalence of microsporidian infection was 19.0% in samples from Antalya, while it was 9.5% in samples from Sakarya/Geyve. In samples collected from Bursa, nematode infection was detected at a prevalence of 10.2%. In conclusion, to maximize the effectiveness of *C. sycophanta* as a biological control agent and to ensure the success of mass-rearing programs, adult beetles should be routinely screened for potential pathogens before mass rearing begins, and only pathogen-free populations should be selected for production.

INTRODUCTION

Calosoma sycophanta (Linnaeus, 1758), commonly known as the forest caterpillar hunter, is a large ground beetle that has long been recognized as an effective predator in the biological control of Lepidopteran pests. It feeds on a wide range of Lepidopteran species, including Dasychira pudibunda, Euproctis chrysorrhoea, Hyphantria cunea, Lymantria dispar, Lymantria monacha, Thaumetopoea spp. and Tortrix viridana thereby playing an important role in the natural suppression of pest populations (Çanakçıoğlu, 1993; Oğurlu, 2000; Kanat and Mol 2008; Yaman et al., 2019a). In Turkey, C. sycophanta, which plays an important role particularly in the natural suppression of pine processionary moth (T. pityocampa) populations, is mass-reared in insectaries for use in biological control programs (Tosun, 1977; Oğurlu, 2000; Kanat, 2002). However, these rearing programs require considerable effort and substantial costs (Kanat and Özbolat 2006; Yaman et al., 2019a). C. sycophanta, by feeding on both larval and pupal stages of T. pityocampa, is considered an effective biological control agent for regulating pine processionary moth population density during outbreak periods (Kanat and Mol 2008). The use of healthy individuals in biological control programs enhances the efficacy of biological control (Yaman et al., 2010a; Bjørnson and Oi 2014). Pathogenic viruses, bacteria, fungi, protists, and nematodes can cause chronic infections in predatory insects reared in laboratories for biological control. Therefore, the use of healthy insects in biological control programs can significantly enhance their efficacy and overall success (Yaman et al., 2016; Yaman et al., 2019a). It is well known that high mortality rates are observed during the mass rearing of C. sycophanta and after the released individuals are introduced into their natural environment. A substantial proportion of these mortalities is believed to be associated with diseases, as supported by previous studies on diseases affecting similar predatory insects (Yaman and Radek 2007; Yaman et al., 2010a; 2010b). Therefore, the mass rearing of C. sycophanta should aim to produce healthy individuals capable of surviving in the natural environment and reproducing successful1ly. To improve production efficiency, disease-causing agents in C. sycophanta should be identified during mass rearing, and rearing laboratories should be routinely screened for these pathogens. This study investigated the current distribution of microsporidian and nematode infections in C. sycophanta populations from insect rearing laboratories used for biological control programs across Türkiye.

MATERIAL AND METHOD

Insect Samples

From seven rearing laboratories in Türkiye (Antalya, Balıkesir, Bursa, Isparta, İzmir/Bergama, Manisa and Sakarya/Geyve) 447 dead adult specimens of *C. sycophanta* were procured.

Microscopic Examination

Firstly, the samples were taken for macroscopic examination. *C. sycophanta* adult samples were dissected in Ringer's solution and then prepared wet smears including host fat body, malpighian tubules, gut epithelium, and hemolymph were examined for the presence of the entomopathogen infection under a light microscope at a magnification of 400–1000X. When infection was found, the slides were air-dried and fixed with methanol, then stained with freshly prepared 5% solution of Giemsa stain. They were then washed in running tap water, air-dried, and examined under a microscope (Yaman et al., 2019b; Yaman and Sağlam Güvendik 2024).

RESULTS AND DISCUSSION

In this study, Microsporidian infection was detected in samples obtained from the mass-rearing laboratories in Antalya and Sakarya/Geyve**,** whereas Nematode infection was detected exclusively in samples collected from the laboratory in Bursa province (Table 1).

Table 1. Prevalence of Microsporidian and Nematode infections in *Calosoma sycophanta* populations

Location	Number of examined	Number of Microsporidia	Microsporidian infection (%)	Number of Nematode	Nematode infection (%)	Total (%)
Antalya	43	8	19	-	-	19
Balıkesir	103	-	-	-	-	-
Bursa	49	-	-	5	10.2	10.2
Isparta	10	-	-	-	-	-
İzmir/Bergama	84	-	-	-	-	-
Manisa	74	-	-	-	-	-
Sakarya/Geyve	84	8	9.5	-	-	9.5
Total	447	16	3.6	5	1.1	4. 7

The presence of a microsporidian pathogen in C. sycophanta adults reared in insectaries in Türkiye was first reported by Yaman et al. (2016)**.** A microsporidian pathogen was detected in *C. sycophanta* adults from Demirci (Manisa), Selçuk (İzmir), Burhaniye (Balıkesir), and Antalya, and the infection site in the host was identified as the hemolymph (blood cells) (Yaman et al., 2016). In the present study, a microsporidian pathogen was detected in C. sycophanta adults from Antalya and Sakarya/Geyve, and, consistent with the findings of Yaman et al. (2016), the infection was observed predominantly in the hemolymph (blood cells) of the host. The prevalence of microsporidian infection was 19.0% in samples obtained from Antalya**,** whereas the prevalence was 9.5% in samples obtained from Sakarya/Geyve (Table 1)**.** In a study investigating the distribution of a microsporidian pathogen in C. sycophanta populations obtained from rearing laboratories in Türkiye, the prevalence of microsporidiosis was found to vary among C. sycophanta populations from different regions of Türkiye across different years, with a particularly increasing trend in the occurrence of microsporidian infection in Antalya over the years (Yaman et al., 2019a). In the present study, microsporidian infection was still detected in C. sycophanta populations in Antalya in 2026. In contrast, no previous record of microsporidian infection had been reported from Sakarya/Geyve. In the present study, microsporidian infection was detected for the first time in the C. sycophanta rearing laboratory in Sakarya/Geyve.

Microsporidia cause chronic diseases in predatory insects reared in laboratories for biological control, thereby reducing their foraging ability and fecundity (Yaman et al., 2010b; Bjørnson and Oi 2014). Additionally, microsporidia have been shown to prolong larval and pupal development and reduce the fecundity and survival rates of adult predatory insects (Bjørnson and Keddie 1999; Joudrey and Bjørnson 2007; Bjørnson and Oi 2014).

In the samples examined, the pathogen's spore is the most characteristic stage. Light microscopy examinations of live and dead samples revealed the presence of pathogen spores in the intestine

and body cavity (Figure 1). The presence of infection spores was confirmed using the Giemsa staining technique (Figure 2). Giemsa-stained spores were measured. Giemsa-stained spores measured 3.18 ± 0.59 × 1.63 ± 0.26 µm.

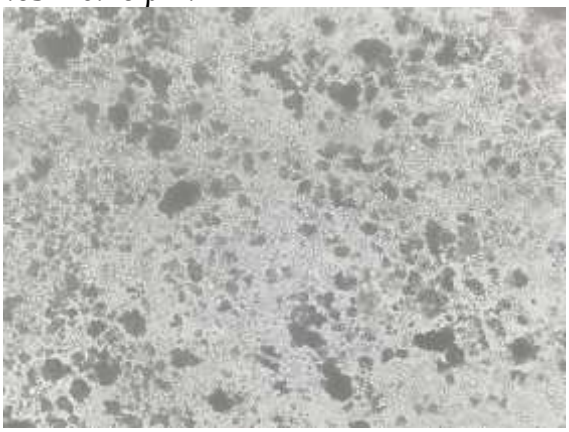

Figure 1. Light microscopy micrographs of microsporidian infection in Calosoma sycophanta

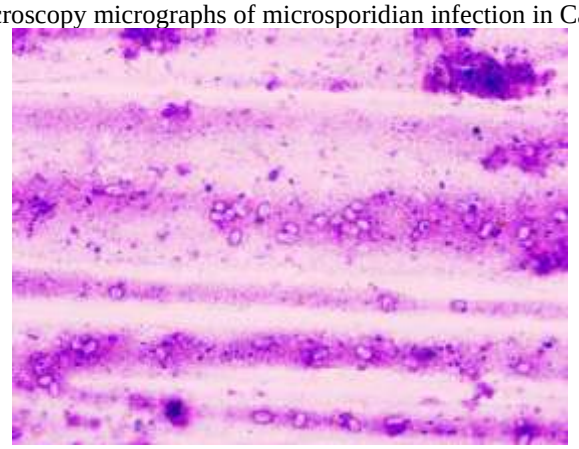

Figure 2. Light microscopy micrographs of Giemsa-stained microsporidian spores in *Calosoma sycophanta*

The infective juvenile stages of nematodes that cause diseases in insects enter their insect hosts through the mouth, anus, or directly through the cuticle. They penetrate the intestinal wall and enter the hemocoel, usually causing the host insect to die within 24–72 hours. Therefore, nematode infection in C. sycophanta is also undesirable. A literature review revealed that nematodes were detected in C. sycophanta individuals in Türkiye as part of a project conducted by Yaman (2007). In the present study, nematode infection was detected at a relatively high prevalence of 10.2% in samples obtained from Bursa (Table 1, Figure 3).

Figure 3. Light microscopy micrographs of nematode in Calosoma sycophanta

CONCLUSIONS

In conclusion, to maximize the effectiveness of *C. sycophanta* as a biological control agent and ensure the success of mass-rearing programs, it is of great importance that adult beetles be routinely screened for potential pathogens before rearing begins and that only pathogen-free populations be used for production. Given that individuals may be exposed to stress in mass-rearing laboratories because the environmental conditions encountered in nature cannot be fully replicated, and that stress may increase susceptibility to infections, pathogens should be regularly monitored and kept under control throughout the rearing process.

ABSTRACT

Ips sexdentatus Boerner (Coleoptera: Curculionidae: Scolytinae) is one of the most destructive bark beetle species, responsible for substantial economic damage in coniferous forests of the Western Mediterranean Region, Türkiye. Pheromone trapping, together with mechanical and chemical control strategies, has long been employed for the management of this pest. However, increasing concerns regarding environmental sustainability have intensified interest in biological control agents and their associated natural enemies. In contrast, entomopathogenic organisms, as natural enemies of insects, possess several advantages over chemical insecticides. Entomopathogenic organisms play an important role as biological control agents against insect pests because of their widespread distribution and high prevalence of infection in insect populations. This preliminary study aimed to determine the presence of nematodes and gregarines in *I. sexdentatus* specimens collected from the Western Mediterranean Region (Antalya, Burdur and Isparta), Türkiye. A total of 120 adult *I. sexdentatus* specimens, including 85 live and 35 dead individuals, were examined in this study. Each beetle was dissected in a physiological solution (0.8% NaCl) and examined microscopically at magnifications of 400×-1000×. The study revealed that the gregarine pathogen was detected only in live *I. sexdentatus* specimens from Burdur province. Nematodes were abundantly detected in the hemolymph of both live and dead *I. sexdentatus* specimens from Isparta, Antalya and Burdur provinces. The detected gregarine pathogen co-occurred with nematodes. The highest nematode infection rates in the examined samples were found in Burdur (34.3%), Isparta (30%), and Antalya (20%). The average infection rate was 31%. The gregarine infection rate was found only in Burdur, at 1.4%. The detected natural enemies may play an important role in the biological control of *I. sexdentatus*, as they have the potential to affect its survival and reproductive capacity. Therefore, this preliminary study provides important baseline data for future studies on the natural enemies of *I. sexdentatus* in the Western Mediterranean Region of Türkiye.

Keywords: *Ips sexdentatus, Gregarine, Nematode, Western Mediterranean Region, Türkiye*

INTRODUCTION

Ips sexdentatus Boerner (Coleoptera: Curculionidae: Scolytinae) is one of the most important and destructive bark beetle species causing severe economic damage and losses in coniferous forests of the Western Mediterranean Region of Türkiye (Sarıkaya et al., 2012). It is a quarantine pest included in the EPPO A2 List and is recognized as one of the most important bark beetle species causing damage to forest ecosystems in Türkiye (EPPO, 2016; Erdoğan, 2024). *I. sexdentatus* was first recorded in Türkiye in 1928 by Bernhard in the spruce forests of Trabzon province. It was subsequently recorded in different regions of Türkiye, where pheromone traps have been widely used as the primary method for its control (Defne, 1954; Chararas, 1966; Beşceli ve Ekici, 1969; Tosun, 1975; Serez, 1984; Sekendiz, 1991; Yüksel, 1996, Cebeci, 2003; Eyüboğlu, 2011; Akkuzu ve Güzel, 2015; Özcan, 2017; Şahin, 2019; Erdoğan, 2024). Adult *I. sexdentatus* are highly efficient fliers, enabling them to actively search for and locate suitable host trees. In the Antalya, Burdur, and Isparta regions, its population may occasionally reach higher levels, and depending on climatic conditions, it can cause outbreaks (Sarıkaya et al., 2012). Although pheromone trapping, mechanical control, and chemical control methods have long been employed for the management of *I. sexdentatus*, these conventional control strategies have often provided limited effectiveness, highlighting the need for alternative and more sustainable approaches to its management. In Türkiye, several chemical insecticides, including cypermetrin and fenitrothion, have also been used to control this pest. However, due to the adverse effects of chemical insecticides on the environment and beneficial insects, as well as their unintended effects on natural predators and parasitoids, chemical control is no longer widely preferred for the management of this pest (Yüksel, 1998; Sevim et al., 2012). Nowadays, growing concerns about environmental sustainability have significantly increased interest in biological control agents and their associated natural enemies. Entomopathogenic organisms, which are natural enemies of insects, offer several advantages over chemical insecticides. Entomopathogenic organisms play an important role as biological control agents against insect pests due to their widespread distribution and high infection prevalence in insect populations (Yaman, 2007; Sevim et al., 2012). In this context, this preliminary study aimed to determine the presence of nematodes and gregarines in *Ips sexdentatus* specimens collected from the Western Mediterranean Region of Türkiye, particularly from Antalya, Burdur, and Isparta provinces.

MATERIAL AND METHOD

Insect Samples

A total of 120 adult *Ips sexdentatus* specimens were collected from the provinces of Antalya, Burdur and Isparta in Türkiye. The sampled individuals consisted of 85 live and 35 dead beetles.

Microscopic Examination

Firstly, the samples were subjected to macroscopic examination. Adult *Ips sexdentatus* specimens were dissected in physiological saline (0.8% NaCl), and wet smears prepared from the fat body, Malpighian tubules, gut epithelium, and hemolymph were examined for the presence of entomopathogenic infections under a light microscope at 400–1000× magnification (Sağlam et al., 2021).

RESULTS AND DISCUSSION

Both live and dead *Ips sexdentatus* specimens were examined in this study. The results revealed the occurrence of gregarine pathogens and nematode infections in the examined *I. sexdentatus* specimens. The gregarine pathogen was detected only in live specimens collected from Burdur Province (Figure 1). Nematodes, however, were detected in high abundance in the hemolymph of both live and dead *I. sexdentatus* specimens collected from Isparta, Antalya, and Burdur provinces (Figure 2). Additionally, the gregarine pathogen detected in Burdur Province was co-detected with nematodes.

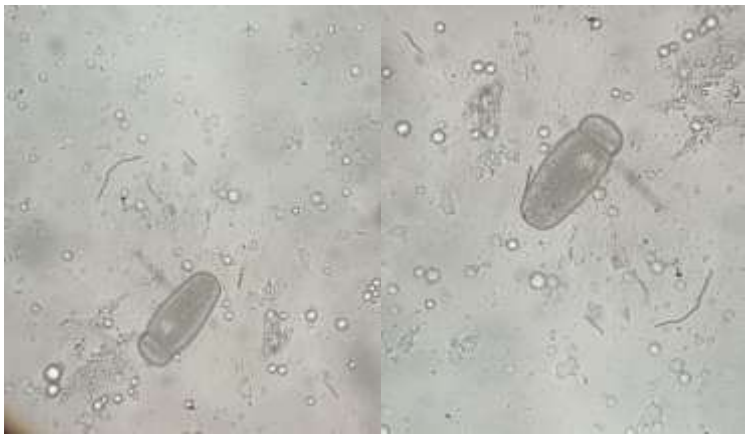

Figure 1. Light microscopy micrographs of gregarine in *Ips sexdentatus*

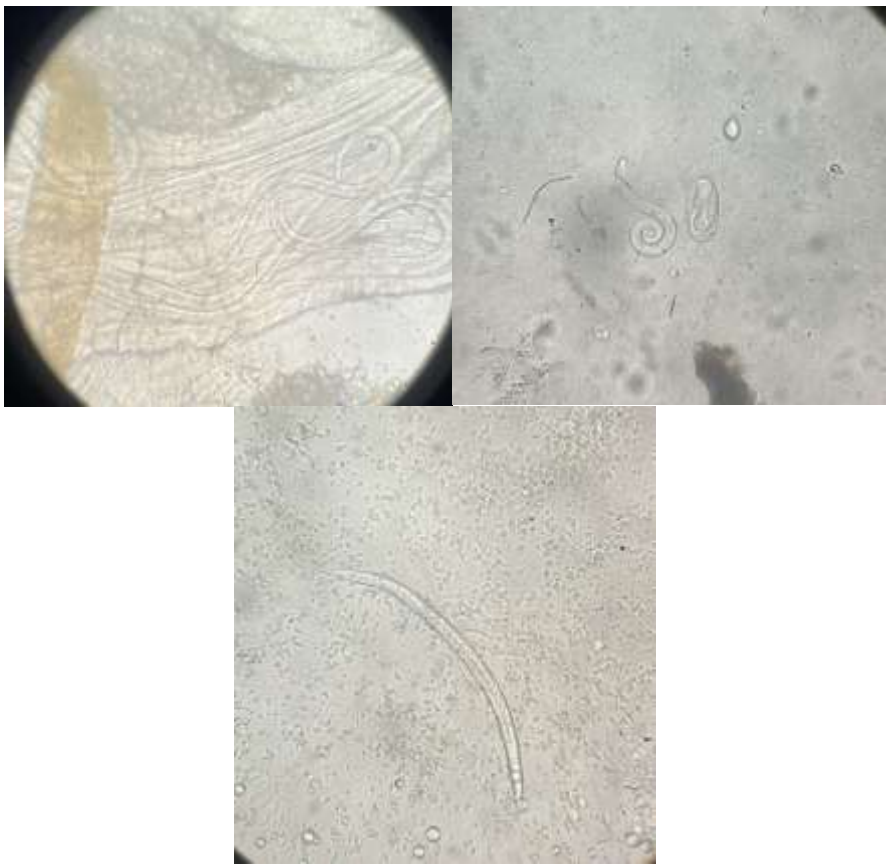

Figure 2. Light microscopy micrographs of nematode in *Ips sexdentatus*

The gregarine pathogen of *I. sexdentatus* was first reported in Türkiye by Yaman (2007). Additionally, the study reported the occasional co-occurrence of a gregarine and a nematode parasite within the same host. In the present study, the gregarine pathogen detected in Burdur Province was also detected in association with nematodes.

Eugregarines that parasitize the midgut epithelial cells cause the most pronounced pathological changes during the intracellular and intercellular developmental stages of their trophozoites (Lipa, 1967; Yaman, 2007). Tanada ve Kaya (1993). It has been reported that midgut damage caused by gregarine infection can be readily repaired through the proliferation and differentiation of cells within the regenerative crypts, and that the pathological effects of gregarines are generally limited. However, the effects of nematode parasites on *I. sexdentatus* have been previously investigated (Lieutier, 1980, 1982, 1984). These two natural enemies may simultaneously reduce the host's lifespan and reproductive potential (Yaman, 2007). In the present study, nematodes were detected in both live and dead *I. sexdentatus* specimens collected from Isparta, Antalya, and Burdur provinces, while both nematode and gregarine parasites were simultaneously detected in specimens collected from Burdur Province.

The infection rates of gregarines detected in *I. sexdentatus* were reported as 27.4% in Bulgaria (Takov et al., 2007), 16.7–45.5% in Austria (Wegensteiner et al., 2005), and 6% in Türkiye (Yaman, 2007). In the present study, the gregarine infection rate was detected exclusively in Burdur province, at 1.4% (Table 1).

Table 1. Gregarine and Nematode Infections in *Ips sexdentatus* Populations in the Western Mediterranean Region

	Alive sample	**Nematode**	**Gregarine**	**Total (%) (alive)**	**Dead sample**	**Nematode**	**Total (%) (dead)**	**Total (%)**
Antalya	15	3	-	20	5	1	20	20
Burdur	50	18	1	36 Nematode 2 Gregarine	20	6	30	34.3 Nematode 1.4 Gregarine
Isparta	20	7	-	35	10	2	20	30
Toplam	85	28	1	33 Nematode 1.2 Gregarine	35	9	26	31 Nematode 0.8 Gregarine

In the present study, nematode parasites were detected in the hemolymph of both live and dead *I. sexdentatus* specimens. The nematode infection rates were 34.3% in Burdur, 30% in Isparta, and 20% in Antalya. The mean infection rate was 31% (Table 1). Rühm (1956) recorded three nematode species, *Contortylenchus acuminata*, *Parasitaphelenchus acuminati* and *Parasitorhabditis acuminata* in the hemolymph of *Ips acuminatus.* However, nematodes associated with species of the genus *Ips* have been reported to belong to the orders Diplogasterida, Rhabditida, and Tylenchida (Grucmanova and Holusa 2013; Yaman et al.,

2016). In future stages of the study, the nematodes detected will be identified to the genus or species level.

CONCLUSIONS

The detected natural enemies may play an important role in the biological control of *Ips sexdentatus*, as they have the potential to affect its survival and reproductive capacity. Therefore, this preliminary study provides important baseline data for future studies on the natural enemies of *I. sexdentatus* in the Western Mediterranean Region of Türkiye.

ABSTRACK

The genus Ferula L. is distributed primarily in arid desert and mountainous regions. There are 48 species of this genus in Uzbekistan. Ferula species are medicinal, essential oil, fodder and honey plants. Many species of Ferula contain a large amount of resin and are used in soap making, dye production, as well as in the textile and paper industries. The article analyzes the distribution and reserves of some species of the genus based on the methodology of M.G. Pimenov, K.A. Pupikina and others. *F. varia* is distributed in mountainous and foothill areas, and *F. foetida* - in desert areas. The reserve of *F.varia* is 41,21±2,49 tons on an area of 1512 hectares, and the reserve of *F.foetida* is 6564,74±233,88 tons on an area of 14037 hectares.

Key words: ferula, fodder, food, honey, medicinal plants, field studies, herbarium materials, chemical composition.

INTRODUCTION

The genus *Ferula* L. belongs to the tribe Peucedaneae Dumort., subfamily Apioideae Drude, family Apiaceae Lindl. (Umbelliferae). At present, approximately 180–210 species of the genus Ferula are known. These are perennial herbaceous geophytic plants. The genus is distributed almost exclusively within the central regions of Eurasia, with the greatest species diversity concentrated in Central Asia and the adjacent territories of Iran and Afghanistan. In Central Asia, 106 species have been recorded, of which 48 species occur in Uzbekistan. Most species of Ferula inhabit arid climatic zones, particularly desert and mountainous regions [2,9,10,15].
The flora of Uzbekistan is highly diverse; however, in recent years, climate change and anthropogenic impacts have significantly influenced plant diversity and vegetation cover [2,5,11]. The majority of Ferula species, according to their seasonal developmental rhythm, belong to the group of ephemeroids - perennial plants characterized by a short annual period of growth and development and a prolonged dormancy period occurring during unfavorable seasons. The underground organ of Ferula species is represented by a thickened storage root. The genus includes both giant species, such as *F. gigantea* (2–2.5 m in height), and dwarf species, such as *F. nuda* (25–30 cm).
The name *Ferula* L., originally proposed by Tournefort (1700), was later adopted by Carl Linnaeus (1753), under which the genus entered scientific botanical nomenclature. During the eighteenth century, botanical knowledge of this genus accumulated gradually, as botanists described new species, sometimes not from natural habitats but from specimens cultivated in botanical gardens [3,10].
A significant contribution to the study of the genus Ferula L. was made by such researchers as E.Regel, B.A.Fedtschenko, B.M. Kozo-Polyansky, M.P.Petrov, L.A.Utkin, I.A.Zakharyants, I.T. Vasilchenko, E.P. Korovin, R.V.Kamelin, M.S. Baitenov, M.G. Pimenov, Kh.A.Nishanbaeva, S.Melibaev, as well as scientists from Iran, Afghanistan, Turkey, and China [3].

Species of the genus *Ferula* L. are considered promising essential oil-bearing, forage, food, melliferous, and medicinal plants. They represent an exceptionally rich source of biologically active compounds, including essential oils, coumarins, sesquiterpene lactones, esters, and other natural substances. Since ancient times, plants of this genus have attracted the attention of researchers from various scientific fields, including botany, chemistry, and pharmacology [4,12,17].

For nearly a thousand years, species of the genus *Ferula* have played an important role in folk and traditional medicine, particularly owing to their oleo-gum-resins such as asafoetida, sagapenum, galbanum, and others [1].

Many Ferula species containing considerable amounts of resin may be utilized in the soap-making, paint and varnish, textile, and paper industries. The fruits of Ferula species contain proteins and other nutritive substances and are used as nutrient-rich poultry feed, as well as in the treatment of haemonchosis in animals.

Species of *Ferula* may also be applied in other sectors of the national economy. Numerous species are regarded as valuable forage plants, especially in desert and semi-desert ecosystems, while some are also used as hay-producing plants. Important forage species include *F. foetida, F. varia*, *F. kuhistanica*, *F. karatavica, F. tenuisecta* and others.

Among the representatives of the genus *Ferula* L. occurring in Uzbekistan, particular attention is given to the mountain species *F. tenuisecta, F. kuhistanica, F. tadshikorum*, as well as the desert species *F. foetida* and *F. varia* (Fig.1-2). The latter species are also recognized as valuable forage plants and are used in the establishment of artificial agrophytocenoses aimed at enriching the fodder resources for livestock breeding in the South-Western Kyzylkum region.

It should be emphasized that numerous species of *Ferula* L. are widely used in agriculture as forage plants. They are readily consumed by cattle and sheep, with both the aerial parts and fruits serving as feed resources. The inclusion of fruits of *F. foetida* in cattle diets has been reported to increase milk productivity.

Plants of the genus *Ferula* L. occupy an important position in the formation of the vegetation cover of Uzbekistan. Species such as *F. kuhistanica*, *F. foetida*, *F. tenuisecta,* and others are regarded as important edificators with significant landscape-forming value [7,8,9].

Fig.2. General view of *F. foetida*

RESEARCH OBJECTIVES

The aim of the present study was to investigate the biological and ecological characteristics, as well as the growth and developmental patterns, of different *Ferula* species under various ecological conditions of their habitats. The study also focused on the development of scientific and practical foundations for the adaptive utilization of agroecological resources, including the optimization of floristic composition, assessment of biological diversity, and evaluation of the resource potential of natural vegetation.

MATERIALS AND METHODS

The following methods were employed during the research. Species identification and taxonomic verification were carried out using the multi-volume publication “Key to the Plants of Central Asia” (Vol. I–X, 1963–2016). The assessment of productivity and reserves of aboveground biomass was conducted according to the methods proposed by M.E. Pimenova et al. (1970), M.E. Pimenova (1971), M.G. Pimenov et al. (1976), and K.A. Pupykina et al. (2019) [10,16,17,18,19].The nomenclature of the studied species follows the publications “Key to the Plants of Central Asia” (1963–2016) and the database Plants of the World Online [5].

RESULTS AND DISCUSSION

As a result of field investigations conducted during 2020–2024 within the territory of Uzbekistan, extensive research surveys were carried out and herbarium specimens were collected. The collected material was subsequently processed and analyzed together with relevant literature sources. Among the representatives of the genus *Ferula* L. occurring in Uzbekistan, approximately 39 species are resin-containing, 39 are essential oil-bearing, 4 are starch-producing, 22 are melliferous, 13 are forage plants, 10 are edible, and 22 possess medicinal properties.

To determine the reserves of plant raw materials, experimental plots measuring 10 × 10 m were established. In the Navoi region, nine populations of *F. varia* located at elevations of 250–600 m above sea level were investigated, covering a total area of 1,512 ha (Fig. 3). It was determined that the average biological reserve within the investigated territories in 2024 (Table 1) amounted to an exploitable reserve of 41.21 ± 2.49 tons.

9.	Navoi-Zarafshan (193 km)	2	9	0,09±0,004
	Total:		**1512**	**41,21±2,49**

Fourteen surveyed habitats of *F. foetida* located at elevations of 140–500 m above sea level covered a total area of 14,037 ha. It was determined that the average biological reserve within the investigated territories in 2024 amounted to an exploitable raw material reserve of 6564.74 ± 233.88 tons (Table 2).

Table 2.

Area of Thickets and Reserves of Aboveground Biomass of *F. foetida* (Air-Dry Weight), **2024**

№	Key area	Category	Area of thickets, ha	Exploitable reserve of raw material, t
1.	Ayakagit-ma District	2	793	311,41±10,77
2.	Shingeldy Village District	1	1118	694,94±19,11
3..	Bolokarak Village District	1	391	160,11±6,12

10.	Along the Navoi–Zarafshan road (62 km)	1	1280	405,89±19,89
11.	Along the Navoi–Zarafshan road (92–94 km)	1	460	199,96±8,19
12.	Along the Navoi–Zarafshan road (195 km)	1	95	33,12±1,17
13.	Along the Navoi–Zarafshan road (207–221 km)	1	1820	630,63±29,52
14.	Along the Navoi–Uchkuduk road (262–263 km)	1	183	95,19±3,01
	Total:		**14037**	**6564,74±233,88**

CONCLUSIONS

Considering the above-mentioned data and based on the analysis of the obtained research results, the current status of the resources of *F. varia* and *F. foetida* in Uzbekistan has been determined. At present, the average area of resource significance in the Navoi region amounts to 15,549 ha. The analysis of long-term scientific data demonstrates that the exploitable raw material reserves of *F. varia* and *F. foetida* in Uzbekistan are undergoing a significant decline.

ABSTRACT

This study examines the herbarium specimens of the genus *Lythrum* L. preserved in the National Herbarium of Uzbekistan (TASH). All available specimens were inventoried, digitized, and analyzed using herbarium label data and standardized according to the *Plants of the World Online* (POWO) database. A total of 246 specimens representing seven identified species and one unidentified taxon were documented. *Lythrum salicaria* was the most represented species, while most collections were made between 1928 and 1938. The results highlight the scientific importance of the TASH herbarium for documenting the diversity, distribution, and collection history of *Lythrum* in Uzbekistan. Digitization of the collection improves data accessibility and supports future taxonomic, floristic, and biodiversity research.

Keywords: *Lythrum*; TASH; herbarium digitization; taxonomy; biodiversity; Uzbekistan.

INTRODUCTION

Herbarium collections constitute one of the most reliable sources for studying plant diversity, taxonomy, and historical changes in floristic composition. More than 381 million herbarium specimens are currently preserved in over 3,000 herbaria worldwide, reflecting centuries of botanical exploration and documentation. These collections provide valuable information on the spatial and temporal distribution of plant species and serve as an essential resource for biodiversity research.

In recent decades, the digitization of herbarium collections has become increasingly important for biological documentation, the development of virtual floras, and the creation of global biodiversity databases. Digital herbarium resources facilitate taxonomic, floristic, ecological, and biogeographical studies while ensuring broader accessibility of scientific data.

The National Herbarium of Uzbekistan (TASH), recognized among the world's largest herbarium collections, represents a significant repository of botanical diversity in Central Asia. The present study focuses on the digitization and analysis of herbarium specimens belonging to the genus *Lythrum* L. preserved in the TASH collection.

MATERIAL AND METHOD

The main objective of this study was to investigate the herbarium specimens of the genus *Lythrum* L. preserved in the National Herbarium of Uzbekistan (TASH). Specifically, the study aimed to inventory and digitize all available specimens, verify their taxonomic identity using the *Plants of the World Online* (POWO) database, and analyze their species composition, geographical distribution, collection history, and collector contributions. In addition, the study sought to evaluate the scientific value of the TASH *Lythrum* collection for taxonomic, floristic, and biodiversity research and to demonstrate the importance of herbarium digitization for improving data accessibility and supporting future botanical studies in Uzbekistan.

Species of the genus *Lythrum* L. in Central Asia have been investigated primarily within the framework of regional floristic studies. Important information on the distribution, ecology, and diagnostic characteristics of the genus was provided in the fundamental works *Flora Uzbekistana* and *Flora of the USSR*. Contemporary studies increasingly employ herbarium digitization, Geographic Information Systems (GIS), and molecular genetic approaches to investigate the genus comprehensively.

The genus *Lythrum* has attracted scientific attention for centuries. Its first formal taxonomic description was provided by Carl Linnaeus in *Species Plantarum*, where representatives of the genus were systematically characterized. This work established the classical taxonomic foundation of the genus.

Subsequent studies conducted by Augustin Pyramus de Candolle, George Bentham, and Joseph Dalton Hooker significantly advanced the systematics of the family Lythraceae and enabled a more detailed understanding of the morphological characteristics of *Lythrum*. During the twentieth century, the classification systems proposed by Arthur Cronquist and John Hutchinson contributed substantially to clarifying the evolutionary position of the genus within dicotyledonous plants.

More recently, molecular phylogenetic studies conducted by Shirley A. Graham and other researchers have utilized DNA markers to investigate relationships within Lythraceae. These studies confirmed the monophyly of *Lythrum* and provided new insights into its evolutionary relationships with closely related genera.

Regional floristic sources, including *Flora Uzbekistana* and *Flora of the USSR*, continue to serve as essential references for understanding the distribution, ecology, and taxonomy of *Lythrum* species in Central Asia. These works provide a valuable scientific foundation for ongoing and future studies of the genus.

The examination of herbarium collections enables researchers to assess intraspecific variability, evaluate the stability of diagnostic characters, identify geographical differentiation, and clarify taxonomic synonymy. Such investigations are particularly important for morphologically similar species, including *Lythrum salicaria*, *Lythrum virgatum*, and *Lythrum hyssopifolia*, which often present taxonomic challenges.

Herbarium specimens of *Lythrum* have been collected by numerous botanists over different historical periods. While the earliest investigations can be traced to the work of Carl Linnaeus, subsequent contributions by Shirley A. Graham, Rogers McVaugh, L. A. Kenoyer, P. D. Strausbaugh, and other researchers considerably expanded the available herbarium resources.

These collections remain invaluable for understanding morphological variation and defining taxonomic boundaries within the genus.The present study is based on herbarium materials preserved in the National Herbarium of Uzbekistan (TASH). All available specimens of *Lythrum* were inventoried, digitized, and analyzed. Label information, including collection locality, date of collection, collector name, and habitat characteristics, was entered into a digital database and subjected to comparative and statistical analyses. The resulting dataset provides a foundation for evaluating the floristic diversity, geographical distribution, and collection history of *Lythrum* species in Uzbekistan.

RESULTS AND DISCUSSION

Global distribution of the genus *Lythrum* L.

The genus *Lythrum* L. (Lythraceae) is widely distributed across temperate and subtropical regions of the Northern Hemisphere, with a primary center of diversity in Eurasia. Species of the genus are typically associated with wetland, riparian, and periodically flooded ecosystems, reflecting their strong hygrophilous ecological preference.

At the global scale, *Lythrum* species are native to Europe, Asia, North Africa, and North America, with several taxa exhibiting broad ecological amplitudes. The most widely distributed species, *Lythrum salicaria* L., is native to Eurasia but has become naturalized in North America and parts of Australia, where it is often considered an invasive species in wetland ecosystems.

In Europe, *Lythrum* is mainly represented by *L. salicaria*, *L. virgatum*, and *L. hyssopifolia*, which occupy riverbanks, marshes, and disturbed wet habitats. In Asia, particularly in Central and Western Asia, the genus shows higher taxonomic diversity, including several regionally restricted species adapted to arid and semi-arid wetland systems.

North American populations are largely represented by introduced *L. salicaria*, which has expanded rapidly due to its high reproductive capacity and tolerance to environmental variability. In contrast, African distribution of the genus is more limited and mainly confined to northern and Mediterranean-adjacent regions.

Phytogeographically, the genus *Lythrum* L. exhibits a predominantly Holarctic distribution pattern, extending across the Palaearctic and Nearctic regions. Its highest species richness is concentrated in Eurasia, particularly in Mediterranean, Euro-Siberian, and Irano-Turanian floristic regions. The wide distribution of L. salicaria and its successful establishment outside its native range demonstrate the genus' strong dispersal ability and ecological plasticity, which are key drivers of its expansion into secondary and anthropogenically disturbed habitats.

Overall, the genus demonstrates a Holarctic distribution pattern with a clear preference for humid and semi-aquatic habitats. This wide geographical range, combined with ecological plasticity, makes *Lythrum* an important model group for studying plant adaptation, invasion biology, and wetland ecosystem dynamics.

The study was based on herbarium specimens of the genus *Lythrum* L. preserved in the National Herbarium of Uzbekistan (TASH). Species nomenclature and synonymy were verified and standardized using data from the Plants of the World Online (POWO) database. The examination and inventory of the collection provided valuable information on the taxonomic composition, geographical distribution, ecological preferences, and collection history of *Lythrum* species occurring in Uzbekistan.

The analysis revealed that *Lythrum salicaria*, *L. virgatum*, and *L. hyssopifolia* are the most frequently represented species in the herbarium collection. The majority of specimens were collected from riverbanks, wetlands, irrigated agricultural areas, and other humid habitats. These findings are consistent with the ecological characteristics of the genus, which is predominantly composed of hygrophilous species adapted to moist and periodically flooded environments.

Comparative morphological examination of the herbarium specimens enabled the identification of reliable diagnostic characters distinguishing closely related species. Furthermore, the analysis provided insights into intraspecific morphological variability and contributed to a clearer understanding of taxonomic boundaries within the genus. Herbarium materials proved particularly valuable for evaluating variation in vegetative and reproductive traits across different geographical regions and ecological conditions.

The genus *Lythrum* is widely distributed throughout temperate and subtropical regions of the world and represents one of the ecologically significant groups of wetland plants. According to current taxonomic treatments, the genus comprises approximately 30–40 species worldwide, with its greatest diversity occurring in Europe, Asia, and North America. Several representatives of the genus are known from Central Asia, where they occupy a variety of wetland and riparian habitats.

In the flora of Uzbekistan, eight species have traditionally been reported: *Lythrum salicaria*, *L. tribracteatum*, *L. siliinoides*, *L. nanum*, *L. linifolium*, *L. intermedium*, *L. thymifolia*, and *L. hyssopifolia*. The inventory conducted in the TASH herbarium confirmed the presence of numerous specimens representing these taxa and demonstrated the scientific value of historical and contemporary collections for documenting the diversity of the genus in the region.

The herbarium collections preserved in TASH constitute an important source of information for studying species distribution patterns, habitat preferences, phenological characteristics, and morphological variation of *Lythrum* species. In addition, these collections provide a historical record of floristic investigations carried out in Uzbekistan and serve as an essential foundation for future taxonomic, ecological, conservation, and biogeographical studies.

The ongoing digitization of herbarium materials significantly enhances the accessibility and scientific utility of these collections. Digital databases facilitate data sharing, taxonomic verification, biodiversity assessments, and the integration of herbarium records into global biodiversity information systems. Therefore, the digitization and systematic analysis of *Lythrum* specimens preserved in TASH represent an important contribution to the documentation and conservation of Uzbekistan's plant diversity.

Species Composition of *Lythrum* in the TASH Herbarium Collection

Table 1. Species of the genus *Lythrum* L. preserved in the National Herbarium of Uzbekistan (TASH) and the number of herbarium specimens.

№	Species	Number of Herbarium Specimens
1	*Lythrum intermedium* Fisch. ex Colla First published in Herb. Pedem. 2: 399 (1834)	37
2	*Lythrum salicaria* L.	102

	First published in Sp. Pl.: 446 (1753)	
3	*Lythrum virgatum* Spreng. ex DC. First published in Prodr. 3: 82 (1828), not validly publ.	49
4	*Lythrum hyssopifolia* L. First published in Sp. Pl.: 447 (1753)	23
5	*Lythrum silenoides* Boiss. & Noë First published in P.E.Boissier, Diagn. Pl. Orient., ser. 2, 2: 55 (1856)	11
6	*Lythrum tribracteatum* Salzm. ex Spreng. First published in Syst. Veg., ed. 16. 4(2): 190 (1827)	23
7	*Lythrum nanum* Kar. & Kir. First published in Bull. Soc. Imp. Naturalistes Moscou 15: 422 (1842)	8
8	*Lythrum sp.*	1
Total Number of Specimens		**n=246**

As shown in Table 1, the herbarium collection of the genus *Lythrum* L. preserved in the National Herbarium of Uzbekistan (TASH) comprises a total of 246 specimens representing seven identified species and one unidentified taxon (*Lythrum* sp.). The collection demonstrates considerable taxonomic diversity and provides a valuable basis for floristic and systematic studies of the genus in Central Asia.

Among the recorded taxa, *Lythrum salicaria* L. is the most abundantly represented species, accounting for 102 specimens (41.5% of the total collection). The second most frequent species is *L. virgatum* Spreng. ex DC., represented by 49 specimens (19.9%), followed by *L. intermedium* Fisch. ex Colla with 37 specimens (15.0%). Together, these three species constitute 76.4% of all examined herbarium materials, indicating their prominent role in the flora of Uzbekistan and their broad ecological amplitude within wetland and riparian ecosystems.

Moderately represented taxa include *L. hyssopifolia* L. and *L. tribracteatum* Salzm. ex Spreng., each represented by 23 specimens (9.3%). In contrast, *L. silenoides* Boiss. & Noë and *L. nanum* Kar. & Kir. are comparatively rare within the collection, accounting for only 11 (4.5%) and 8 specimens (3.3%), respectively. A single specimen (0.4%) remained unidentified and was recorded as *Lythrum* sp.

The unequal distribution of specimen numbers among species may reflect differences in their geographical distribution, habitat availability, population abundance, and historical collecting intensity. The predominance of *L. salicaria* and *L. virgatum* is likely associated with their wider ecological tolerance and frequent occurrence in river valleys, marshlands, irrigation systems, and other humid habitats. Conversely, the relatively low representation of *L. silenoides* and *L. nanum* may indicate narrower ecological requirements, restricted distributions, or insufficient collecting efforts in their natural habitats.

Overall, the analyzed herbarium collection highlights the significant floristic diversity of *Lythrum* in Uzbekistan and emphasizes the scientific value of TASH as a repository of historical and contemporary botanical data. The documented specimens provide an important resource for future taxonomic revisions, biodiversity assessments, ecological investigations, and conservation-oriented studies of wetland flora in Central Asia.

Herbarium specimen records of the genus *Lythrum* L. preserved in the National Herbarium of Uzbekistan (TASH), collected between 1906 and 1982, are presented in Figure 1.

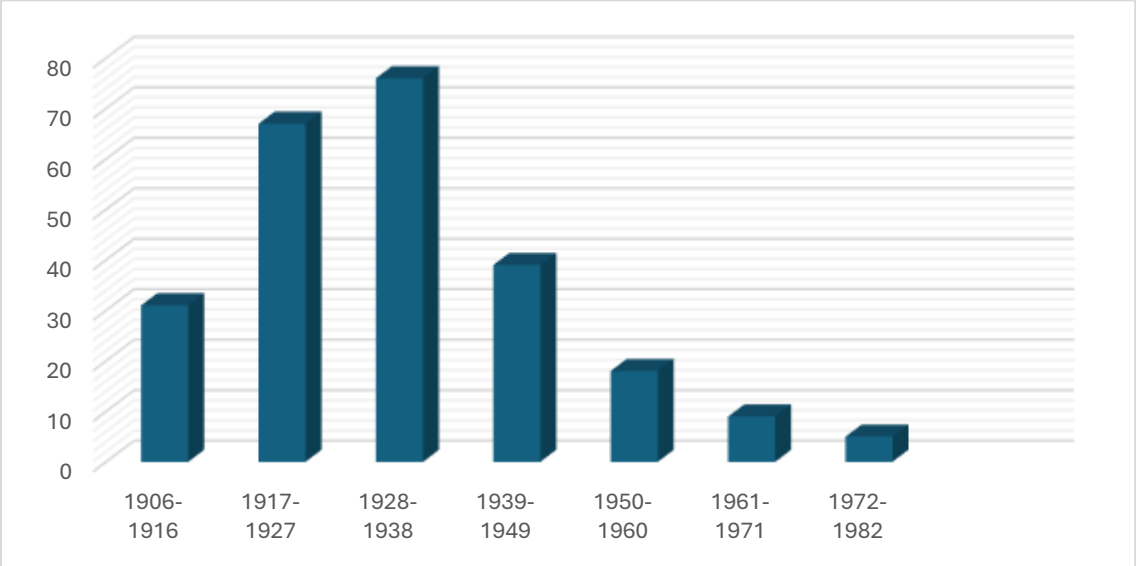

Figure 1. Temporal distribution of *Lythrum* L. herbarium specimens in the TASH collection.

The analysis shows that the majority of herbarium specimens were collected during the period 1928–1938, totaling 76 specimens, which accounts for more than 30.8% of the entire *Lythrum* collection currently preserved in TASH. This peak in collection activity is closely associated with the establishment of early botanical research initiatives in Central Asia, the development of major scientific publications on the regional flora, the foundation and strengthening of higher education institutions in the 1920s, and the intensification of systematic vegetation studies conducted by professional botanists during that period.

As illustrated in Figure 1, 29 specimens were collected during 1906–1916, while the number increased significantly to 67 specimens in the period 1917–1927. The highest level of collection activity was recorded in 1928–1938, with 76 specimens documented. Subsequently, a gradual decline in collection intensity is observed, with only 4 specimens recorded during 1972–1982. This decreasing trend in later decades may be attributed to a reduction in intensive floristic fieldwork and the incomplete integration of newly collected herbarium materials into the main TASH collection. In addition, changes in research priorities and documentation practices may have contributed to the reduced number of specimens formally registered within the herbarium database.

Overall, the temporal distribution of specimens reflects historical fluctuations in botanical exploration activity in Uzbekistan and highlights the importance of herbarium collections as archival resources for reconstructing the history of floristic research in the region.

Table 2. Major collectors of *Lythrum* L. herbarium specimens in the TASH collection

№	Collectors	Years	Number of Herbarium Specimens
1	Abolin R.I.	1917-1926	21
2	Kudryashev S.N.	1930-1939	19
3	Popov M.G.	1922-1941	18
4	Saxobiddinov S.X	1947-1949	15
5	Chevrenidi S.X.	1954-1955	14
6	Gomoliskiy P.	1926-1931	11

15	Muzafarov M.	1944-1946	4
Overall			**150**

Figure 2. Herbarium specimens of selected *Lythrum* L. species from Central Asia.

The analysis of herbarium specimens of the genus *Lythrum* L. preserved in the National Herbarium of Uzbekistan (TASH) indicates that the collection was formed through the

contributions of a relatively limited number of key botanists (Table 2). In total, 150 specimens were attributed to 15 principal collectors active between 1917 and 1956. The most prominent contributor was R. I. Abolin, who collected 21 specimens during 1917–1926. He was followed by S. N. Kudryashev with 19 specimens (1930–1939) and M. G. Popov with 18 specimens (1922–1941). Together, these three collectors account for a significant proportion of the total material, highlighting their major role in botanical exploration and floristic documentation of Central Asia. Moderate levels of contribution were recorded for S. X. Saxobiddinov (15 specimens), S. X. Chevrenidi (14 specimens), P. Gomoliskiy (11 specimens), A. I. Granitov (10 specimens), and V. T. Paziy (9 specimens). These researchers played an important role in expanding the geographical and taxonomic coverage of the herbarium collection during the early–mid twentieth century.

Lower individual contributions were recorded for Ye. Ye. Korotkova (7 specimens), B. Mironov (6 specimens), I. Pyataeva (6 specimens), V. P. Drobov (5 specimens), A. Usmanov (5 specimens), T. Gnezdillo (5 specimens), and M. Muzafarov (4 specimens). Although their contributions are relatively small in number, they collectively add important historical and taxonomic value to the herbarium dataset.

It should be noted that the year range “19035–1936” for B. Mironov appears to be a typographical error and is likely intended as 1905–1936 or a similar corrected interval.

Overall, the distribution of collector contributions reflects historical patterns of botanical exploration in Uzbekistan, with a concentration of intensive fieldwork in the first half of the twentieth century. These collections remain crucial for reconstructing floristic diversity, understanding species distribution patterns, and documenting the history of botanical research in the region.

During the preparation of the catalog of *Lythrum* L. specimens preserved in the National Herbarium of Uzbekistan (TASH), particular attention was given to the composition of collectors. For this purpose, a comprehensive list of all botanists who contributed to the collection of *Lythrum* specimens during the period 1917–1946 was compiled. The resulting dataset includes more than 55 researchers; however, a clear dominance of classical botanists who conducted floristic investigations in Central Asia was observed in terms of specimen numbers (Table 2).

Among them, A. D. Pyatayeva, M. Nabiyev, S. X. Chevrenidi, S. N. Kudryashev, A. Ya. Butkov, E. M. Demurina, M. G. Popov, E. E. Korotkova, P. Gomolitskiy, V. P. Drobov, O. N. Bondarenko, and V. P. Bochantsev made particularly significant contributions to the formation of the herbarium collection (Table 2).

A detailed analysis of the dataset revealed that 15 collectors can be considered principal contributors to the *Lythrum* collection. Among them, R. I. Abolin was the leading collector, with 21 herbarium specimens recorded. Other major contributors include S. N. Kudryashev, M. G. Popov, S. X. Saxobiddinov, and S. X. Chevrenidi, all of whom significantly contributed to the documentation and preservation of *Lythrum* diversity in Uzbekistan.

In addition to these primary contributors, numerous other botanists played an important supporting role in the accumulation of herbarium material. These include A. F. Ioffe, B. S. Zakrijevskiy, V. Pitya, A. Abdullayev, V. Yarobov, I. Aveden, V. Pasubov, N. Nikiforova, V. Kernev, M. Igrevskaya, L. Korotkova, I. Raykoza, and P. Krassovskiy, among others. Although

their individual contributions were relatively limited, collectively they significantly enriched the herbarium database and contributed to its historical depth.

Additional herbarium records from Samarkand State University herbarium

The herbarium collection of Samarkand State University (SamSU) includes three specimens of the genus *Lythrum* L. Among them, two specimens were identified as *Lythrum salicaria* L., while one specimen remained unidentified at the species level and was recorded as *Lythrum* sp. All identified specimens (*L. salicaria*) were collected from the Chupan-ota locality in the Samarkand region. The specimens were gathered by M. G. Popov, a prominent botanist who contributed significantly to floristic studies in Central Asia.

Although the number of specimens in the SamSU herbarium is limited, these records provide additional evidence for the occurrence of *L. salicaria* in the Samarkand region and contribute to the broader understanding of its distribution within Uzbekistan. The presence of an unidentified specimen also indicates the need for further taxonomic revision and detailed morphological or molecular analysis of the local *Lythrum* populations. Although limited in number, these specimens are significant for validating historical occurrences of Lythrum salicaria in the Samarkand region and may serve as baseline material for future molecular and taxonomic study.

CONCLUSIONS

The present study provides a comprehensive analysis of *Lythrum* L. specimens preserved in the National Herbarium of Uzbekistan (TASH). The results confirm that herbarium collections represent a crucial scientific resource for studying the flora of Uzbekistan. The collected materials allow for detailed analysis of species distribution, collection localities, temporal patterns, and collector contributions.

The majority of specimens were collected during the peak period of floristic exploration (1928–1938), which corresponds to intensive botanical inventory activities in Central Asia. In contrast, a noticeable decline in specimen collection during later decades, particularly 1972–1982, suggests a reduction in targeted taxonomic studies on this genus.

A similar trend is observed in collector activity, where classical botanists played a dominant role, while recent decades show limited involvement of local researchers in *Lythrum*-focused studies. The development of such catalogues and their analytical interpretation is essential for identifying poorly studied regions and taxonomic groups, as well as for improving research planning within the National Herbarium.

Overall, these findings highlight the importance of herbarium-based studies not only for biodiversity documentation but also for guiding future systematic research. Strengthening such investigations will support large-scale floristic studies and contribute to capacity building among emerging botanists in Uzbekistan.

ASSESSMENT OF ORGANIC POLLUTION AND BDI TREND IN THE ERZEN RIVER, ALBANIA (2014–2024)

ABSTRACT

The rapid increase of economic activities including agriculture, industrial development, uncontrolled gravel abstraction and unregulated urban wastewater discharges and lack of adequate infrastructure and management, has significantly increased pressure on rivers quality in Albania, thereby contributing to enhanced pollution levels. Land use particularly nearby rivers for different industrial activities and agriculture represent one of major sources of many organic and inorganic pollutants in surface and groundwater. Meanwhile untreated municipal and industrial wastewater can significantly affect the ecological functioning of river ecosystems. This study aims to assess the long-term variation of organic pollution in the Erzeni River during 2014–2024 using the biodegradability index (BDI), calculated as the ratio of five-day biochemical oxygen demand to chemical oxygen demand (BOD_5/COD). Monitoring data covering the study period, reported in the annual environmental status reports published by the Albanian National Environmental Agency (NEA), together with the pressure analysis presented in the official Erzen River Basin Management Plan, were analyzed for two representative official monitoring sites. The results indicate persistent presence of organic pollution, particularly in areas affected by urban, industrial, and agricultural pressures. Individual BOD_5 concentrations range from 5 to 20 mg/L, with no clearly distinguishable seasonal pattern. BDI values showed relatively limited interannual variation and generally ranged between 0.5 and 0.6. The highest individual BDI (0.89) was observed in 2021 and the lowest (0.38) in October 2014. The predominance of BDI values above 0.5 indicates that a substantial proportion of the organic matter present in the river was readily biodegradable. However, the continued occurrence of measurable BOD_5 and COD concentrations throughout the studied period suggests persistent organic inputs. The EU WFD promotes the integrated management of water resources to support environmentally sustainable development and reduce pressures associated with excessive water abstraction and pollution. Albania has transposed such requirements in the national legislation and continuous to improve secondary legislation to better manage pollution control, environmental permitting, and water quality monitoring. Nevertheless, effective implementation of these requirements depends on robust monitoring systems, well-equipped laboratories, and clear data-sharing mechanisms. At present, these prerequisites are only partially established and operational. An integrated management approach is therefore required to (i) reduce organic and nutrient loads originating from urban wastewater discharges and agricultural activities, (ii) identify and control of heavy metal sources (urban/industrial sources), including the role of sediments in their accumulation and potential remobilization; and (iii) improve monitoring programmes through the systematic inclusion of WFD priority substances, thereby enabling a comprehensive and WFD-compliant water quality assessment of the Erzeni River.

Keywords: River pollution, BOD/COD ratio, freshwater quality assessment.

INTRODUCTION

EU Water Framework Directive representing the fundamental legal act in shaping the water management sector since 2000 across the European countries, foresees an analysis of anthropogenic impact, as a cyclical process, in the context of the river basin management planning (1). In Albania, this approach is embedded in the national legislation therefore chemical, and not only, pollution should be frequently measured and adequately controlled. This study aims to assess the long-term variation of organic pollution in the Erzen river using the biodegradability index (BDI), calculated as the ratio of BOD/COD, where both parameters represent routine analyses of the water quality and are significantly important in controlling the total content of pollution and the management of water environment (2).
The BDI must be smaller or equal to 1.0; the higher the value, the more serious the pollution of organic matter and the higher the level of biodegradability (3), (4); (5). Rivers are often considered a sink and source of many pollutants (6) and especially if there are discharges of industrial and/or urban wastewaters induced in the water system, they show high levels of BOD_5 and COD. High presence of organic matter in water leads to a decrease of dissolved oxygen due to consumption.

Official datasets for BOD_5 and COD concentrations during 2014–2024, as published by responsible authorities in regular reports, were analyzed in two NEA representative official monitoring sites. Albania has transposed EU WFD requirements in the main but its effective implementation however depends on robust monitoring systems, well-equipped laboratories and clear data-sharing/reporting mechanisms to ensure a better pollution control management, environmental permitting tools and adequate water quality monitoring. At present, these prerequisites are only partially established.

MATERIAL AND METHOD

Two NEA representative official monitoring sites were selected for this study (Ura Beshirit and Ura Sallmonaj) based on the analysis of pressures presented in the official river basin management plan including agriculture, various industrial activities and gravel mining upstream. Data series between 2014 – 2024, as officially reported by NEA through yearly environmental status reports (7) and the official river basin management plan for Erzen river basin (8) were analyzed and selected data have been plotted to identify BDI trend and potentially asses changes in pollution patters during these years.

Yearly individual mean data of the two selected monitoring sites were analyzed to observe any differences on BDI and be able to judge over the level of pollution. According to official reports, water samples have been taken on irregular seasonal basis over the years, between two to four times per year. All BOD > COD values were excluded to ensure credibility of the results and respective BDI ratio is not considered in the trend analysis.

RESULTS AND DISCUSSION

Individual BOD_5 values range from 5 to 20 mg/L, with no clearly distinguishable seasonal pattern. BDI values showed relatively limited interannual variation and generally ranged between 0.5 and 0.6. The highest individual BDI (0.89) was observed in 2021 and the lowest (0.38) in October 2014. The predominance of BDI values above 0.5 (Table 1) indicates that a substantial proportion of the organic matter present in the river was readily biodegradable.

The BOD and COD fluctuates at both monitoring sites through the years and also on seasonal basis. (9) argues that this might be due to organic matter which comes from anthropogenic activities active in the study area (e,g plant extracts, solid wastes dumping, sewage discharges, and agricultural run-off. When BDI values range between 0.3 – 0.6 it confirms that the pollutants in waters belong to slow degradable category and >0.6 they are biodegradable (10). Results indicate persistent presence of organic pollution, particularly in areas affected by urban, industrial, and agricultural pressures and the continued occurrence of measurable BOD_5 and COD concentrations throughout the studied period suggests persistent organic inputs. BDI mean value, combining both monitoring sites increases through the years, particularly visible from 2014 to 2016 (
Figure 1).
In a snapshot overview the trend is stable after 2022 showing lower values compared to an increased one before 2020. Nevertheless, the overall trend is near to 0.5 is mostly associated with consistent discharges of urban waters and agricultural activities in the areas nearby the river area.

Few cases were observed where the individual concentrations of BOD_5 and COD were excluded from the BDI analysis due to information inconsistency.

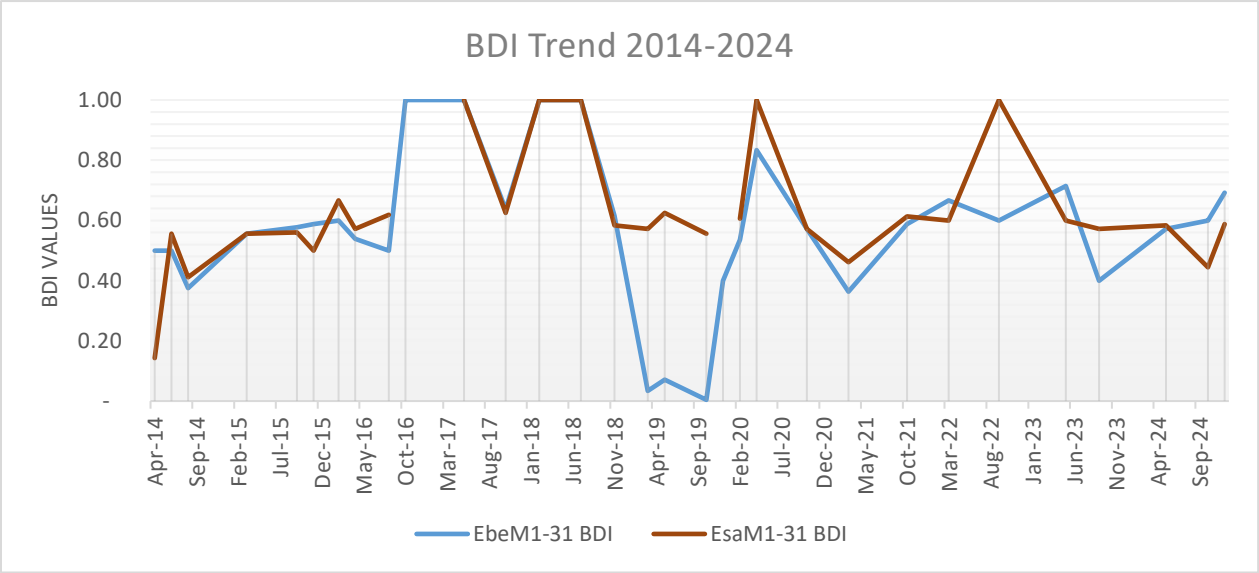

Figure 1 BDI trend concentration during 2014-2024

CONCLUSIONS

The predominance of BDI values above 0.5 indicates that a substantial proportion of the organic matter present in the river was readily biodegradable. Continued occurrence of measurable BOD_5 and COD concentrations throughout the studied period suggests persistent organic inputs. Higher BDI values in longer periods of time observed in the second monitoring site. An integrated management approach is therefore required to reduce organic and nutrient loads originating from urban wastewater discharges and agricultural activities, to identify and control of heavy metal sources (urban/industrial sources), including the role of sediments in their accumulation and potential remobilization, and to improve monitoring programmes through the systematic inclusion of WFD priority substances.

ABSTRACT

This study was conducted to determine the effects of planting density and stem number on yield and pomological characteristics of the local hazelnut (*Corylus avellana* L.) cultivar 'Ata-baba' under the ecological conditions of Azerbaijan during 2023-2025. The experiment was established at the Zagatala Experimental Station using two planting schemes (6×7 m and 7×3 m) and different stem number treatments (7, 15, and 20 stems for 6×7 m; 4, 8, and 12 stems for 7×3 m). Growth parameters, leaf area, stem thickening, fruit weight, kernel ratio, kernel weight, nut number per husk, and yield per shrub and per hectare were evaluated. The results showed that leaf area generally decreased with increasing stem number among the regulated treatments, and was lowest of all in the untreated control. Stem thickening was generally highest in south-facing stems among the managed treatments, though this pattern did not hold in the untreated control. In the 7×3 m scheme, the highest yield per shrub was obtained from the 12-stem treatment (5.389 kg), whereas in the 6×7 m scheme the 15-stem treatment produced the highest yield (9.981 kg); yield in the untreated control remained lower than in any managed treatment in both schemes (3.485 kg and 5.861 kg, respectively, in 2024). Kernel ratio was highest at moderate stem densities, while fruit weight was highest at low-to-moderate densities depending on planting scheme; both were substantially higher in all managed treatments than in the untreated control, whose kernel ratio remained around 37-38% regardless of scheme or year. Yield per hectare increased with higher planting density despite slight reductions in individual nut traits. However, yield in 2025 was lower than in 2024, likely due to climatic factors and increased damage from the brown marmorated stink bug. Overall, the findings indicate that optimal stem number depends on planting density, and moderate stem densities (12 stems in 7×3 m and 15 stems in 6×7 m) provide the best balance between vegetative growth, yield, and nut quality for the 'Ata-baba' cultivar in Azerbaijan.

Keywords: *Corylus avellana* L., 'Ata-baba', planting density, stem number, hazelnut yield, Azerbaijan, Brown Marmorated Stink Bug.

INTRODUCTION

European hazelnut (*Corylus avellana* L.), a species belonging to the *Betulaceae* family, is a perennial shrub that has been cultivated in Azerbaijan since ancient times. Azerbaijan is among the leading hazelnut-producing countries in the world, with the main production concentrated in the northern regions of the country. Most of the hazelnut production in the country is carried out by small-scale farms, where the plants are cultivated in a multi-stem shrub form similar to the "ocak" system in Turkiye (Islam, 2018; Ahmadov, 2025). Smallholder farmers account for

60-70% of the country's total annual hazelnut output, and Zagatala together with the surrounding northwestern districts supplies the majority of national production (FAO, 2023).

Naturally reaching heights of 3-10 meters and capable of producing numerous suckers (Mehlenbacher, 1991), the European hazelnut in Azerbaijan has traditionally been propagated by separating root suckers from the parent plant. Due to its prolific sucker production, it is typically cultivated with a varying number of stems per plant. Because suckering aptitude varies among cultivars and continues throughout the growing season, regular removal of unwanted suckers is considered essential for keeping stem number and canopy density under control in multi-stemmed hazelnut orchards (Pacchiarelli et al., 2022).

In other countries, different training systems and corresponding planting schemes are applied for hazelnut cultivation (Beyhan, 2007). High planting density increases competition among plants for resources such as light, water, and nutrients, which may reduce yield and nut quality. However, with proper management, it is possible to maintain high yield and nut quality even at higher planting densities (Portarena et al., 2024).

Traditionally, hazelnut is grown in a multi-stem bush form in Turkiye, Italy, and Spain. When mechanical harvesting is intended, trees are trained on a single trunk. Some newly established young orchards in Oregon State, certain European countries, and other hazelnut-producing nations are being cultivated using the Vase training system (Baldwin, 2015). This shift away from the traditional multi-stemmed shrub form is largely driven by the goal of improving light penetration into the canopy and enabling mechanized orchard operations, even though multi-stemmed systems remain widespread in the Mediterranean basin and allow gradual plant renewal through sucker selection (Pacchiarelli et al., 2026).

Although numerous studies have been conducted on hazelnut planting density and training systems (Bignami et al., 2004; Beyhan, 2007; Ellena et al., 2012; Sokol, 2017; Balta et al., 2024; Portarena et al., 2024; Pacchiarelli et al., 2025), there appears to be a lack of sufficient research in this area within our country.

The main objective of the study is to investigate the yields of the Ata-baba hazelnut cultivar, which is the main cultivar grown in Azerbaijan, under different planting schemes and with different stem numbers during the 2023-2025 period, and to determine the most suitable number of stems for each planting scheme. During the research, additional vegetative and fruit parameters were also measured.

MATERIAL AND METHOD

The research was conducted during 2023-2025 in a hazelnut orchard located at the Zagatala Experimental Station of the Research Institute of Horticulture and Tea Growing. As the experimental material, plants of the local hazelnut cultivar *Ata-baba* were used under two different planting schemes (6×7 m and 7×3 m). For each planting scheme, different stem number treatments were determined. For the 6×7 m planting scheme, stem number treatments of 7, 15, and 20 stems were applied, while for the 7×3 m planting scheme, 4, 8, and 12 stems were selected. In addition, one untreated control variant for each scheme was included in the study. The control variant consisted of shrubs within the same planting scheme in which the number of stems had not been regulated and no systematic agrotechnical management practices had been applied. For each stem number treatment, 4 shrubs were chosen (8 shrubs in total with two replications).

In November 2023, the selected plants were pruned according to the predetermined stem numbers. During pruning, excess stems, including suckers, were removed, and only the specified number of stems was retained. Suckers were pruned twice a year, in November and July.

To determine annual stem thickening, stem circumference measurements were taken at the beginning and end of the vegetation period. Circumference was measured at 1 m above ground level for four stems located in four different directions using a flexible measuring tape (cm), and the measurement points were marked with oil-based paint (Figure 1). The same point was re-measured at the end of the vegetation period (after leaf fall and before pruning). Annual lateral thickening (ΔC) was calculated as follows:

$$\Delta C = C_2 - C_1 \quad (1)$$

Where: C_1 is the circumference measured at the beginning of the vegetation period (cm);

C_2 is the circumference measured at the end of the vegetation period (cm).

Leaf area was calculated using the leaf area estimation formula proposed by Cristofori et al. (2007):

$$LA = 2.59 + 0.74LW \quad (2)$$

Where: LA is leaf area (cm^2);

L is leaf length;

W is leaf width.

The first harvest was carried out on 4 September 2024 and on 5 September 2025. Fruits were collected manually from the ground by shaking the stems and were separated into husked and dehusked nuts, placed into separate bags according to stem number and planting scheme. On the same day, nuts were dehusked and weighed using an electronic balance with a sensitivity of 0.001 kg, and yields were recorded for each treatment. Harvesting was repeated five times at four-day intervals.

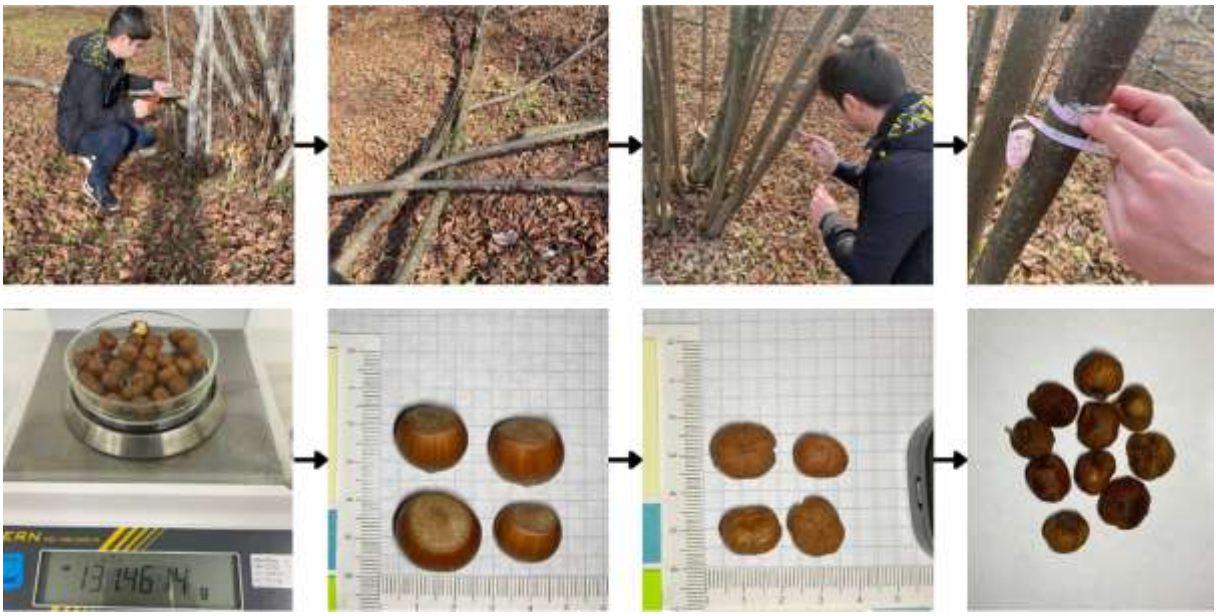

Figure 1. Sequential steps of the experimental workflow for field data collection and morphological characterization of *Corylus avellana* L. cv. Ata-baba

After the final harvest and weighing, yield per individual shrub was determined, and mean yield was calculated for each treatment.

In both years, the number of nuts per husk, nut and kernel weight, kernel percentage, and the percentages of empty and rotten nuts were determined, allowing the calculation of the percentage of healthy nuts. In recent years, the intensity of the brown marmorated stink bug has increased in the country, resulting in higher levels of damaged and rotten nuts.

Nut and kernel weights were determined by weighing 100 nuts using a balance with 0.01 g sensitivity. Kernel yield was calculated as the ratio of kernel weight to nut weight.

Data were analyzed separately for each planting scheme using one-way Analysis of Variance (ANOVA), with stem number (including the untreated control) as the factor. Where ANOVA indicated significant differences ($p<0.05$), Duncan's Multiple Range Test was performed to separate the means and identify the most productive stem densities. The analyses were conducted using SPSS Statistics (IBM Corp., Version 26.0, Armonk, NY, USA).

RESULTS AND DISCUSSION

Leaf area varied depending on the number of stems and the planting scheme, and in general it was higher at lower stem numbers. In the 7×3 planting scheme, the highest leaf area was recorded in the treatment with 4 stems (121.5 cm²). This was followed by the 12-stem (86.8 cm²) and 8-stem (85.2 cm²) treatments, which were close to each other. In the 6×7 planting scheme, the highest leaf area was observed in the 7-stem treatment (108.4 cm²), followed by the 15-stem treatment (92.6 cm²) and the 20-stem treatment (84.5 cm²). The untreated control recorded the lowest leaf area of all variants in both planting schemes, at 75±6.27 cm² in the 7×3 m scheme and 80.6±9.13 cm² in the 6×7 m scheme. This pattern is consistent with findings that denser hazelnut canopies intercept less photosynthetically active radiation at the lower and inner canopy levels, which limits leaf expansion and reduces fruit number and weight compared with more open canopy structures (Gutiérrez-Gamboa et al., 2025).

Table 1. Average Leaf Area (cm^2) of Hazelnut Cultivar 'Ata-baba' Under 7×3 m and 6×7 m Planting Schemes with Different Stem Numbers

Average leaf area (cm²) under the 7×3 planting scheme			
4 stems	**8 stems**	**12 stems**	**Control**
121.5±12.06	85.2±5.30	86.8±6.88	75±6.27
Average leaf area (cm²) under the 6×7 planting scheme			
7 stems	**15 stems**	**20 stems**	**Control**
108.4±8.32	92.6±5.08	84.5±4.71	80.6±9.13

Differences were observed in stem thickening depending on stem orientation. In all treatments of the 6×7 planting scheme, except for the 20-stem treatment and control, the greatest thickening was observed in south-facing stems, while the least thickening generally occurred in north-facing stems. The second highest thickening was recorded in east-facing stems, followed by west-facing stems. In the 7×3 planting scheme, the greatest stem thickening was observed in the south-facing stems of the 4-stem treatment (2.98 cm), whereas among the stem-number treatments the lowest thickening was recorded in the north-facing stems of the same treatment (1.04 cm); the untreated control showed even less thickening overall, with the smallest change recorded in the east-facing stems (0.03 cm). In the 6×7 planting scheme, the

highest thickening was observed in the south-facing stems of the 15-stem treatment (3.14 cm), while among the stem-number treatments the lowest thickening was recorded in the east-facing stems of the 7-stem treatment (0.72 cm), the control again showed minimal thickening in all directions, with the smallest change recorded in the east-facing stems (0.03 cm).

Control	12.88	13.26	0.38	18.22	18.31	0.09	16.18	16.21	0.03	17.44	17.5	0.06

Compared to 2024, fruit weight was higher in all treatments in 2025. Under the 7×3 planting scheme, the highest mean fruit weight was recorded in the 4-stem treatment (1.84 g), whereas under the 6×7 planting scheme it was observed in the 15-stem treatment (2.15 g). The lowest fruit weight in the 7×3 scheme was found in the 12-stem treatment in 2024 (1.64 g); in 2025, however, the untreated control recorded the lowest fruit weight of all variants (1.68 g), just below the 12-stem treatment (1.71 g). Under the 6×7 planting scheme, the lowest fruit weight in both years was consistently found in the 20-stem treatment (1.86-1.91 g), remaining lower than the control (1.97-2.01 g).

An increase in kernel percentage was also observed in the second year compared with the first year. The highest kernel percentage was recorded in the 12-stem treatment under the 7×3 planting scheme (54.88%) and in the 15-stem treatment under the 6×7 planting scheme (56.86%). Among the stem-number treatments, the lowest kernel percentage was observed in the 8-stem treatment under the 7×3 planting scheme (46.97-52.94% across years) and in the 20-stem treatment under the 6×7 planting scheme (49.05-49.16% across years). The untreated

control, however, recorded by far the lowest kernel percentage overall: only 38.03-38.08% in the 7×3 scheme and 37.06-38.04% in the 6×7 scheme, roughly 9-19 percentage points below every managed treatment.

Under the 7×3 planting scheme, the highest kernel weight was recorded in the 4-stem treatment (0.999 g), while the lowest among the stem-number treatments was in the 12-stem treatment (0.948 g). The untreated control recorded the lowest kernel weight overall (0.641-0.645 g). Under the 6×7 planting scheme, the highest kernel weight was observed in the 15-stem treatment (1.242 g), and the lowest among the treatments in the 20-stem treatment (0.956 g), with the control again recording the lowest value overall (0.738-0.761 g).

Yield per hectare (kg)	1564±140	2375±482	2311±229	1395±326	1434±316	2159±189	1969±383	1195±320

The number of stems per plant did not demonstrate a consistent or significant linear correlation with the number of nuts per husk across the experimental periods. In the 7×3 planting scheme, a marginal downward trend was observed as stem density increased (e.g., from 2.2 to 2.02 in 2024). However, this pattern was not replicated in the 6×7 scheme, which exhibited a non-linear relationship where the mid-range density (15 stems) produced the fewest nuts per husk (1.98 in 2024 and 1.92 in 2025) before increasing again at 20 stems.

In a related study, Bak and Karadeniz (2021) investigated different stem numbers across two hazelnut cultivars and reported that fruit and kernel weights typically decrease as the number of stems increases. While our findings in the 7×3 planting scheme align with this observation, the 6×7 scheme showed a distinct deviation from this trend. Furthermore, while Bak and Karadeniz (2021) noted that the number of nuts per husk increases with higher stem counts, our results indicated a more stable or non-linear response, suggesting that planting density and layout may influence these parameters differently.

Differences were observed in yield indicators among planting schemes and stem numbers. Overall, yield values in 2025 were lower compared to 2024. This is thought to be related both to climatic conditions and to the increasing spread of the Brown Marmorated Stink Bug, which has become a serious problem in Azerbaijan in recent years. Year-to-year climatic variability, particularly temperature fluctuations during the growing season, has similarly been identified as a significant driver of interannual hazelnut yield variation in other production regions (An et al., 2020; Ahmadov, 2024).

Under the 7×3 planting scheme, the highest yield was recorded in the 12-stem variant (5.389 kg), followed by the 8-stem (4.663 kg) and 4-stem (3.537 kg) variants; yield in the untreated control was lower still (3.485 kg). In the 6×7 planting scheme, the highest yield was observed in the 15-stem variant (9.981 kg), followed by the 20-stem (9.71 kg) and 7-stem (6.571 kg) variants, with the untreated control again yielding the least (5.861 kg).

According to the 7×3 planting scheme, yield per hectare for the 4-stem variant in 2024 and 2025 was 1684±232 kg and 1591±240 kg, respectively; for the 8-stem variant, 2220±276 kg and 1947±330 kg; for the 12-stem variant, 2565±259 kg and 2176±318 kg; and for the control 1659±444 kg and 1559±412 kg respectively. In the 6×7 planting scheme, yield per hectare was 1564±140 kg and 1434±316 kg for the 7-stem variant, 2375±482 kg and 2159±189 kg for the 15-stem variant, 2311±229 kg and 1969±383 kg for the 20-stem variant and 1395±326 kg and 1195±320 kg for the control in 2024 and 2025, respectively.

Portarena et al. (2024) report that although yield efficiency is highest under medium-density planting, the highest yield per hectare is observed under high-density planting. Bignami et al. (2004) also state that high plant density is associated with higher productivity. Erdoğdu (2025) notes that productivity in the early years is higher in denser plantings, while in later years it is possible to maintain yield stability through different horticultural management methods. Balta et al. (2024) also report a positive correlation between plant density and yield per hectare.

It should be noted that yield was expressed as fresh weight, since it was measured immediately after harvest.

Table 4. Percentage of Normal and Abnormal Fruits of Ata-baba Cultivar (2024-2025)

Variant	**Normal (%)**	**Semi-damaged (%)**	**Empty (%)**	**Rotten (%)**	**Twin (%)**
2024					
Ata-baba (6×7)	88.52	4.09	3.51	3.22	0.64
Ata-baba (7×3)	83.07	2.88	11.18	2.56	0.32
2025					
Ata-baba (6×7)	79.64	7.58	4.39	7.58	0.80
Ata-baba (7×3)	78.62	4.61	13.28	3.22	0.27

Özpınar and Yıldırım (2025) note that the damage rate of the brown marmorated stink bug is closely related to its population density. They report that the damage rate ranged between 31% and 53% during 2023-2024 in Türkiye. This pest is now recognized as a major global threat to tree fruit and nut crops, and rising temperatures associated with climate change are expected to further favor its spread and the number of generations it completes per year (Pajač Beus et al., 2024). In hazelnut orchards specifically, direct feeding on developing kernels by the brown marmorated stink bug has been shown to cause substantial economic losses, underlining the need for integrated monitoring and management programs as the pest becomes established in new production regions such as Azerbaijan (Walton et al., 2022).

CONCLUSIONS

Planting density and stem number significantly affected vegetative growth, yield, and nut characteristics of the 'Ata-baba' hazelnut cultivar under Azerbaijani conditions. Among the regulated treatments, leaf area decreased as stem number increased, and leaf area was lowest of all in the untreated control. Stem thickening was generally greatest in south-facing stems among the managed treatments, although this pattern did not hold in the untreated control, where north-facing stems thickened most in the 6×7 m scheme. Under the 7×3 m planting scheme, the highest yield was obtained with 12 stems per shrub, whereas in the 6×7 m scheme, 15 stems provided the best yield performance; yield in the untreated control remained lower than in any managed treatment in both schemes. Extremely high stem numbers did not proportionally increase yield and negatively affected certain fruit traits, while, regardless of stem number, all regulated treatments markedly improved kernel ratio and kernel weight compared with the unmanaged control. Yield per hectare increased with planting density; however, production in 2025 declined compared to 2024, likely due to climatic stress and increased damage from the brown marmorated stink bug. Moderate stem densities (12 stems at 7×3 m and 15 stems at 6×7 m) are recommended for optimizing yield and nut quality of the 'Ata-baba' cultivar in Azerbaijan, and the results confirm that actively managing stem number (even at non-optimal levels) is preferable to leaving shrubs unpruned.

ABSTRACT

Vegetables, including arugula, are essential components of a balanced diet due to their low caloric content and high nutritional value, contributing significantly to human health. Arugula, as cruciferous vegetable, is a rich source of fiber, vitamins A, C, K, B9, and various minerals, and possess antioxidant properties like neutralizing free radicals. Heavy metals are chemical elements that have toxic effects in living organisms. Environmental factors such as soil, water, and air pollution all contribute to heavy metal contamination in foods, particularly vegetables. Consumption of vegetables contaminated with heavy metals and foodborne pathogens, including *Escherichia coli*, could cause a significant concern to public health due to their tendency to bioaccumulation in the body and their toxic effects. The purpose of this study was to examine the resistance to heavy metal copper in the *E. coli* isolates from arugula using the broth microdilution method to determine the minimum inhibitory concentration (MIC) and the PCR method to amplify the *pcoR* gene, which encodes copper resistance. *E. coli* isolates from arugula and reference strains, including *E. coli* ATCC 8739 and *Enterobacter cloacae* NCIMB 13597, were tested for copper resistance. All tested arugula *E. coli* isolates had an MIC of 1600 µg/mL. The presence of the *pcoR* gene encoding copper resistance was detected in none of the arugula *E. coli* isolates. *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597 contained the *pcoR* gene and had MICs of 1600 µg/mL. In conclusion, in this study, *E. coli* isolates from arugula plants were evaluated for resistance to copper, a heavy metal that poses a risk to human health.

Keywords: copper resistance, *pcoR* gene, *Escherichia coli*, minimum inhibitory concentration, arugula

INTRODUCTION

Leafy green vegetables play an important role in a healthy lifestyle thanks to their fiber, vitamin, and antioxidant content. Arugula, a member of the Brassicaceae family, is a vegetable favored for its slightly bitter, tangy flavor in various applications, such as salads, smoothies, and sauces. The consumption of arugula is steadily increasing due to the vitamins, polyphenols, and other health-beneficial compounds it contains. In addition, its bioactive compounds have been associated with beneficial effects on gastrointestinal and cardiovascular health, as well as anticancer activity (Inestroza-Lizardo et al., 2016; Najmi et al., 2023; Santos et al., 2024).

Heavy metals are one of the most concerning environmental pollutants because of their toxicity, persistence in the environment, and facility to bioaccumulate along the food chain (Liao et al., 2023; Heydari et al., 2025). Primary sources of heavy metals are such as weathering rocks,

volcanic activity, marine aerosols (Halem et al., 2024). Moreover, heavy metals can be detected in the environment as a result of fossil fuel combustion, agrochemical fertilizer use, sewage sludge supplementing, and industrial deposition processes (Halem et al., 2024).

Vegetables that are grown in soils contaminated with heavy metals can accumulate these heavy metals in their tissues' health (Santos et al., 2024). The accumulation of heavy metals in plants has numerous adverse effects, such as stunted growth and a reduced capacity for photosynthesis (Ojo et al., 2023). Through this process, heavy metals can enter the food chain, and consumption of these plants adversely affects human health, such as blindness, immunosuppressive functions and neurological damage (Ojo et al., 2023; Santos et al., 2024; Heydari et al., 2025).

Exposure of soil microorganisms to heavy metals leads to a reduction in microbial diversity and enzymatic activities (Ojo et al., 2023; Heydari et al., 2025). Bacteria have developed mechanisms to tolerate the toxic effects caused by heavy metals. Examples of these resistance mechanisms include enzymatic detoxification, intracellular and extracellular sequestration, efflux pumps, and active transport (Ojo et al., 2023).

Heavy metals are naturally occurring elements with atomic numbers above 20 and densities more than 5 g/cm^3. Many heavy metals are essential for various biological processes (Mihdir et al., 2016; Gillieatt and Coleman, 2024). Essential metals include Zn, Cu, Mn, Fe, Co, Mo, and Ni. However, excessive concentrations of these metals can exert toxic effects on living organisms (Gillieatt and Coleman, 2024).

Although copper is an essential metal, the accumulation of excessive amounts within the cell is toxic to bacteria. Consequently, bacteria have developed copper resistance mechanisms. These resistance mechanisms are generally mediated by genes located on bacterial plasmids. In *E. coli*, the structural genes *pcoA, pcoB, pcoC*, and *pcoD* function in copper resistance, while the *pcoR* gene acts as a DNA-binding regulatory protein involved in the regulation of copper resistance genes (Chihomvu et al., 2015). Excessive copper intake, depending on the period of exposure, can cause major immediate or chronic adverse consequences such as cardiovascular diseases, neurological diseases, gastrointestinal issues and renal dysfunction (Najmi et al., 2023).

Escherichia coli is a rod-shaped, Gram-negative bacterium that belongs to the *Enterobacteriaceae* family. (Bhunia, 2008). It is generally motile and facultatively anaerobic and commonly occurs in the intestinal tract of humans and other warm-blooded animals (WHO, 2018; CDC, 2024). Although most *E. coli* strains are harmless and part of the normal intestinal microbiota, certain pathogenic strains such as Shiga toxin-producing *E. col*i (STEC), Enterohemorrhagic *E. coli* (EHEC) and Enteropathogenic *E. coli* (EPEC) can cause foodborne diseases ranging from mild diarrhea to severe bloody diarrhea (FDA, 2020; CDC, 2024).

Among the pathogenic *E. coli* strains, STEC is of particular concern because it can progress to hemolytic uremic syndrome (HUS) (WHO, 2018; CDC, 2024). Although most STEC infections are self-limiting, HUS can develop particularly in young children and older adults and may result in acute kidney failure.

Fresh vegetables can become contaminated with *E. coli* through direct contact with animals or through contact with faecally contaminated soil, irrigation water and during harvesting (FDA, 2020).

Heavy metal resistance is considerable because heavy metals are persistent in the environment, cannot be degraded and can cause long-term selective pressure among the bacterial populations. This selective pressure can be the cause of dissemination of metal resistance. In addition, heavy metal resistance may be associated with antibiotic resistance through co-selection, as resistance determinants against metals and antibiotics can be located on the same mobile genetic elements,

such as plasmids and transposons (Heydari et al., 2025). Therefore, exposure to heavy metals can contribute to the dissemination of antimicrobial resistance among the bacterial populations. The widespread occurrence of heavy metals in agricultural environments makes investigating heavy metal resistance in foodborne bacteria such as *E. coli* is important for a food safety concern (Mihdir et al., 2016; Gillieatt and Coleman, 2024).

The aim of this study is to investigate the resistance of *E. coli* isolates from arugula to copper, a heavy metal that is harmful to human health. The resistance of isolates to metal was evaluated using the broth microdilution method, and the presence of the *pcoR* gene, which is responsible for copper resistance, was determined using PCR.

MATERIALS AND METHODS

Bacterial isolates

Nine *Ecoli* isolates that were isolated from arugula by Özdemir (2024) and as reference, *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597 are used as a positive control in this experiment. Nine *E. coli* isolates and reference strains stored in stock culture at -20 °C in Tryptic Soy Broth with 20% glycerol. These isolates were activated from stock cultures using Tryptic Soy Broth for 24 hours at 37°C. After that, the culture streaked on to Eosin Methylene Blue (EMB) agar (Merck, Germany) for obtaining pure colonies exhibiting a suspicious metallic green sheen characteristic of *E. coli*. For further analyses, the selected colonies exhibiting metallic green sheen were subcultured on to EMB agar (Merck, Germany).

Minimum inhibitory concentration of heavy metal copper

The minimum inhibitory concentration assay (MIC) was used to assess copper resistance in nine *E. coli* isolates. The MIC was defined as the lowest concentration of copper that completely inhibited visible bacterial growth. Growth inhibition was determined by measuring the absorbance at 600 nm using a Thermo Electron Corporation microplate reader. All experiments were done in triplicate, with *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597 serving as control strains.

The MIC of copper was determined by the broth microdilution method using sterile U-bottom 96 well microtiter plates according to the Clinical and Laboratory Standards Institute standards (CLSI, 2012). Previously cultured *E. coli* isolates cultured on Eosin Methylene Blue (EMB) agar were collected using a sterile cotton loop and suspended in Mueller Hinton Broth (MHB). The bacterial suspension was adjusted to 0.5 McFarland, which corresponds to roughly 1×10^8 colony forming units (CFU) per mL. The suspension diluted 1:150 ratio in MHB. Copper solutions prepared by two-fold serial dilution in MHB. Final copper concentrations ranged from 3200 to 6.25 µg/mL. For each test, sterility and growth controls are included and the microtiter plates were incubated (37 °C/ 24 hours).

Minimum bactericidal concentration of heavy metal copper

The Clinical and Laboratory Standards Institute (2012) defined the minimum bactericidal concentration (MBC) as the lowest concentration capable of killing 99.9% of the bacterial population. MBC values were calculated using the findings of the minimal inhibitory concentration (MIC) test. Briefly, 10 µL of sample from the first eight wells were spot-inoculated onto Mueller Hinton Agar and incubated at 37 °C for 24 hours.

DNA extraction and identification of the *E. coli* isolates

E. coli isolates were inoculated into 5 mL of sterile Tryptic Soy Broth (TSB) and incubated overnight at 37 °C. After that, 950 µL of each culture was transferred to sterile microcentrifuge tubes and centrifuged. Bacterial genomic DNA then isolated utilizing the cetyltrimethylammonium bromide (CTAB) method (Ausubel et al., 1991). For further PCR analysis, the extracted DNA was suspended in TE buffer and stored at −20 °C.
For species-level identification of *E. coli*, the *uspA* gene, which is encode the *E. coli* specific universal stress protein A, was amplified by PCR as previously described by Chen and Griffiths (1998). The PCR reaction was expected to yield an 884-bp amplicon. PCR amplification were performed in a T100 thermocycler (Bio-Rad). The reaction mixture had a final volume of 50 µL and contained 31.7 µL of PCR-grade water, 5 µL of 10X buffer, 4 mM $MgCl_2$, 0.2 mM dNTP mix (Amplicon), 0.4 µM of each primer, 4 µL of template DNA and 1.5 U of Taq polymerase (Thermo Scientific). The PCR cycling conditions were as follows: an initial denaturation at 94 °C/ 5 min; 30 cycles of denaturation at 94 °C/ 2 min, annealing at 60 °C/ 1 min, and extension at 72 °C/ 1 min; followed by a final extension at 72 °C/ 10 min. The products of PCR were separated on a 1% agarose gel and analyzed by agarose gel electrophoresis using a Bio-Rad system. *E. coli* ATCC 8739 was used as a positive control.

PCR amplification of the *pcoR* gene

The *pcoR* gene, which is related with copper resistance, was detected by PCR amplification. The *pcoR* gene encodes a transcriptional regulatory protein involved in the copper resistance. The primer for the *pcoR* gene were the forward primer, 5' CAGGTCGTTACCTGCAGCAG 3' , and the reverse primer, 5' CTCTGATCTCCAGGACATATC 3' (Trajanovska et al., 1997). The expected PCR product size is 636 bp. The amplification performed in a total volume of 50 µL. Each 50 µL PCR reaction mixture contained 30.7 µL of PCR-grade water (AppliChem), 5 µL of 10× buffer (Thermo Scientific), 4 µL of $MgCl_2$ (Thermo Scientific), 1 µL of dNTP mix (Amplicon), 2 µL of each primer pair, 0.3 µL of Taq DNA polymerase (Thermo Scientific), and 5 µL of template DNA. The PCR amplification was carried out in a Bio- Rad T100 thermal cycler with an initial denaturation step at 94 °C for 8 minutes, followed by 35 cycles comprising denaturation at 94 °C / 1 minute, annealing at 64 °C / 1 minute, and extension at 72 °C / 90 seconds, with a final extension at 72 °C/ 8 minutes. All PCR products separated on %1 agarose gel by electrophoresis. The products stained with ethidium bromide and visualized (DNR Minilumi). A 100 bp ladder (Vivantis) used to determine the size of the amplified DNA fragments. *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597 were used as a positive control in the experiment.

RESULTS AND DISCUSSION

In this study, a total of nine *E. coli* isolates from arugula and two positive reference strains, *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597, were evaluated for heavy metal copper resistance by using both phenotypic and genotypic methods. Figure 1 presents the results of the phenotypic characteristics of copper resistance *E. coli* isolates from arugula and two positive controls based on MIC and MBC values obtained by the broth microdilution method. The MBC/MIC ratio is given in Figure 2. The heavy metal copper showed bactericidal activity against all *E. coli* isolates from arugula. Figure 3 shows a representative image of the minimal bactericidal concentration of heavy metal copper against *E. coli* isolates. The copper resistance is associated with the *pcoR* gene and is performed by PCR amplification. The *pcoR* gene was

not detected in any of the nine *E. coli* isolates except for the reference strains. The representative PCR products of the *pcoR* gene in the *E. coli* isolates from arugula are shown in Figure 4.

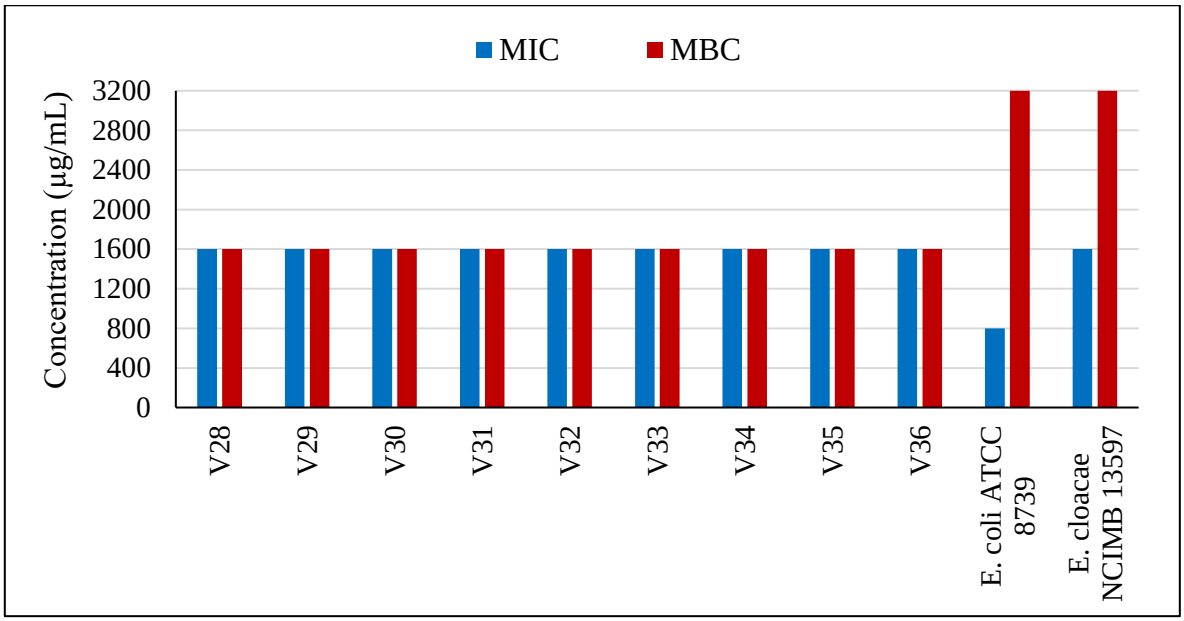

Figure 1. Minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) of heavy metal copper against the *E. coli* isolates from arugula and two positive control strains.

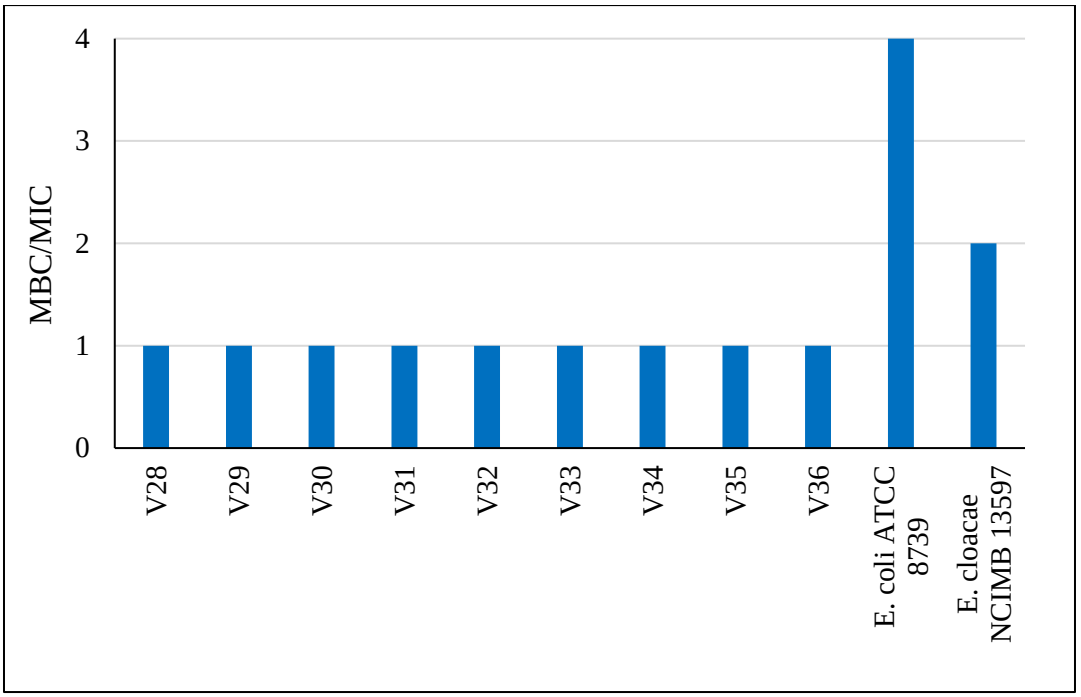

Figure 2. Ratio of minimum bactericidal concentration (MBC) to minimum inhibitory concentration (MIC) for heavy metal copper in the *E. coli* isolates from arugula and two positive controls. MBC/MIC ratio ≤ 4 means bactericidal activity and > 4 bacteriostatic activity.

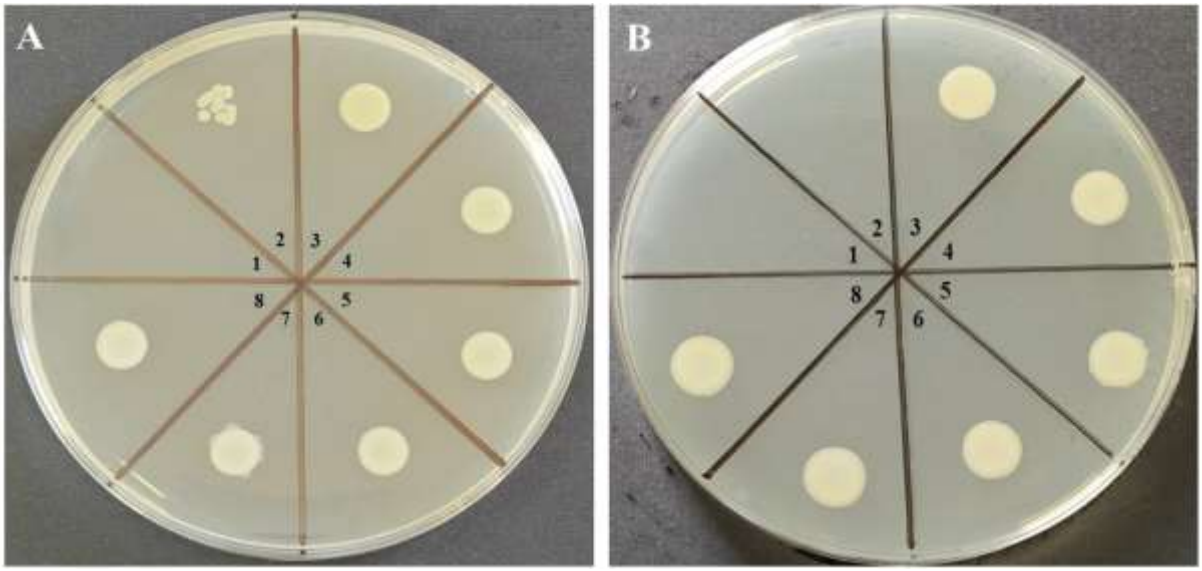

Figure 3. The representative image for the minimum bactericidal concentration (MBC) of the heavy metal copper against *E. cloacae* NCIMB 13597 (A) and V30 arugula *E. coli* isolate (B). The concentrations shown by the numbers 1-8 are 3200, 1600, 800, 400, 200, 100, 50, and 25 µg/mL.

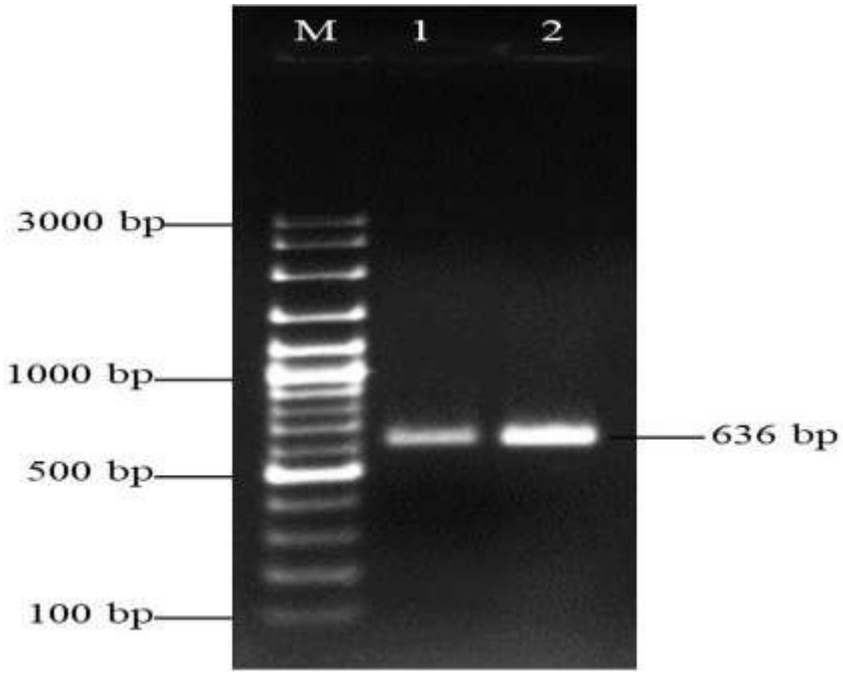

Figure 4. Agarose gel electrophoresis displaying polymerase chain reaction amplification of the *pcoR* gene (636 bp). Lane M: DNA ladder (100 bp). Lanes 1-2: *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597 positive reference strains for the *pcoR* gene.

In the current study, all tested *E. coli* isolates from arugula exhibited a MIC of 1600 µg/mL for the heavy metal, copper. Moreover, the *pcoR* gene associated with copper resistance was not detected among the *E. coli* isolates. Furthermore, the copper MIC values of *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597 were 800 and 1600 µg/mL, respectively. However, these reference strains, *E. coli* ATCC 8739 and *E. cloacae* NCIMB 13597, had the *pcoR* gene. These conflicts may suggest that copper tolerance may be mediated by other resistance mechanisms than the *pcoR* gene.

Dahanayake et al. (2016) reported that 37% of *Aeromonas* spp. isolates were resistant to copper. Najmi et al. (2023) investigated nine different heavy metals in leafy vegetables and reported that arugula has the highest heavy metal concentration among the other vegetables. The copper concentration in arugula ranged from 5.36 to 9.18 mg/kg dry weight. Nguyen et al. (2025) investigated the *pcoR* gene in *E. coli* and *S.* Typhimurium isolates, which are obtained from goat feces, and reported a prevalence of 9.36%. Islam et al. (2025) detected the *pcoR* gene among the *E. coli* isolates and reported a Cu^{2+} MIC of 2000 µg/mL.

In this study, the isolates showed a Cu^{2+} MIC of 1600 µg/mL and didn't show the *pcoR* gene. These results may suggest that the response of *E. coli* to heavy metal copper may not be dependent on the *pcoR* gene. Other copper efflux mechanisms may contribute to copper tolerance. Similar to our findings, Sendolo et al. (2022) didn't detect heavy metal resistance traits in clinical isolates; on the other hand, environmental isolates showed resistance-associated traits to silver and arsenic. The absence of copper-associated determinants in the study, as well as the absence of the *pcoR* gene, may imply that heavy metal resistance disruption varies depending on the bacterial source and environment.

CONCLUSIONS

This study evaluated the heavy metal copper resistance of *E. coli* isolates obtained from arugula. The MIC values of copper against all tested isolates were 1600 µg/ mL. The *pcoR* gene, which is linked to copper resistance, was not found in any of the examined *E. coli* isolates. In conclusion, studies regarding resistance to the heavy metal copper in *E. coli* isolates obtained from arugula, a popular vegetable, are important because heavy metal resistance poses potential threats to human health and food safety.

ABSTRACT

In this comprehensive and detailed toxicological investigation, we aimed to model the non-carcinogenic health hazards and potential physiological effects of fluoride exposure from the Sultanköy and Altınyazı Dam Lakes (Northwest Türkiye) for local consumers using an advanced probabilistic risk assessment approach. Based on the long-term hydrochemical datasets of these reservoirs, a multi-pathway probabilistic human health risk assessment was performed to systematically address inherent uncertainties in various environmental exposure parameters. The Hazard Quotient (HQ) values via the drinking water ingestion pathway were simulated across four distinct age cohorts: infants, children, teenagers, and adults, to capture age-dependent susceptibility. The probabilistic risk characterization revealed that the simulated HQ values for fluoride did not exceed the critical toxicological threshold of 1.0 in either reservoir, demonstrating that these surface waters pose no immediate adverse systemic health hazards or chronic fluorosis risks for the regional population. Across all evaluated demographic categories, the highest risk orientation was consistently observed in children, followed by teenagers, adults, and infants, respectively. In a comparative framework, the estimated risk indices for Sultanköy Dam Lake were systematically higher across all age groups than those calculated for Altınyazı Dam Lake due to varying baseline anion levels. From a preventive dentistry and public health perspective, while both aquatic ecosystems are completely safe from a dental or skeletal fluorosis standpoint, the prominently lower exposure profiles in Altınyazı Dam Lake suggest a potential deficit in meeting the daily optimal fluoride requirements necessary for dental caries mitigation, emphasizing the need for targeted nutritional and dental planning in the region.

Keywords: Probabilistic risk assessment, Fluoride exposure, Hazard Quotient, Preventive dentistry, Public health

INTRODUCTION

Fluoride is a double-edged trace element that exerts a foundational control on human oral health. While its integration into dental tissues mitigates dental caries, drinking water remains the primary exposure vector globally (Andezhath et al., 1993; Güner et al., 2016; Tokatlı and Güner, 2018; Onur and Tokatlı, 2020). Dietary habits, pharmaceuticals, and geogenic or industrial processes also contribute to the cumulative fluoride load (Tokatlı et al., 2022; 2023). However, due to its narrow therapeutic index, sustained ingestion above optimal thresholds shifts its profile from cariostatic to toxic, posing risks of endemic dental and skeletal fluorosis.

To address these concerns, health risk assessments have become vital in public health management to delineate the toxicological boundaries of environmental contaminants (Taghipour et al., 2016; Jannat et al., 2022; Din et al., 2024). Recently, integrating probabilistic modeling into these frameworks has advanced water resource management. Unlike deterministic estimations, probabilistic risk assessment accounts for natural variations and uncertainties in physiological factors, body weights, and water ingestion rates, enabling the precise identification of vulnerable demographic cohorts for targeted preventive dentistry interventions.

In Northwest Türkiye, the Sultanköy and Altınyazı Dam Lakes represent two pivotal reservoirs in Edirne Province, serving as lifelines for regional drinking water supply and agricultural activities. Established by the General Directorate of State Hydraulic Works (DSİ), these ecosystems are increasingly subjected to anthropogenic threats, where agricultural drainage and domestic wastes introduce substantial contaminant loads (http://www2.dsi.gov.tr/; Tokatlı et al., 2017; Tokatlı, 2019; 2020a; 2020b). Unlike dynamic lotic systems, these stagnant dam lakes are highly susceptible to the long-term accumulation of chemical constituents driven by intense evaporation and diffuse catchment runoff, directly affecting public health safety.

Given these ecological characteristics, this study was designed to bridge environmental hydrochemistry with preventive medical modeling. The explicit objectives were (1) to evaluate the spatial non-carcinogenic health hazards of fluoride exposure from these critical lentic ecosystems and (2) to systematically quantify these potential risks across distinct age cohorts using a comprehensive probabilistic risk assessment approach.

MATERIALS AND METHODS

Research Area and Sample Collection

The topographic configuration of the study area and the spatial distribution of the monitoring stations across the Sultanköy and Altınyazı Dam Lakes are illustrated in Figure 1. Surface water sampling was systematically executed during a single field campaign in the autumn season of 2024. This specific transitional period was strategically selected to coincide with the onset of significant seasonal precipitation. The primary hydrometeorological objective of this timing was to capture the critical phase where intensified surface runoff and atmospheric deposition flush the catchment area, heavily influencing the transport dynamics and concentration variations of fluoride and chloride ions within these lentic ecosystems.

Fluoride Analysis

Fluoride concentrations were quantified using spectrophotometric techniques, employing a Hach Lange DR 3900 spectrophotometer (https://tr.hach.com/) following APHA protocols (1998, 2017). For the determination of fluoride levels, the Hach Lange LCK 323 cuvette test kit was utilized. All analytical procedures were conducted in strict accordance with the manufacturer's protocols to ensure accuracy and reproducibility.

Health Risk Assessment

To address physiological and behavioral variations, the target population was stratified into four age cohorts: infants (<2 years), children (2–6 years), teenagers (6–16 years), and adults (>16 years). Daily fluoride exposure via drinking water ingestion for each demographic category was calculated using Equation 1. The non-carcinogenic health hazards were subsequently characterized using the Hazard Quotient (HQ) according to Equation 2 (Yousefi et al., 2018). An HQ threshold of less than 1.0 indicates a negligible toxicological risk, whereas values

greater than 1.0 signify potential non-carcinogenic health concerns, indicating an increased probability of developing dental or skeletal fluorosis.

$$EDI = \frac{Cf\ x\ Cd}{Bw} \quad (1)$$

$$HQ = \frac{EDI}{RfD} \quad (2)$$

EDI: Estimation of fluoride consumption – daily (mg/kg/day)
C_f: Fluoride level in the investigated drinking water samples (mg/L)
C_d: Mean daily water intake (L/day) (the mean water consumption rates in infants, children, teenagers and adults were 0.08, 0.85, 2 and 2.5 L/day, respectively)
B_w: Body weight (kg) (body weights of investigated groups were considered 10, 15, 50 and 78 kg, respectively)
RfD: Reference dose (mg/kg/day) (it is 0.06 mg/kg/day for fluoride (EPA, 1992).

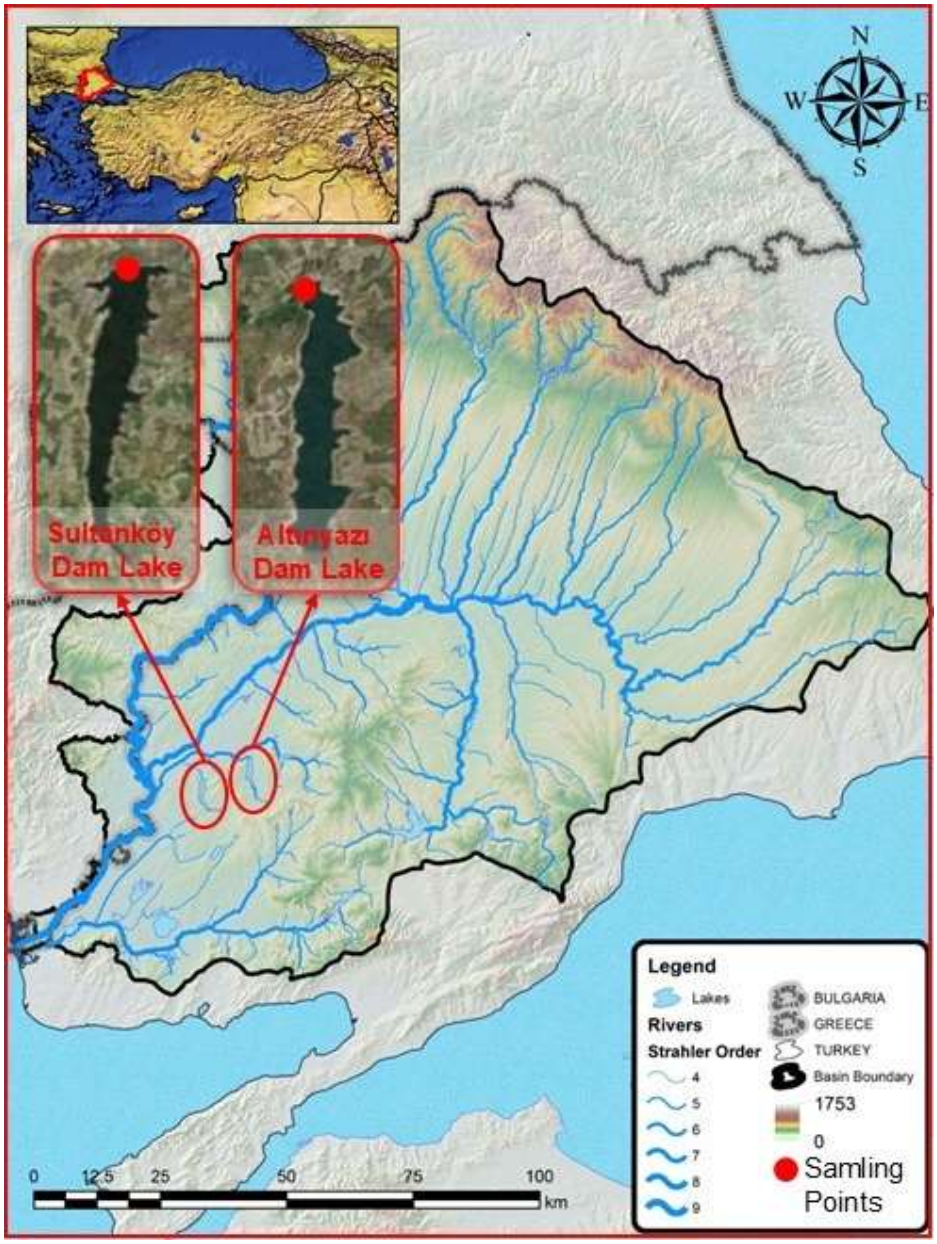

Figure 1. Meriç – Ergene Basin, investigated reservoirs and selected sampling station

RESULTS AND DISCUSSION

The simulated non-carcinogenic risk indices for the studied reservoirs are illustrated in Figure 2. The probabilistic risk characterization for the four distinct age cohorts revealed that all calculated Hazard Quotient (HQ) values were systematically below the critical safety threshold of 1.0, indicating a negligible risk of severe fluorosis among the local population. Specifically, Sultanköy Dam Lake displayed systematically higher risk indices across all cohorts (Infants: 0.05573, Children: 0.39478, Teenagers: 0.27867, Adults: 0.22329) than Altınyazı Dam Lake (Infants: 0.01373, Children: 0.09728, Teenagers: 0.06867, Adults: 0.05502). The modeled outputs showed distinct demographic variations where children consistently exhibited the highest HQ values in both systems (0.39478 for Sultanköy and 0.09728 for Altınyazı), followed by teenagers, adults, and infants, respectively.

These health hazards and exposure risks are closely linked to demographic variables and population-specific consumption characteristics (Taghipour et al., 2016; Tokatlı et al., 2022). The trend of children experiencing the highest susceptibility aligns with global literature highlighting that younger populations face higher chronic risks from drinking water due to their lower body weights relative to daily ingestion rates (Gao et al., 2013; Tokatlı et al., 2023).

From a preventive dentistry perspective, while these low indices guarantee absolute safety against fluorosis, they also introduce a critical oral health concern. The remarkably low exposure profiles, particularly in Altınyazı Dam Lake, suggest that fluoride exposure risks fall drastically below the daily optimal levels necessary for dental caries mitigation. These findings emphasize that probabilistic exposure modeling is an essential tool to balance toxicological safety and oral health protection in regional water supplies.

CONCLUSIONS

In this study, the non-carcinogenic health hazards of fluoride exposure from Sultanköy and Altınyazı Dam Lakes were modeled using a probabilistic approach across four age groups. All simulated Hazard Quotient (HQ) values remained well below the critical threshold of 1.0, indicating a negligible risk of dental or skeletal fluorosis for local consumers. Children were identified as the most vulnerable cohort in both systems, followed by teenagers, adults, and infants, while Sultanköy Dam Lake systematically displayed higher risk indices than Altınyazı Dam Lake. From a public health perspective, these low exposure profiles—especially in Altınyazı Dam Lake—suggest a potential deficit in meeting the optimal daily fluoride ingestion required for dental caries mitigation.

ABSTRACT

In this comprehensive and detailed hydrochemical investigation, the seasonal water quality dynamics, spatial variations, and overall pollution profiles of the Sultanköy and Altınyazı Reservoirs, which hold immense strategic importance for extensive agricultural irrigation practices and regional freshwater reserves within the economically vital Meriç-Ergene Basin, were comparatively evaluated and monitored based on precise fluoride (F^-) and chloride (Cl^-) ion parameters. The extensive analytical results, laboratory data, and field observations revealed that despite both artificial aquatic systems being located within the exact same geographical area and climatic region, the fundamental hydrochemical characteristics and major anion compositions of these two crucial water bodies significantly differ on a critical basin scale. According to the quantitative findings of the monitoring program, Altınyazı Reservoir prominently stands out with its remarkably high chloride concentrations and elevated salinity indicators, whereas fluoride accumulation exhibits a much more dominant, persistent, and distinctive hydrochemical character throughout the Sultanköy Reservoir ecosystem. This sharp contrast in the dominant anion distribution and geochemical fingerprints of the reservoirs clearly points to highly differing anthropogenic pressures occurring along the specific drainage lines feeding the dams, the varying quality and volume of agricultural return waters draining from surrounding crop fields, or the distinct local lithological configurations and geological structures characterizing the respective drainage basins. Consequently, this comparative research study provides critical baseline data, scientific insights, and environmental indicators necessary for implementing sustainable water resource management strategies in the region, protecting aquatic ecosystems, and assessing the future long-term utilization potential and ecological safety of both reservoirs for irrigation and secondary purposes.

Keywords: Sultanköy Reservoir, Altınyazı Reservoir, Fluoride, Chloride, Dental health, Meriç-Ergene Basin

INTRODUCTION

In the 21st century, the degradation of freshwater ecosystems stands out as a paramount environmental crisis, severely jeopardizing aquatic biodiversity and public health (Helvacıoğlu et al., 2025; Din et al., 2023; Muhammad et al., 2025). As vital lentic components, artificial reservoirs perform indispensable functions in irrigation and municipal water supply. Nonetheless, intensifying anthropogenic stressors—primarily driven by agrochemical runoff

and wastewater discharges—frequently induce severe water quality degradation in these critical water bodies (Çiçek et al., 2014; Köse et al., 2020; Ustaoğlu et al., 2022).

The Sultanköy and Altınyazı Dam Lakes represent two pivotal reservoirs in Edirne Province (Türkiye), serving as lifelines for regional drinking water supply and agricultural activities. Established by the General Directorate of State Hydraulic Works (DSİ) to sustain the socioeconomic and ecological equilibrium of the region, these reservoirs are increasingly subjected to anthropogenic threats (http://www2.dsi.gov.tr/). Persistent agricultural drainage and domestic waste loads introduce substantial amounts of contaminants into these lacustrine systems, threatening their long-term sustainability (Tokatlı et al., 2017; Tokatlı, 2019; 2020a; 2020b).

From a public health and dentistry perspective, monitoring specific hydrochemical parameters like fluoride is of utmost clinical significance. Fluoride is a crucial micronutrient fundamental for preventing dental caries, with municipal drinking water being its predominant intake vector (Andezhath et al., 1993; Güner et al., 2016; Tokatlı and Güner, 2018; Onur and Tokatlı, 2020; Tokatlı et al., 2022; 2023). However, its therapeutic window is remarkably narrow; chronic overexposure can precipitate debilitating conditions, most notably dental and skeletal fluorosis. Consequently, determining precise fluoride concentrations in regional water reserves remains a critical cross-disciplinary concern linking environmental science with preventive dentistry.

To address these pressing ecological and public health concerns, the present study was designed to execute a comparative hydrochemical assessment of the Sultanköy and Altınyazı Dam Lakes, with a primary focus on their fluoride (F) and chloride (Cl) profiles.

MATERIALS AND METHODS

Research Area and Sample Collection

Figure 1 illustrates the topographic configuration of the study area, including the spatial distribution of the selected monitoring stations across the Sultanköy and Altınyazı Dam Lakes. Within the scope of this study, surface water samples were systematically collected from the designated stations in the autumn season of 2024. The sampling strategy was specifically scheduled for a single campaign during autumn, as this transitional period marks the onset of significant seasonal precipitation. This hydrometeorological timing was strategically chosen to capture the critical phase where increased surface runoff and atmospheric depositions intensively flush the surrounding watershed, thereby significantly influencing the transport and concentration dynamics of fluoride and chloride ions within the reservoir ecosystems.

Fluoride and Chloride Analysis

Fluoride and chloride concentrations were quantified using spectrophotometric techniques, employing a Hach Lange DR 3900 spectrophotometer (https://tr.hach.com/) following APHA protocols (1998, 2017). For the determination of fluoride levels, the Hach Lange LCK 323 cuvette test kit was utilized. Concurrently, chloride concentrations were measured using the Hach Lange LCK 311 cuvette test kit. All analytical procedures were conducted in strict accordance with the manufacturer's protocols to ensure accuracy and reproducibility.

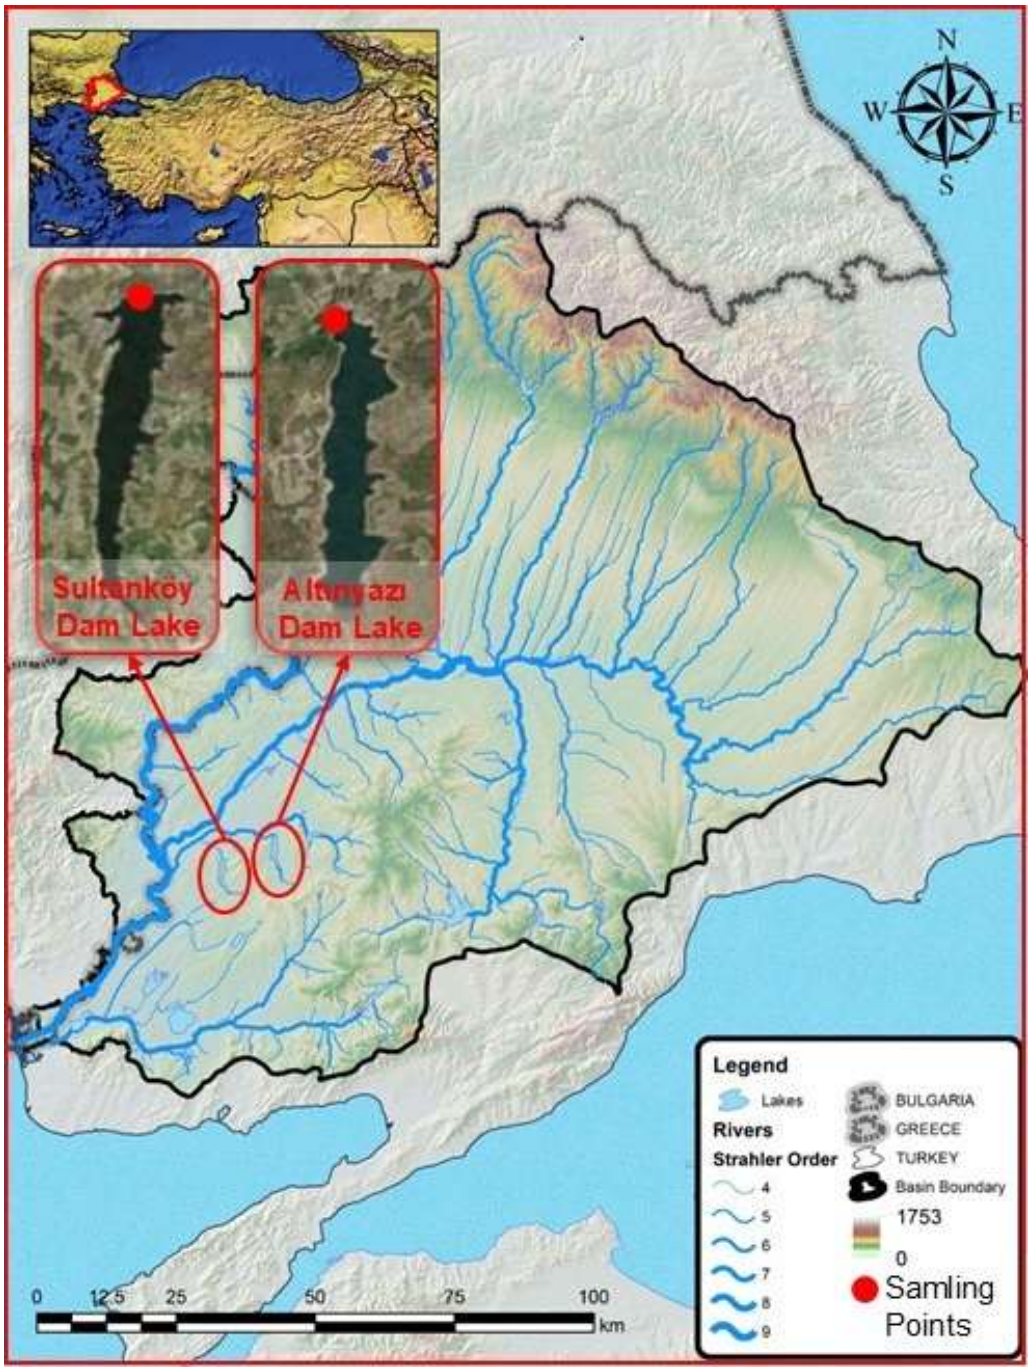

Figure 1. Meriç – Ergene Basin, investigated reservoirs and selected sampling stations

RESULTS AND DISCUSSION

The fluoride and chloride distributions in the Sultanköy and Altınyazı Dam Lakes are illustrated in Figure 2. The analytical results revealed distinct hydrochemical profiles for each reservoir. Chloride concentrations peaked in Altınyazı Dam Lake (158.00 ppm) compared to Sultanköy Dam Lake (89.00 ppm). Conversely, a completely opposite trend was observed for fluoride; Sultanköy Dam Lake exhibited significantly higher levels (0.418 ppm) than Altınyazı Dam Lake (0.103 ppm), showing an approximately four-fold increase between these lentic ecosystems.

Fluoride is a vital trace element with double-edged clinical implications. While its deposition in dental tissues plays a fundamental role in preventing dental caries, excessive exposure can trigger substantial pathological risks depending on concentration and duration (Taghipour et al., 2016; Tokatlı et al., 2022; 2023). Because drinking water supplies serve as the primary exposure vector, maintaining optimal fluoride levels remains a critical cornerstone of dental public health and preventive dentistry. On the contrary, chronic ingestion above therapeutic thresholds can precipitate dental and skeletal fluorosis (Güner et al., 2016; Tokatlı and Güner, 2018; 2020; Jannat et al., 2022; Din et al., 2024).

In the present study, fluoride concentrations in both Sultanköy (0.418 ppm) and Altınyazı (0.103 ppm) reservoirs were well within the permissible drinking water limit of 1.5 ppm stipulated by TS266 (2005), EC (2007), and WHO (2011). Although both lakes pose no fluorosis risk, the significantly lower fluoride level in Altınyazı suggests that supplementary oral health strategies might be required if utilized for municipal supply to ensure adequate protection against caries. Turningly, the higher chloride levels in Altınyazı Dam Lake (158.00 ppm) point toward more intense agricultural runoff or evaporative concentration dynamics in its catchment area.

CONCLUSIONS

This study evaluated the comparative hydrochemistry of Sultanköy and Altınyazı Dam Lakes with a specific focus on fluoride and chloride dynamics. The results revealed a distinct environmental polarization between the two reservoirs; Altınyazı Dam Lake is characterized by higher chloride loads, likely driven by agricultural runoff, whereas Sultanköy Dam Lake exhibits a significantly more dominant fluoride character. From a clinical and dental public health perspective, the fluoride concentrations in both lentic ecosystems remain safely below the maximum permissible drinking water threshold of 1.5 ppm set by WHO, EC, and TS266, indicating no risk of dental or skeletal fluorosis for the local population. However, the remarkably low fluoride levels in Altınyazı Dam Lake highlight a potential insufficiency for optimal dental caries prevention if these waters are integrated into municipal supply grids. Ultimately, these baseline outputs underscore the necessity of cross-disciplinary monitoring strategies that bridge environmental watershed management with preventive dentistry to ensure the dual protection of ecosystem stability and regional oral health.

IMPACTS OF THE 2023 TÜRKİYE EARTHQUAKES ON THE AGRICULTURE SECTOR OF HATAY PROVINCE

A. Aytekin POLAT[1]

[1]*Hatay Mustafa Kemal University, Agriculture Faculty, Department of Horticulture, Antakya, Hatay/Turkey*

Corresponding author e mail: aapolat@mku.edu.tr

ABSTRACT

On 6 February 2023, two major earthquakes (Mw 7.7 and Mw 7.6) struck Kahramanmaraş, Türkiye, followed by a third earthquake (Mw 6.4) in Hatay on 20 February 2023. These earthquakes were among the most devastating disasters in the history of the Republic of Türkiye, affecting approximately 14 million people across 11 provinces. The affected region accounts for nearly 16% of the country's agricultural production, with Hatay being one of the provinces that experienced the greatest destruction. This study assessed the impacts of the February 2023 earthquakes on the agricultural and food sector in Hatay using a mixed-methods approach combining official statistical data, field observations, damage assessment reports, and semi-structured interviews with farmers. The earthquakes caused approximately 24,000 fatalities in Hatay and resulted in the destruction or severe damage of 80,323 buildings. Agricultural lands, irrigation systems, livestock facilities, storage infrastructure, and other production assets sustained extensive damage. According to official records, 2,861 cattle, 13,625 small ruminants, 5,529 barns and livestock shelters, and 9,381 beehives were lost or damaged, while the poultry sector was affected in 39 commercial enterprises. In addition, disruptions in the supply of essential agricultural inputs, including seeds, fertilizers, feed, and irrigation water, significantly constrained agricultural production. Labor shortages caused by large-scale migration and damage to rural infrastructure further delayed agricultural recovery. The findings indicate that the February 2023 earthquakes caused multidimensional disruptions extending well beyond direct physical damage, affecting agricultural production, supply chains, labor availability, and rural livelihoods. Strengthening disaster preparedness, rehabilitating agricultural infrastructure, and integrating resilience-based policies into long-term agricultural recovery strategies are essential for improving the sustainability and resilience of agroecosystems in earthquake-prone regions.

Keywords: agricultural production, disaster recovery, earthquake impacts, Hatay, Türkiye

INTRODUCTİON

Natural disasters threaten human life and the sustainability of many sectors, particularly agriculture. Among these disasters, earthquakes are especially significant because of their frequent occurrence and their widespread impacts (Agızan et al., 2023). In addition to causing delays and interruptions in agricultural activities, earthquakes damage production resources, irrigation infrastructure, and agricultural land through landslides, faulting, and ground fissures. They also trigger migration, reduce agricultural labor availability, and disrupt production

systems, ultimately decreasing both the quantity and quality of agricultural products and contributing to higher food prices (Polat, 2025).

Due to its geographical location, Türkiye is highly prone to earthquakes. Between 1900 and 2023, the country experienced 269 damaging or fatal earthquakes, including 20 events with a magnitude of Mw ≥7.0. Among these, the 2023 Kahramanmaraş earthquakes, together with the 1939 Erzincan and 1999 Gölcük earthquakes, rank as the most destructive in terms of casualties and economic losses (PSB, 2023).

On February 6, 2023, two major earthquakes of Mw 7.7 and Mw 7.6 struck Pazarcık and Elbistan (Kahramanmaraş), followed by a Mw 6.4 earthquake in Yayladağı (Hatay) on February 20. These events represent one of the largest natural disasters in the history of the Republic of Türkiye and one of the most devastating earthquake sequences worldwide. The earthquakes affected approximately 120,000 km² and 14 million people across 11 provinces, causing 53,537 fatalities and 107,204 injuries (PSB, 2024). More than half a million buildings sustained damage, including residential, commercial, public, educational, healthcare, and historical structures, resulting in severe disruption to communication, energy, and transportation infrastructure (PSB, 2024).

The affected region encompasses approximately 4.03 million hectares of fertile agricultural land and accounts for nearly 16% of Türkiye's agricultural production, 15.3% of its agricultural gross domestic product, and 18.7% of its agricultural and forestry exports (PSB, 2023). These provinces produce 16.2% of the country's field crops, 26% of its fruit, and 15.2% of its vegetables, while also containing 13% of the national cattle population and 17.8% of the small ruminant population (TurkStat, 2023a). Hatay, the province most severely affected by the earthquakes, contributes 1.3% of Türkiye's gross domestic product and 1.6% of its agricultural gross domestic product (PSB, 2024). The province is one of the country's leading agricultural production and export centers, accounting for 15.6% of Türkiye's fresh fruit and vegetable exports in 2023. Its agricultural exports reached USD 818 million, with lemons, oranges, and mandarins representing the principal export commodities (Anonymous, 2023a).

Because agriculture constitutes the dominant economic activity in much of the disaster region, the earthquakes had profound consequences for agricultural production and food security. Extensive damage occurred to irrigation systems, livestock shelters, food processing facilities, grain silos, storage infrastructure, fisheries, and agricultural supply chains. Large-scale migration further reduced agricultural labor availability and disrupted production activities. According to the Food and Agriculture Organization (FAO), more than 20% of Türkiye's agricultural production was affected, and the initial economic loss in the agricultural sector was estimated at TL 24.2 billion (USD 1.3 billion) (FAO, 2023a, b).

This study evaluates the strategic importance of Hatay within Türkiye's agricultural sector, assesses the impacts of the 2023 earthquakes on agricultural production and infrastructure, identifies the major challenges faced by the sector, and proposes recommendations to strengthen agricultural resilience, safeguard food security, and improve the sustainability of agricultural supply chains following major natural disasters.

MATERİALS AND METHODS

The study was conducted in Hatay province, one of the regions most severely affected by the devastating earthquakes of February 6 and 20, 2023, and a region of significant importance to Türkiye’s agricultural production. Hatay, located in the Mediterranean Region of Türkiye (Figure 1), lies between 35°52′–37°04′ N latitude and 35°40′–36°35′ E longitude, at an average elevation of approximately 80 m, and is one of the oldest settlements in the country. A typical Mediterranean climate prevails in the area, with average annual temperatures ranging between 15.1°C and 20.0°C. The combination of favorable climatic conditions, soil characteristics, and

topography allows for the cultivation of a wide variety of agricultural products. The province also plays a significant role in both domestic and international agricultural markets.

Figure 1. Location of Hatay Province, in Turkey.

Hatay is one of the provinces most affected by the disaster. Located at the southern tip of Turkey, Hatay is among the oldest settlements in the country. Antakya, the province's central city, has historically been a significant trade center due to its strategic location and multicultural structure. The history of Antakya dates back to 40,000 years ago. Throughout its history, Antakya has remained important and was the third-largest city of the Roman Empire. Historical records and digital photogrammetry indicate that Hatay has experienced 30 recorded earthquakes, seven of which completely destroyed the city, showing that it has been rebuilt multiple times (Beyen et al., 2003; Yüksel, 2023; Çimen, 2023; Candan, 2023). With the 2023 earthquakes, Hatay has now been destroyed for the eighth time.

This study was conducted using both quantitative and qualitative research techniques. Quantitative data were obtained from official reports and secondary sources in the literature and analyzed through document and report review methods. In this context, statistical data for Hatay province were collected from the databases and reports of the Turkish Statistical Institute, the Presidency of the Republic of Türkiye Strategy and Budget Directorate, the Hatay Provincial Directorate of Agriculture and Forestry, the Food and Agriculture Organization, and the Union of Chambers of Turkish Engineers and Architects.

Qualitative data were obtained through field observations and on-site investigations, as well as through individual and group interviews conducted with farmers to assess the impacts of the earthquakes on agricultural activities.

In the first stage of the study, the pre-earthquake structure of Hatay's agricultural sector was analyzed. All data were processed and analyzed using Microsoft Excel and presented in tabular form to facilitate interpretation. In the subsequent stage, the impacts of the earthquakes on the province's agricultural structure, including the extent of damage and destruction, were evaluated using tables and photographic evidence. Based on the findings, recommendations were developed to support the sustainability of agricultural production in the earthquake-affected region and to enhance the effectiveness of support mechanisms for the agricultural sector.

RESULTS AND DİSCUSSİON

General Information About the Province

General data on Hatay Province, including population, population density, and agricultural land availability, are summarized in Table 1. As shown, 275,578 hectares-50% of the province's total land area of 552,400 hectares-consist of agricultural land.

Table 1. General Information on Hatay Province (Anonymous,2023b; 2024)

Population (people)	1.686.043
Total Land Area of the Province (ha)	552.400
Altitude (m)	85
Population Density (per km²)	287
Coastline Length on the Mediterranean (km)	183
Number of Districts	15
Total Agricultural Land (ha)	275.578
Pasture Land (ha)	17.253
Fallow Land (da)	50.891
Forest Area (ha)	219.604

Physical and Geographical Features of Hatay Province

Located in southern Turkey along the eastern shores of the Gulf of Iskenderun, Hatay is bordered by the Mediterranean Sea to the west, Syria to the south and east, Adana to the northwest, Osmaniye to the north, and Gaziantep to the northeast. The province consists of 15 districts (Figure 2). Excluding lakes, Hatay covers an area of 5,524 km². Mountains make up 46.1% of the province's terrain, plains 33.5%, and plateaus 20.4% (Anonymous, 2023b).

Figure 2. Map of Hatay Province (Anonymous,2024)

Population and Settlement

Hatay and its surrounding region, where traces of human activity date back to the 3rd millennium BCE, is one of the earliest settled areas in Anatolia. It has drawn attention due to its dense settlement and demographic characteristics during various historical periods. Reliable population data for Hatay is available from 1940 onward. In that year, the province had a population of 246,138. According to the Address-Based Population Registration System (ADNKS), Hatay's population in 2022 (before the earthquake) was 1,686,043, including 847,128 men and 838,915 women (Anonymous, 2023b).

Structure of the Province's Agricultural Sector Before the Earthquake*Hatay's Place in Türkiye's Agricultural Production*: *Field Crop, Vegetable and Fruit Production*

Owing to its favorable climate, fertile soils, diverse agroecological conditions, and long growing season, Hatay is one of Türkiye's leading agricultural production provinces. Approximately 275,578 ha of agricultural land support intensive production of field crops, vegetables, fruits, and livestock, making the province one of the country's most important agricultural centers.

Hatay ranks first nationally in the production of sweet potato, chard, parsley, and dill, supplying approximately 76%, 72%, 65%, and 64% of Türkiye's total production, respectively. The province is also one of the country's leading citrus-producing regions, ranking second in mandarin production and third in the production of oranges, lemons, grapefruit, and total citrus fruits, contributing approximately 21% of national citrus production. In addition, olive cultivation represents a major component of the provincial economy, with approximately 14.2 million trees producing 178,933 tons of olives annually, equivalent to about 11% of Türkiye's total production and ranking the province third nationally.

Hatay also ranks among the leading producers of several other high-value crops, including carrot, loquat, grapefruit, seed cotton, banana, onion, apricot, garlic, cultivated mushroom, and persimmon. This highly diversified production structure highlights the province's strategic importance for Türkiye's agricultural economy.

Overall, Hatay makes substantial contributions to the national production of fruits, vegetables, citrus, olives, and cotton. Consequently, disruptions to agricultural production in the province have implications that extend beyond the regional level, affecting national agricultural output, food supply chains, agricultural exports, and food security.

Livestock Production and Fisheries

In addition to crop production, Hatay has a well-developed livestock sector comprising cattle, sheep and goat farming, poultry production, beekeeping, and aquaculture. These activities constitute an important component of the provincial agricultural economy and provide substantial income and employment for rural communities.

Prior to the February 2023 earthquakes, Hatay had 141,444 cattle, 558,609 small ruminants, 1,026,159 poultry, and 111,959 beehives, demonstrating the significant contribution of livestock production to the province's agricultural economy. The steadily increasing number of beehives also reflects the growing importance of beekeeping in the region.

Hatay also has an important fisheries and aquaculture sector supported by four fishing harbors. Although the province accounts for approximately 1.6% of Türkiye's total marine aquaculture production, its aquaculture production capacity had increased steadily before the earthquake, reflecting continued investment and the growing importance of this sector within the provincial economy.

Overall, the combined strength of the crop, livestock, and fisheries sectors highlights Hatay's strategic importance within Türkiye's agricultural system. Consequently, the extensive damage caused by the February 2023 earthquakes affected not only regional agricultural production but also national food supply chains, agricultural exports, and food security.

Agro-Based Industry

Hatay has a well-developed agro-based industry, with food manufacturing representing the largest industrial sector and accounting for 26.02% of all industrial enterprises. Until the 1970s, industrial development was closely linked to agriculture, particularly cotton production in the Amik Plain, which stimulated the establishment of numerous ginning and pressing factories as well as food, cottonseed oil, and olive oil processing facilities.

Today, agro-industrial activities remain concentrated on the processing, packaging, and marketing of major agricultural commodities, including wheat, cotton, citrus fruits, olives, onions, parsley, and tomatoes. Most of these enterprises are located in Antakya, İskenderun, Samandağ, and Dörtyol (UCTEA, 2024)

Damage to Agricultural Production after the Earthquakes

Overall Earthquake Damage in Hatay Province

According to the Ministry's Damage Assessment Report dated January 22, 2024, a total of 250,086 residential buildings in Hatay were classified as urgently demolished, destroyed, severely damaged, or moderately damaged. In addition, 44,060 commercial buildings and 2,581 barns and haylofts sustained similar levels of damage (PSB, 2024). Overall, approximately 56%

of the province's building stock was damaged or destroyed, while in central Antakya the damage rate reached 85–90%.
The earthquakes claimed 24,147 lives and caused widespread destruction of housing, public buildings, commercial facilities, and critical infrastructure, including water supply, sewage, transportation, and airport facilities. Damage to the Port of İskenderun also temporarily disrupted maritime transportation. The disaster triggered large-scale migration from Hatay, with estimates ranging from 563,751 to 775,000 displaced people (Erkılıç, 2024; FAO, 2023a). The collapse of residential areas, workplaces, and public services severely affected the province's social and economic structure and created significant challenges for post-disaster recovery.

Damage to Agricultural Production Infrastructure
The earthquakes of February 6 and 20, 2023 caused extensive damage to agricultural production infrastructure and rural settlements throughout Hatay Province, with Antakya, Defne, Samandağ, Kırıkhan, and Arsuz among the most severely affected districts. Damage extended to cultivated land, irrigation systems, agricultural machinery, grain silos, storage facilities, greenhouses, livestock units, food-processing plants, cotton gins, olive oil facilities, aquaculture enterprises, cold storage units, and agricultural input suppliers.

Impact on Crop Production
Agricultural infrastructure and greenhouse equipment across Hatay suffered significant damage, adversely affecting greenhouse cultivation. Seeds, fertilizers, pesticides, plant protection products, and stored produce were also damaged.
Due to heavy damage to tractors and other agricultural machinery, combined with a shortage of inputs, equipment, and labor, and difficulties in accessing agricultural land, land preparation for the spring season-which should have started in February-was either not conducted or delayed in many areas. This led to a decline in crop yield and quality.
In crop production areas, substantial losses occurred in fertilizers, seeds, plant protection products, and irrigation equipment. While seed loss remained limited in Belen and Hassa districts, fertilizer loss ranged between 25% and 50% in Altınözü, Antakya, Defne, and Erzin. In Arsuz, approximately 50% of irrigation pumps were damaged, and in Kırıkhan, many grain silos were affected (FAO, 2023a).
Vegetable growers experienced yield losses due to difficulties in accessing fungicides and plant nutrition products. In Samandağ, 50–75% of irrigation equipment, greenhouses, food processing units, and agricultural warehouses were severely damaged. In Kırıkhan, Samandağ, and Altınözü, major losses in agricultural mechanization were reported. Furthermore, the use of greenhouses as temporary shelters by displaced urban residents or rural dwellers unable to return to their homes significantly reduced greenhouse production.
In some regions, ruptures along fault lines and ground slippages caused fruit trees to be uprooted and orchards to suffer major deformations. For example, a new valley 300 meters long, 50 meters wide, and 40 meters deep formed in an olive grove in the Tepehan neighborhood of Altınözü district (Figure 3).

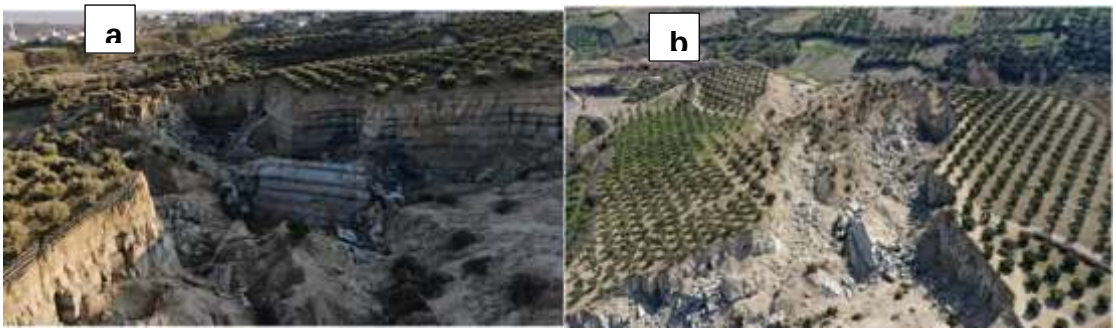

Figure 3. A split olive grove caused by the earthquake (DNA, 2023)

Impact on Livestock Production

The earthquakes caused extensive damage to the livestock sector in Hatay Province. A total of 2,861 cattle and 13,625 small ruminants were lost, while 305 corrals, 5,224 barns, and 9,381 beehives were damaged (Figure 4). The greatest losses were recorded in Antakya, Kırıkhan, Hassa, Kumlu, and Samandağ, highlighting the severe impact on districts where livestock production is a major agricultural activity.

Figure 4. Collapsed barns and corrals after the earthquake

The poultry sector was also significantly affected, with damage reported in 39 poultry enterprises, including four layer farms and one broiler operation. In several broiler farms, the collapse of feed silos and transportation disruptions caused mass bird mortality, resulting in substantial production losses (Akdemir et al., 2023).

The dairy sector experienced considerable disruption. Approximately 500 milking machines were damaged in Samandağ, while milk processing facilities in Defne and Samandağ sustained severe damage. Power outages interrupted milking operations, leading to animal health problems, reduced milk production, and increased veterinary costs. In addition, damage to feed mills, processing plants, storage facilities, transportation infrastructure, and the cold chain disrupted feed supply and milk marketing, causing significant economic losses for livestock producers.

Impact on the Fisheries Sector

The fisheries sector also suffered extensive damage. Fishing ports in İskenderun, Samandağ, Arsuz, and Dörtyol experienced severe damage to operational facilities and cold-chain infrastructure. Approximately 60% of fishing boats were damaged or destroyed; in Samandağ alone, 30 of 100 boats were completely destroyed and another 30 were partially damaged. The Food and Agriculture Organization estimated the total economic loss at approximately USD 4.5 million (FAO, 2023a, c). In addition, the İskenderun Fishing Port, which served as both a landing site and a shelter for approximately 250 fishing vessels, sustained extensive structural damage (Figure 5).

Figure 5. Fishing port in İskenderun, Hatay

As the İskenderun Fishing Port remained out of service until repairs were completed, fishing vessels were temporarily relocated to Madenli Fishing Port, located 22 km away. According to the Ministry of Transport and Infrastructure, the total damage to fishing ports was estimated at TL 489.7 million. Hatay's ornamental fish sector was also severely affected: one production facility was completely destroyed, another ceased operations following the death of its owner, and two additional farms experienced extensive fish losses due to earthquake-induced failures of earthen ponds.

Impact on Agricultural Tools and Equipmen

The earthquakes caused extensive damage to agricultural machinery and equipment across Hatay Province. A total of 410 tractors and 6,914 agricultural tools and equipment were damaged (Figure 6). Tractor losses were highest in Kırıkhan (150), followed by Antakya (122) and Hassa (69), whereas damage to agricultural machinery and equipment was most severe in Antakya (4,125 units), followed by Kırıkhan (1,749) and Kumlu (536). These losses substantially reduced agricultural mechanization capacity, thereby hindering agricultural production and post-earthquake recovery efforts.

Figure 6. Tractors and machinery buried under rubble

Impact on Agro-Industry

The earthquakes caused extensive damage to Hatay's agro-industrial sector. In districts such as Antakya, Kırıkhan, and Samandağ, widespread building collapses and severe damage to food-processing facilities brought agro-industrial activities to a standstill. Damage to transportation, energy, water supply, sewage, and communication infrastructure further disrupted agricultural production, processing, and marketing.

Following the disaster, 2,798 sales and mass-consumption enterprises and 485 manufacturing enterprises ceased operations. Business closures were concentrated in Antakya (1,760 sales enterprises and 313 manufacturing enterprises), followed by Kırıkhan and Samandağ. In addition, 485 agricultural production and processing facilities became non-operational,

including 335 bakeries, 29 fruit packing and processing facilities, 20 milk processing plants, and smaller numbers of slaughterhouses, egg-packing, spice-processing, and edible oil filling facilities. These losses severely disrupted the agricultural value chain by reducing the region's capacity to process, distribute, and market agricultural products.

Of the 121 facilities established under the Ministry of Agriculture and Forestry's Rural Development Program, 55 sustained earthquake damage, with total losses estimated at approximately TL 150.5 million (Table 14).

Table 14. Damage to Rural Development Enterprises by Sector

Sector	**Number of Enterprises**	**Estimated Loss (TL)**
Cotton (Ginning Factory)	13	50.000.000
Greenhouse	7	5.500.000
Cold Storage Facility	2	15.000.000
Livestock (Dairy Production)	2	20.000.000
Winery	1	1.000.000
Flour Factory	4	5.000.000
Animal Feed Factory	2	24.000.000
Olive Oil Factory	24	30.000.000
Total	**55**	**150.500.000**

Impact on Migration, Agricultural Labor, and Land Use

The earthquakes triggered large-scale migration, resulting in severe labor shortages in the agricultural sector. According to AFAD, approximately 564,000 people migrated from Hatay, while the Food and Agriculture Organization estimated the number at 775,000 (FAO, 2023a). This population displacement significantly disrupted planting and harvesting activities, threatening the sustainability of agricultural production.

According to the Farmer Registration System, the number of registered farmers in Hatay declined from 21,712 in 2022 to 20,044 in 2023. In addition, 7,913 decares of pastureland were rezoned for post-disaster housing and 424 decares for industrial development (Anonymous, 2023b). The establishment of container settlements and temporary shelters on agricultural land further reduced the area available for cultivation and negatively affected rural livelihoods.

Impact on the Physical Structure of Agricultural Lands

The earthquakes caused significant changes to the physical structure of agricultural lands. Soil uplift, fault-induced ground deformation, and topographic changes were observed across the affected areas, resulting in inconsistencies between land parcel records and geographic information system (GIS) data. Surface ruptures and ground displacement disrupted land consolidation projects and cadastral systems, while in some locations, large fault-induced valleys split fruit orchards into two (Figure 7).

Figure 7. Valley formed in an olive grove due to earthquake-induced landslide (DNA, 2023).

Impact on Logistics and Foreign Trade

The earthquakes caused severe liquefaction and lateral spreading in Antakya, Samandağ, and İskenderun, resulting in extensive damage to airports, highways, and railways and seriously disrupting transportation throughout Hatay. Blocked roads further restricted access to the affected areas during the emergency response period.

According to FAO field assessments, liquefaction along the İskenderun coast caused parts of the port to subside by approximately 1.5 m below sea level, severely damaging port infrastructure and forcing the temporary suspension of operations (FAO, 2023a). Numerous export-ready containers were destroyed, and fires at the port (Figure 8) caused the spoilage of food and agricultural products, resulting in substantial economic losses. Because the Port of İskenderun is a strategic logistics hub for Hatay, the Çukurova Region, and Eastern and Southeastern Anatolia, the disruption of its operations adversely affected regional agro-industrial activities and foreign trade (Özsalman and Yıldırım, 2024; Ketboga, 2024).

Figure 8. Burned container depot in İskenderun Port (a); post-earthquake condition of the depot (b) (UCTEA, 2023).

Liquefaction in the Amik Plain also damaged the Antakya–Cilvegözü highway, Hatay Airport runway (Figure 9), and railway infrastructure, leading to the suspension of civilian air transport and further restricting freight movement.

Previous studies have shown that earthquake-related damage to transportation infrastructure significantly disrupted both exports and imports (Özsalman and Yıldırım, 2024; Bardakçı and Demirtaş, 2023; Can et al., 2024). Hatay was among the three provinces experiencing the greatest export losses, and together these provinces accounted for 7.5 percentage points of the overall 11.1% decline in exports recorded across the earthquake-affected region.

Figure 9. Damaged runway (a) and airport connection roads (b) at Hatay Airport (UCTEA, 2023; Gokceoglu, 2023)

Impact on Production and Foreign Trade

The earthquakes caused widespread damage to production infrastructure in Hatay, temporarily bringing commercial activities to a standstill. Physical destruction of production facilities, workforce losses due to fatalities and migration, and disruptions to transportation and supply chains significantly reduced production capacity and export performance. In particular, damage to the road network (Figure 10) severely hindered logistics operations, resulting in production delays, order cancellations, and substantial losses in foreign trade (Yucel, 2023).

Figure 10. Earthquake damage to highways between Hatay-Kırıkhan (a) and Kırıkhan-Reyhanlı (b)

Debris Management and Its Impact on Ecosystems

The post-earthquake debris removal process was often conducted without adequate environmental safeguards, resulting in substantial impacts on natural ecosystems and agricultural landscapes. Unregulated disposal of rubble threatened biodiversity-rich areas in Hatay (Figure 11a), while debris dumping near residential areas and agricultural land (Figures 11b and 11c), including fruit and vegetable production areas, created environmental and public health concerns and disrupted agricultural activities.

Olive groves, mandarin orchards, and other agricultural lands were buried beneath debris, causing considerable economic losses and hindering agricultural recovery. In addition, the transport and disposal of construction waste contributed to the contamination of surface and groundwater (Figures 11b and 11c), posing potential risks to soil quality, agricultural production, and the food chain. The Asi River and the Mileyha Wetland, where the river flows into the Mediterranean Sea, were heavily affected by construction waste, while dust and particulate matter generated during debris removal (Figure 11d) further threatened environmental quality and human health (UCTEA, 2024).

Figure 11. Rubble dump areas: (a) Composition of waste in dump sites; (b-c) Rubble sites in İskenderun Sarımazı and Pirinçlik—located near settlements, agricultural land, and groundwater recharge zones; (d) Dust cloud formed after dumping (UCTEA, 2023).

CONCLUSION

This study provides a comprehensive assessment of the impacts of the February 6 and 20, 2023 earthquakes on the agricultural production system of Hatay Province, the region most severely affected by the disaster. The earthquakes caused extensive damage to agricultural infrastructure, including farmland, irrigation systems, greenhouses, storage facilities, livestock production units, and agro-industrial enterprises. Beyond physical destruction, they significantly disrupted agricultural production, supply chains, rural livelihoods, and the province's capacity to sustain food production.

The findings indicate that losses in crop, livestock, fisheries, and agro-industrial sectors, together with damage to transportation and logistics infrastructure and large-scale migration, considerably weakened the regional agricultural economy and reduced agricultural productivity.

Based on these findings, the following recommendations are proposed:

a) Reconstruct agricultural infrastructure through district-based prioritization, with emphasis on irrigation systems, greenhouses, livestock shelters, agricultural machinery, and rural enterprises.

b) Mitigate labor shortages by supporting the return of displaced farmers and agricultural workers through housing, financial assistance, and social support programs.

c) Update GIS databases and the Farmer Registration System to address land record inconsistencies caused by earthquake-induced land deformation.

d) Strengthen the resilience of logistics infrastructure, including ports, transportation networks, cold-chain facilities, processing plants, and agricultural supply systems.

e) Promote disaster-resilient agriculture through risk reduction strategies, early warning systems, resilient agricultural insurance schemes, continuous monitoring of fault-affected areas, and sustainable land management practices.

Urgent recovery priorities include restoring access to agricultural inputs, irrigation water, credit, and markets to enable producers to resume agricultural activities.

In conclusion, the agricultural losses experienced in Hatay represent not only a regional challenge but also a national concern for food security and agricultural sustainability. Long-term recovery will require an integrated, data-driven, and locally adapted reconstruction strategy that simultaneously supports agricultural production, rural livelihoods, and the resilience of the agricultural sector.

ABSTRACT

High production costs remain a major constraint for loquat cultivation. The expansion of loquat orchards in Turkey depends on cost reduction, increased productivity, and the supply of early and profitable products. High-density orchards using dwarf or semi-dwarf early cultivars offer a potential solution. The aim of the study is to investigate the vegetative growth and phenological characteristics of the loquat cultivar grafted on some quince rootstocks. In the experiment, 'Hafif Çukurgöbek (HÇG)' loquat cultivar grafted on three Quince rootstocks (BA 29, Quince A = MA, Quince C = MC) was used. The experiment was laid out in a completely randomized design with 5 replications and 6 plants were used in each replicate. In the study, vegetative growth parameters such as annual shoot length, trunk diameter of stock and scion and also structure canopy, phenological observations such as *inflorescence characteristics* (number of peduncles per cluster, number of flower buds per cluster, and number of flowers per cluster), and fruit set ratios (percent blossom ratios, % initial fruit set, and % final fruit set) of the cultivar/rootstock combinations were determined. Quince-C rootstock gave higher values in terms of annual shoot length, scion and rootstock diameter compared to Quince-A and BA-29 rootstocks. The differences between the rootstocks in terms of vegetative parameters were found to be statistically significant at 5% level. According to the three-year average, the flowering rate was found the highest in BA-29 rootstock, the lowest in MA rootstock. MA rootstock yielded the lowest value in the ratio of fruit harvested, while MC and BA-29 gave close values to each other. The data shows that BA-29 and MC give better results than the MA rootstock.

Keywords: loquat, quince rootstocks, vegetative growth, flowering, fruit set

INTRODUCTION

Loquat (*Eriobotrya japonica* Lindl.) is an evergreen fruit species belonging to the family Rosaceae within the order Rosales. It is mainly cultivated under subtropical climatic conditions, generally between latitudes 20° and 35° in both hemispheres. Loquat trees can tolerate winter temperatures down to –10 °C; however, flowers and developing fruits are susceptible to damage at approximately –3 °C (Polat, 2019).

Due to its early ripening period—coinciding with a season when most other fruit species are not yet harvested—loquat commands high market demand and premium prices. For this reason, it represents an economically valuable fruit crop for both producers and consumers (Polat and Kaşka, 1991; Polat, 1996; Özçağıran et al., 2011). Nevertheless, loquat trees typically reach heights of 5–10 m and develop large, spreading canopies, which increase production costs and

complicate cultural practices. Controlling tree vigor is therefore essential, and the use of dwarfing rootstocks is among the most effective approaches. Dwarfing rootstocks enable high-density planting systems that facilitate pruning, spraying, thinning, and especially harvesting, thereby reducing labor requirements while improving yield, fruit quality, and marketable production.

Considerable research has been conducted to identify suitable dwarfing rootstocks for many fruit species. In particular, clonal quince rootstocks—also evaluated in the present study—have been widely and successfully used in pear production, where they provide significant vigor control and improved orchard management. However, studies investigating their potential use in loquat cultivation remain limited. Previous research on loquat rootstocks has primarily focused on graft compatibility with wild *Eriobotrya* species (Zhang et al., 2007, 2010, 2011), graft success on loquat seedlings and quince rootstocks (Polat and Kaşka, 1992a, 1992b; Pio et al., 2010; Polat, 2018a, 2019, 2020, 2021b, 2021c), effects on vegetative growth (Polat and Kaşka, 1992a, 1992b; Polat, 1995; Baratta et al., 2001; Pio et al., 2007), and tolerance to salinity in irrigation water or soils (Garcia-Legaz et al., 2005; Lopez et al., 2007; Manuel et al., 2008). Despite these efforts, the identification of effective dwarfing rootstocks for loquat—comparable to those used in apple and pear—remains a critical research need for the development of high-density orchards.

One of the major constraints limiting the expansion of loquat cultivation is the large canopy size of trees grafted onto seedling rootstocks, which increases the cost of cultural operations, particularly pruning and fruit thinning. Reducing production costs, improving productivity, and achieving earlier yields are therefore essential objectives. Previous high-density planting studies have reported promising results, including reduced tree size (e.g., average heights around 1.87 m) and substantially lower labor requirements. These findings indicate that high-density loquat production with dwarf trees can provide earlier cropping, higher yield per unit area, and improved economic returns.

Several studies have suggested that quince can be used as a rootstock for loquat (Morton, 1987; Lin et al., 1999; Pio et al., 2007; Hummer and Janick, 2010; Badenes et al., 2013; Polat, 2018b). Earlier reports (Polat and Kaşka, 1992a, 1992b; Polat, 1995) indicated that quince rootstocks induced approximately 20–25% dwarfing compared with loquat seedlings, and BA-29 in particular was recommended for evaluation in high-density loquat orchards (Polat et al., 2003, 2004). Likewise, Pio et al. (2007) emphasized quince as a promising rootstock due to its capacity to reduce tree size and facilitate orchard operations.

Although some literature indicates that quince rootstocks have a dwarfing effect on loquats, studies that evaluate the effects of these rootstocks on fruit yield, quality, and vegetative growth are scarce. There is also a lack of comparative studies detailing how different quince rootstocks affect these characteristics. Therefore, in a study initiated in 2016 and still ongoing, the effects of clonal quince, hawthorn, and loquat seedling rootstocks on vegetative growth, flowering phenology, fruit set, fruit quality, and yield in loquats are being investigated. Preliminary data have been obtained regarding the effects of quince rootstocks on the vegetative development, phenological traits, yield, and fruit quality parameters of loquat cultivars grafted onto them, but it has been stated that these results are not yet conclusive and that the studies must be continued (Akkuş and Polat, 2021, 2022). This paper, which is part of the ongoing research, presents a comparative analysis of the effects of Quince-A, Quince-C and BA 29 rootstocks on vegetative growth of the HÇG loquat cultivar.

MATERIAL AND METHODS

Material

This study was conducted in Hatay, Turkey (36°12′E, 36°52′N; 80 m a.s.l.) over three consecutive years: 2018, 2019, and 2020. The experimental site is characterized by a typical

Mediterranean climate, with an average annual temperature of 18.3°C and an annual precipitation of 1168 mm, most of which occurs during the winter and spring seasons. The soil at the site is alkaline (pH 7.76), contains low levels of lime (2.4%), moderate salinity (EC: 446 µS/cm), and has a sandy-loam texture (57.37% sand, 25.32% loam, and 12% clay).
One-year-old 'Hafif Çukurgöbek' loquat trees, budded onto BA-29, Quince-A, and Quince-C quince rootstocks, were planted in January 2017 at a spacing of 1.0 × 0.5 m (equivalent to 2000 trees per decare) (Figure 1). Drip irrigation and standard horticultural practices were applied throughout the study period. Trees were trained using the open-center system.

Rootstocks and Varieties
The rootstocks BA-29, Quince-C, and Quince-A used in the experiment were originally selected at the East Malling Research Station, United Kingdom.
'Hafif Çukurgöbek' is an early-maturing loquat cultivar selected in Turkey (Demir, 1987). It produces medium-sized, orange-colored fruits that are very tasty and sweet. The cultivar is self-fertile and resistant to black spot disease caused by *Spilocaea eriobotryae*.

Method
The experiment was designed as a completely randomized design (CRD) with five replications. Each replication consisted of six plants.

Inflorescence Characteristics, Flowering, and Fruit Set Rate
For each rootstock, ten trees were selected, and four shoots per tree were used for the following measurements: number of peduncles per cluster, number of flower buds per cluster, and number of flowers per cluster. In accordance with the methodology described by Polat (2007, 2015) and Akkuş and Polat (2022), these observations were conducted at approximately 3-day intervals starting when the clusters first became visible on the shoots.
The flowering rate (%), initial fruit set (%), and small and final fruit set ratios (%) were calculated according to the methods proposed by Westwood (1995) and Polat (2007, 2015). To determine fruit set rate, four branches were selected randomly (one in each cardinal direction) and were tagged. Approximately 250-300 flower buds were counted at the pre-blossom phase on each of the selected branches. Thus, ca. 1000-1200 flower buds were selected on each tree. The flowers of each tagged branch were counted, and blossom rate was calculated as the proportion of the flower to bud number. At the end of blossoming, the number of initial fruits was counted, and initial fruit set percentage was calculated dividing this value by the flower number. Final fruit set percentage was determined by calculating the proportion of the number of harvested fruits to the number of flowers.

Vegetative Growth Measurements
Tree vegetative growth was assessed at mid of May every years measuring the following parameters:
Annual shoot length (cm): The length of four shoots per tree (one for each cardinal direction) was measured with a 5-meter measuring tape.
Trunk diameter (mm): Trunk diameters of both the scion and rootstock (5 cm above and below the graft union) were measured with a digital caliper (Mitutoyo, Kawasaki, Japan) with 0.01 mm sensitivity.
Crown height (cm): The vertical distance between the first branching point of the scion (or tree trunk) and the trees apex was measured with a 5-meter measuring tape.

Tree height (cm): The vertical distance between the bud union and the tree apex was measured with a 5-meter measuring tape.

Data Analysis and Statistics

The data were analyzed using analysis of variance (ANOVA) based on a completely randomized design. Mean comparisons were performed using Tukey's HSD multiple comparison test at the 0.01 significance level (Steel and Torrie, 1980). Percentage values were subjected to angular (arcsine) transformation to improve normality prior to ANOVA.

RESULTS AND DISCUSSION

Inflorescence Characteristics, Flowering, and Fruit Set Rate

Inflorescence Traits

The results presented in Table 1 show that the rootstock had significant effects on the number of peduncles per cluster, flowering rate, and final fruit set. Trees on Quince-C produced significantly higher number of peduncles per cluster than BA-29 (Table 1).

Table 1. The effects of rootstocks on the inflorescences properties, blossoming and fruit set rates of 'Hafif Çukurgöbek' loquat cultivar (2018–2020).

Rootstocks	No. of peduncle per cluster	No. of flower buds per cluster	No. of flowers per cluster	Flowering Rate (%)	Initial fruit set (%)	Small fruit(%)	Final fruit(%)
Quince-A	15.8 ab	142.7	118. 5	82.9 b	12.0	6.9	2.5 b
Quince-C	16.5 a	148.8	137.5	91.9 a	10.6	6.0	4.6 a
BA-29	14.7 b	139.4	128.2	93.1 a	10.8	6.2	4.8 a
Significance	**	NS	NS	**	NS	NS	**

(x) Means within each column followed by different letters are significantly different according to Tukey's HSD test at $p < 0.01$. (y) NS: Not significant.

In the literature, the number of studies evaluating comprehensively inflorescence characteristics, flowering behavior, and fruit set rates for trees grafted onto the rootstocks used in our research is fairly limited. Akkuş and Polat (2022) and Polat and Sezer (2022) reported that, in trees grafted onto the Quince-A rootstock, the number of peduncles per cluster ranged between 12.8 and 17.7, the number of flower buds per cluster ranged between 172.2 and 128.0, and the number of open flowers ranged between 150.3 and 102.5. In the same studies, these parameters were reported to be, respectively, 10.5–19.5, 133.2–156.5, and 124.8–143.8 for trees on Quince-C rootstock, and 10.83–16.69, 131.80–143.17, and 119.41–132.64 for trees on BA-29 rootstock. In an earlier study, the numbers of peduncles, flower buds, and open flowers were reported to be, respectively, 9.0, 123.3, and 115.3 in trees grafted onto hawthorn rootstock, and 10.3, 156.9, and 139.6 in trees grafted onto loquat seedling rootstock (Polat, 2023). These values are substantially similar to those obtained in the present study.

Flowering Rate (%)

Rootstock effect on flowering rate was highly significant ($p < 0.01$) with trees on Quince-C (91.9%) and BA-29 (93.1%) exhibiting higher flowering rates than those on Quince-A (82.9%)(Table 1). This suggests that Quince-A restricted vegetative growth and partially reduced flowering potential. Polat and Sezer (2022) reported flowering rates of 91.6%, 93.5%, and 90.7% for trees grafted onto Quince-A, Quince-C, and BA-29 rootstocks, respectively, while Akkuş and Polat (2022) found, for trees grafted onto same rootstocks, values of 80.1%, 91.9%, and 92.7%, respectively. In another study, the flowering rate was 93.5% in plants

grafted onto hawthorn rootstock and 89.0% in those grafted onto loquat seedling rootstock (Polat, 2023). The findings obtained in our study are consistent with these reported values.

Initial Fruit Set (%)

Although differences among rootstocks were not statistically significant ($p > 0.05$), trees on Quince-A displayed slightly higher initial fruit set than BA-29 and Quince-C (Table 1). Previous studies have reported that the initial fruit set rate ranged between 8.4% and 13.8% in trees on Quince-A rootstock, between 9.8% and 11.0% in trees on Quince-C, and between 10.5% and 10.9% in trees on BA-29 (Akkuş and Polat, 2022; Polat and Sezer, 2022). In another study, this parameter was found to be 11.2% in trees grafted onto hawthorn rootstock, and 10.0% in those grafted onto loquat seedling rootstock (Polat, 2023). The findings obtained in our study are consistent with these previous reports.

Percent of Small Fruit (%)

Although differences between rootstocks in *percent of small fruit* were not statistically significant, trees on Quince-A tended to have higher percent of small fruit, suggesting possible limitations in resources allocation to fruit (Table 1). Akkuş and Polat (2022) and Polat and Sezer (2022) reported small fruit ratios ranging between 4.5% and 8.0% for trees on Quince-A, between 5.3% and 6.3% for trees on Quince-C, and between 6.1% and 6.2% for trees on BA-29 rootstocks. Polat (2023) found that the small fruit ratio was 7.9% and 5.6% in trees on hawthorn rootstock and loquat seedling rootstock, respectively.

Final Fruit Set (%)

The final fruit set rate was significantly affected by the rootstock ($p < 0.01$). Trees on BA-29 (4.8%) and Quince-C (4.6%) exhibited higher fruit retention compared to those on Quince-A (2.5%), suggesting that trees on Quince-A, despite a relatively high flowering rate, were more prone to fruit drop. Previous studies (Akkuş and Polat, 2022; Polat and Sezer, 2022) reported that the final fruit set (fruit harvested) rates were 2.2–3.0%, 3.7–5.2%, and 4.7–4.9% for trees on Quince-A, Quince-C, and BA-29 rootstocks, respectively. Polat (2023) found that the final fruit set rates was 6.3% in plants grafted onto hawthorn rootstock, and 4.2% in those grafted onto loquat seedling rootstock. Overall, Quince-C and BA-29 rootstocks induced the highest overall performance in terms of flowering and fruit set, confirming that these rootstocks are more suitable for the 'Hafif Çukurgöbek' loquat cultivar. These findings are consistent with previous studies by Polat et al. (2004), Durgaç et al. (2006), Polat (2018), Akkuş and Polat (2022), and Polat and Sezer (2022), who reported significant effects of quince rootstocks on loquat flowering intensity and fruit set

Vegetative growth

Regarding annual shoot length and trunk diameters of both scion and rootstock, plants grafted onto the Quince-C rootstock exhibited more vigorous growth and significantly higher values compared to those on Quince-A and BA-29 rootstocks (Figures 2–4).

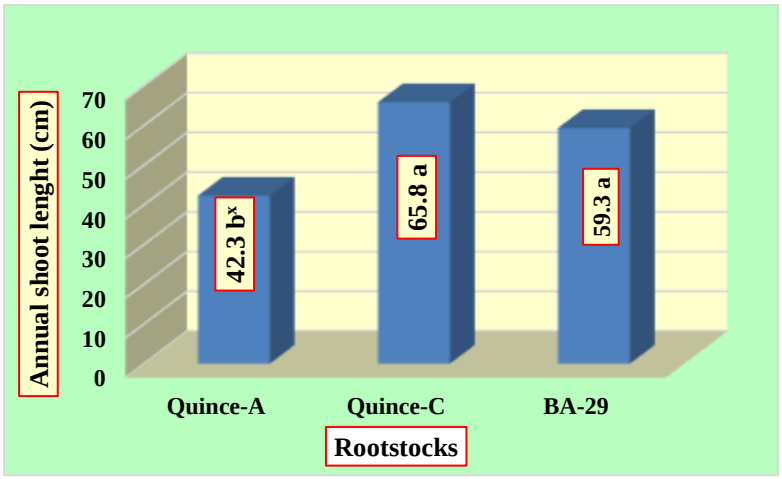

Figure 2. Average annual shoot length of 'Hafif Çukurgöbek' loquat grafted onto quince rootstocks during 2018–2020.
(x) Means followed by different lowercase letters indicate significant differences according to Tukey's test at $p < 0.05$.

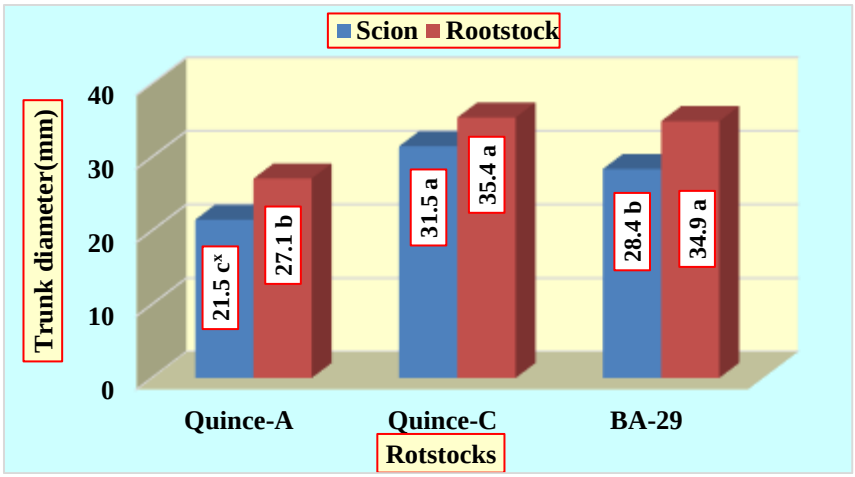

Figure 3. Average scion and rootstock trunk diameters of 'Hafif Çukurgöbek' loquat grafted onto quince rootstocks during 2018–2020.
(x) Means followed by different lowercase letters within the same parameter indicate significant differences according to Tukey's test at $p < 0.05$.

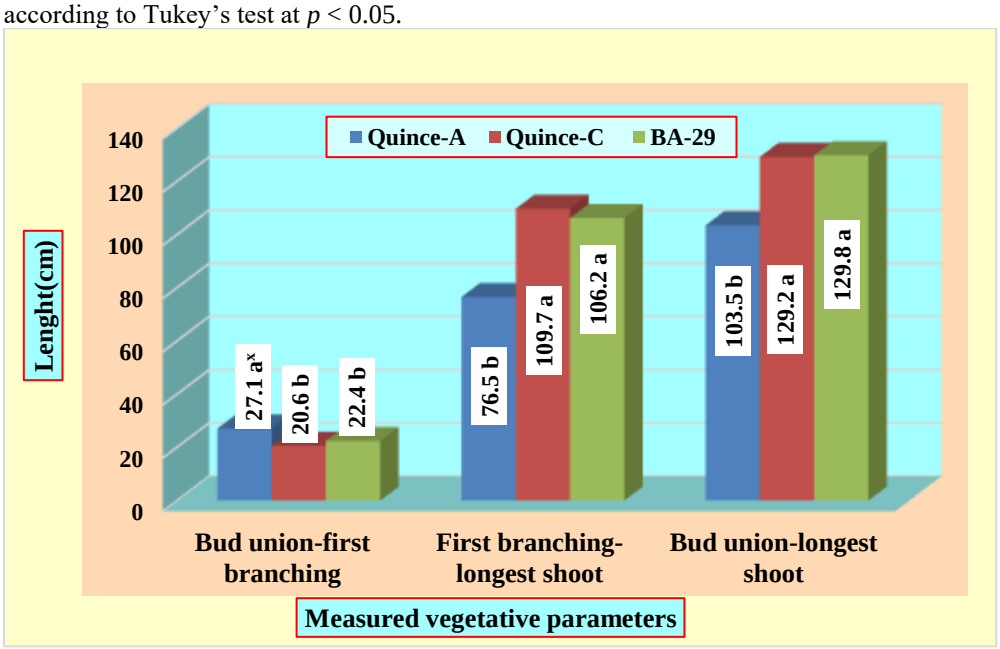

Figure 4. Some vegetative growth parameters of 'Hafif Çukurgöbek' loquat grafted onto quince rootstocks (2018–2020 average).
(x) Means followed by different lowercase letters within the same parameter indicate significant differences according to Tukey's test at $p < 0.05$.

The Quince-A rootstock showed lower values than the other two rootstocks for all parameters except for the distance between the budding point and the first branching on the trunk. In this particular measurement, Quince-A recorded the greatest distance, followed by BA-29, while Quince-C exhibited the shortest. Differences among rootstocks in terms of vegetative growth parameters were statistically significant at the 5% level.
Tree growth was initially rapid; however, crop load and pruning management appeared to regulate tree height and canopy volume. Currently, most trees have nearly occupied their allotted planting space, with average heights ranging from 1.51 to 1.85 m and trunk diameters between 27.01 mm and 38.54 mm. These results are consistent with those reported by Hueso et al. (2007) in their study on the 'Magdal' cultivar grafted onto Quince-C rootstock.
In previous studies, Polat and Kaşka (1992a) reported an average shoot growth of 23.4 cm for plants grafted onto the Quince-A rootstock. Polat (1995) measured scion diameters in loquat seedlings ('Akko-XIII' and 'Armut Şekilli' cultivars) grafted onto Quince-A rootstocks as 18.24 mm, 30.15 mm, and 36.39 mm, and seedling heights as 74.3 cm, 120.2 cm, and 124.4 cm during the period between 1993 and 1995, respectively. The values obtained in the present study are consistent with those reported by Polat and Kaşka (1992a) and Polat (1995).

CONCLUSION

Reducing vegetative growth is very important in loquat cultivation due to its very high tree size. The most effective method for this is the use of dwarfing rootstocks such as quince (Cydonia oblonga). In this study, the effect of Quince-A, Quince-C and BA 29 quince clone rootstocks on phenological properties, flowering and fruit set rates of the HCG variety was studied in detail. Our preliminary findings indicate that dwarfing quince rootstocks are suitable for intensive loquat plantings. Among the rootstocks tested, BA-29 and Quince-C outperformed Quince-A. However, it is of great benefit to continue the further work to make a definitive judgment about the possibilities of using BA-29, and Quince-C rootstocks as new dwarfing rootstocks. Therefore, researches need to be continued, especially to determine all the characteristics regarding yield and fruit quality.

ABSTRACT

The widespread adulteration of Diammonium Phosphate (DAP) fertilizer severely undermines agricultural productivity and inflicts significant economic losses on farmers, who lack access to costly and centralized laboratory verification methods. This paper presents the design and implementation of a novel, low-cost, and portable electronic device for the on-site detection of DAP adulteration. The core detection principle is based on a precise density measurement, leveraging the standard density of pure DAP (1379 kg/m³). The system hardware integrates a custom 3D-printed conical frustum vessel of fixed volume with a high-precision load cell for mass measurement, a microcontroller for data processing, and an LCD for user-friendly result display. The embedded firmware calculates the density and classifies the sample's purity. Extensive testing validated the system's performance, demonstrating a 95% accuracy in identifying adulterated samples when benchmarked against standard value of the density. This consumer-grade electronic solution empowers farmers with immediate, in-field quality control. Future work will focus on enhancing the system through IoT connectivity for data logging and the integration of multi-sensor fusion for a more robust analysis.

Keywords: Adulteration Detection, Smart Sensor, Precision Agriculture, Embedded Systems, Di-ammonium Phosphate, Fertilizer Quality.

INTRODUCTION

Agriculture is the backbone of Pakistan’s economy and a crucial sector of many countries worldwide. It supplies a livelihood for a significant portion of the population [1] and is the most essential source of food [2] and raw materials such as fiber and biomass for green energy [3].

Over the past few centuries, the global population has been increasing at an alarming rate. In 1800, the world population was around 1 billion, and it reached approximately 7.875 billion by 2021 [4, 5]. According to the World Food Summit, the global population is expected to grow by about 72% between 1995 and 2050. This rapid growth indicates a potential shortage of food in the future. To address this challenge, it is essential to focus on advancements in agricultural technology and the use of high-quality fertilizers and pesticides in farming systems. Food production must increase by nearly 70% to meet the nutritional demands of an estimated 9 billion people by 2050 [6, 7].

The use of fertilizers and pesticides in agriculture is an essential strategy for ensuring global food security. Fertilizers not only contribute to soil processes but also play a significant role in enhancing crop production and improving soil fertility [8]. However, due to climatic factors and the improper use of fertilizers, such as the application of impure or substandard products, soil fertility and crop yields are not increasing at the rate required to meet the demands of the growing population. Among all fertilizers, di-ammonium phosphate (DAP), with the chemical formula $(NH_4)_2HPO_4$, is one of the most widely used. It provides approximately 18% nitrogen and 46% phosphorus, which are vital for strong and healthy plant growth [9].

Farmers commonly use DAP fertilizer to enhance crop growth, as it is beneficial for nearly all crop types. Phosphorus in DAP promotes flowering and fruiting, while nitrogen supports overall plant growth. By applying DAP, farmers can improve crop production using the same land resources. For instance, if a farmer cultivates hybrid rice on two acres without using DAP, the yield may be around 5–6 tons. However, applying a 50 kg bag of DAP to the same area can increase production by approximately 2 tons, assuming all other conditions remain constant. Similar improvements can be observed in other crops as well. Thus, DAP fertilizer offers a significant advantage in agriculture, enabling higher yields and improved soil fertility without expanding cultivated land [10].

It can be concluded that farming without DAP is better than having no fertilizer at all; however, the use of DAP significantly enhances crop yield. The effectiveness and importance of DAP can be observed from Fig 1(a) and Fig 1(b). Hybrid rice (Tahafuz-413) from the Sungro company was cultivated on two acres in District Kasur, Punjab, Pakistan, under identical conditions and with the same land resources, as shown in the figures. The crop shown in Figure 1(a) received a 50 kg bag of DAP and developed an average of 35 tillers per plant. In contrast, the rice crop shown in Figure 1(b), which was not provided with DAP, produced only 22 tillers per plant. Both crops were grown under the same conditions and had completed their growth cycle. Therefore, it is evident that the crop shown in Fig 1(a) produced a higher yield than that in Fig 1(b). These results demonstrate that applying pure DAP fertilizer can significantly increase crop production.

Figure 1. Comparison of rice growth with and without DAP fertilizer. (a) A higher number of tillers and yield were observed with DAP application. (b) Reduced tiller count and yield without DAP

Although DAP is more expensive than other fertilizers, its alkaline properties and high solubility make it essential for nearly all crops. In August 2025, the price of DAP is approximately 1,300 PKR per 50 kg bag in Pakistan [11], which is often unaffordable for small-scale farmers. Nevertheless, since it is a basic requirement for crop growth, many farmers still

purchase it with their hard-earned income. Unfortunately, the reality is concerning: fertilizers sold by local dealers are often impure. According to the Soil Research Development Institute (SRDI), about 40% of fertilizers used in agriculture are adulterated with irrelevant materials such as sand, soil, salt, and colored stones, as reported by a leading Bangladeshi daily [12].

Despite the availability of various processes to assess fertilizer quality, good-quality fertilizer is still difficult to find in the market, and adulterated products continue to be sold [13]. Some local dealers mix or color stones, nitrogen, phosphorus, and potassium (NPK), and single super phosphate (SSP) fertilizers, and then sell them as pure DAP. This problem has worsened with the rising price and demand for DAP, which is significantly more expensive than NPK and SSP. Consequently, some dealers adulterate DAP to increase their profit margins, resulting in impure fertilizer reaching farmers. When farmers purchase and apply such impure DAP, they often observe no improvement in crop growth and become disheartened, unaware that they were deceived at the time of purchase. As a result, crop yield remains low, and their investment is wasted. Various methods available to check the quality of DAP are discussed in the related work section, but all the discussed methods have some disadvantages, and farmers face challenges in verifying DAP quality.

To overcome these challenges, a density-based system has been designed to check the quality of DAP fertilizer. Common adulterants include salt, sand, soil, colored stones, and colored NPK and SSP fertilizers [12]. Each of these materials has a true density different from that of pure DAP, as shown in the table below. The true density of pure DAP is approximately 1380 ± 24 kg/m^3 [14].

In the proposed system, a cone-shaped cup with a fixed volume was designed in SolidWorks. The cup is filled with DAP, and its true density is calculated using the formula density = mass/volume. A load cell (HX711) module measures the weight of the DAP in the fixed-volume cup for density calculation. An ESP-32 microcontroller receives the signal from the load cell and compares the measured density of the DAP with the true density. The LCD shows the result, indicating whether the DAP sample is pure or impure. Protective casing and the cup were both designed in SolidWorks and fabricated using a 3D printer. The proposed system is low-cost, automatic, portable, and user-friendly, allowing farmers to easily assess the quality of DAP fertilizer and avoid deception during purchase.

In order to systematically comprehend the background and driving factors of the proposed system, the following section reviews previous research on fertilizer adulteration detection and related sensing or testing technologies.

This study is motivated by the need for a rapid, user-friendly, and low-cost device to evaluate the quality of DAP fertilizer. The key contributions of this research are:

- The design and development of a low-cost device to assess DAP fertilizer quality based on true density.

- A user-friendly system that is both cost-effective and efficient, allowing farmers, suppliers, and quality control agencies to verify DAP quality.

- Reliance on physical properties rather than complex chemical composition, making it suitable for on-site quality assessment.

This device addresses a critical gap in existing DAP testing techniques, which are predominantly laboratory-based and time-consuming, thereby supporting quality verification for agricultural development.

RELATED WORK

Fertilizers play a crucial role in agriculture, but DAP is among the most widely used because it helps crops grow strong and healthy. The importance and demand for DAP fertilizers are higher than for other fertilizers, which makes them more susceptible to adulteration. Possible adulterants include salt, sand, soil, colored stones, and sometimes colored NPK and SSP fertilizers [12]. The true density of pure DAP differs from that of all potential adulterants. Specifically, the density of pure DAP is approximately 1370 kg/m³, which is distinct from the densities of other adulterated materials, as shown in Fig 2(a). Several expensive studies have proposed different methods and techniques that include flame photometry, vacuum desiccators, gravimetric methods, near-infrared (NIR) spectroscopy, chlorophyll meters (SPAD-502), and fertilizer sphericity analysis [15, 16].

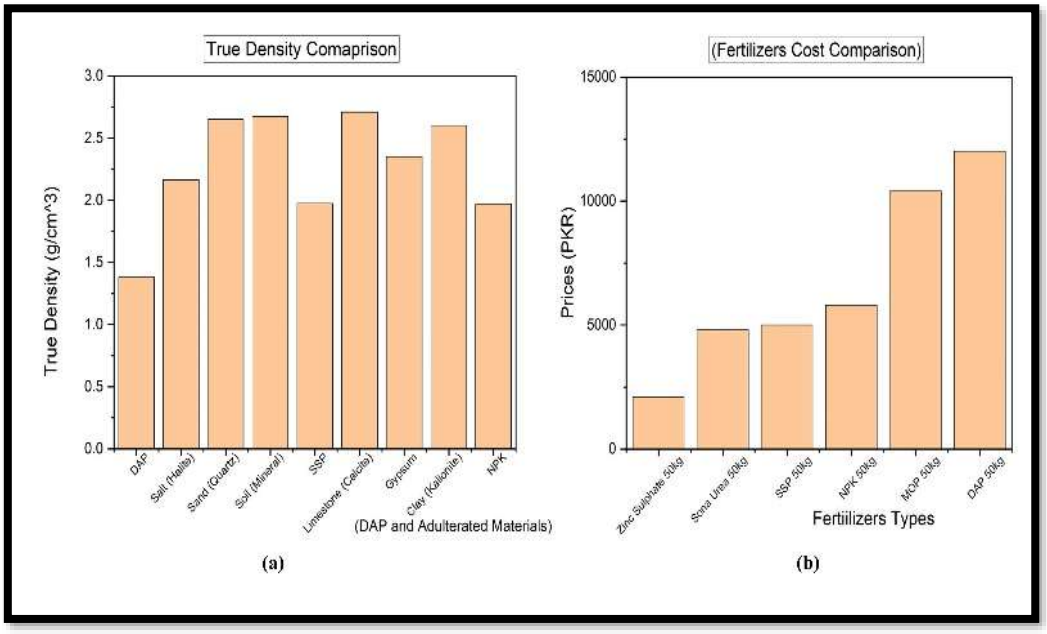

Figure 2. (a) True Density of DAP and Possible adulterated material (b) Cost Comparison of all Fertilizers

Chemical composition methods utilize expensive laboratory instruments to measure nutrient contents such as nitrogen and phosphorus in DAP, which are often unaffordable for farmers [17]. X-ray fluorescence is a non-destructive technique used to determine elemental composition and moisture content of DAP to assess its purity [18]. It operates by exiting atom in the sample with X-rays of specific elements that allow to detect the major nutrients like nitrogen and phosphorus. However, this method is not fully reliable because moisture levels vary with weather conditions. Similarly, NIR spectroscopy is another non-destructive approach, but it requires complex calibration models and reference data [19]. Although this method can also be used to check the quality of DAP, its accuracy can be affected by the particle size, color, and moisture variation of DAP. These methods can be used to evaluate fertilizer quality, but they are generally expensive, time-consuming, and impractical for farmers. The importance and demand for DAP fertilizers are higher than for other fertilizers, which makes them more susceptible to adulteration. This is primarily due to its comparatively high price, approximately 12,000 to 13,000 PKR per bag, as shown in Fig 2(b). In contrast, fertilizers such as zinc sulfate are available at much lower prices. To increase profit, some local dealers coat or mix lower-cost fertilizers, such as NPK and SSP, and sell them as pure DAP. This fraudulent practice allows dealers to exploit the price difference between DAP and other fertilizers for financial

gain. Various methods, both expensive and inexpensive, are available to check the quality of DAP fertilizer. Farmers sometimes use inexpensive, homemade methods—such as heating fertilizer on a griddle to test its quality—but these techniques are largely inaccurate, manual, and highly uncertain. On the other hand, several international devices are available for fertilizer quality testing; however, they are very expensive and unaffordable for most farmers. Laboratory equipment can also be used to determine the phosphorus content in DAP, but the process typically takes up to two days to produce results. Therefore, existing methods have several limitations—they are time-consuming, manual, inaccurate, and difficult for farmers to operate. As mentioned earlier. The proposed system is designed to evaluate the quality of DAP based on its density. The comparison of the proposed method with existing techniques, along with their respective advantages and drawbacks, is presented in Table 1 of the Results section.

METHODOLOGY

To overcome the limitations of existing methods, the proposed system provides a low-cost, user-friendly, and portable solution that enables farmers to evaluate the quality of DAP fertilizer through a straightforward procedure, as shown in Fig 3.

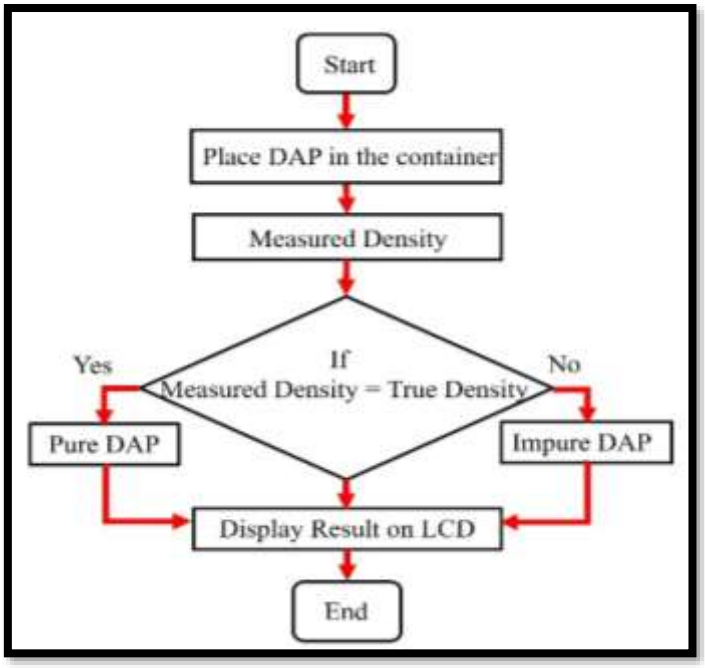

Fig 3: Flowchart illustrating the complete system workflow

In this approach, a DAP sample is placed into a cone-shaped cup with a fixed volume of 2.05 × 10^4 mm^3, and its mass is measured to calculate density. The overall process is illustrated using a flowchart, which presents a clear and practical depiction of the system workflow. The significance of flowcharting for process visualization was recognized as early as 1972 by Robert G. Staples, who described it as an effective graphical tool for representing workflows and project management processes [20, 21].

The proposed system operates through a series of steps to detect adulteration in DAP fertilizer. First, a sample of DAP is placed into the cone-shaped cup to determine its density. As discussed earlier, pure DAP has a distinct true density compared to adulterated materials. The measured density is then compared with the known true density of DAP. If both values match, “Pure DAP” is displayed on the LCD. Conversely, if the measured density deviates from the true value, “Impure DAP” is displayed, marking the completion of the process.

This enables farmers to obtain immediate and reliable results, protecting them from fraudulent or deceptive purchases. Furthermore, reliance on laboratory testing is minimized, which is especially beneficial for farmers in rural areas who lack access to such facilities. The portable and easy-to-use design allows the device to be conveniently carried to the fields for on-site quality assessment. No specialized technical skills are required, making it accessible even to uneducated farmers. By providing real-time, unaltered results, the system helps reduce delays in decision-making. Overall, the proposed method ensures efficiency, affordability, and sustainability, offering a practical solution for maintaining fertilizer quality.

To measure the mass of the DAP sample, a load cell (HX711 module) is employed, which converts the applied force into an electrical voltage signal. The HX711 load cell module is designed to measure weight by converting mechanical force or pressure into a measurable electrical output. In the proposed system, the load cell measures the mass of the DAP sample to calculate its density using the formula:

$$Density = \frac{Mass}{Volume}$$

A cone-shaped cup is filled with a DAP sample and placed at the center of the load cell to ensure accurate mass measurement. The volume ( ) of the conical frustum-shaped cup is determined using Equation (1) [22].

$$V = \frac{1}{3}\pi h(R^2 + r^2 + Rr) \quad (1)$$

Where R is the upper radius, r is the lower radius, h is the height of the cup, and π is a constant. By substituting the measured values into Equation (1), the calculated volume of the cup is approximately 2.05×10^4 mm³. The frustum-shaped conical cup was designed in SolidWorks and fabricated using a 3D printer for density measurement. The cup has an upper radius of 42 mm, a lower radius of 25.8 mm, and a height of 72 mm, as shown in Fig 4(a) below:

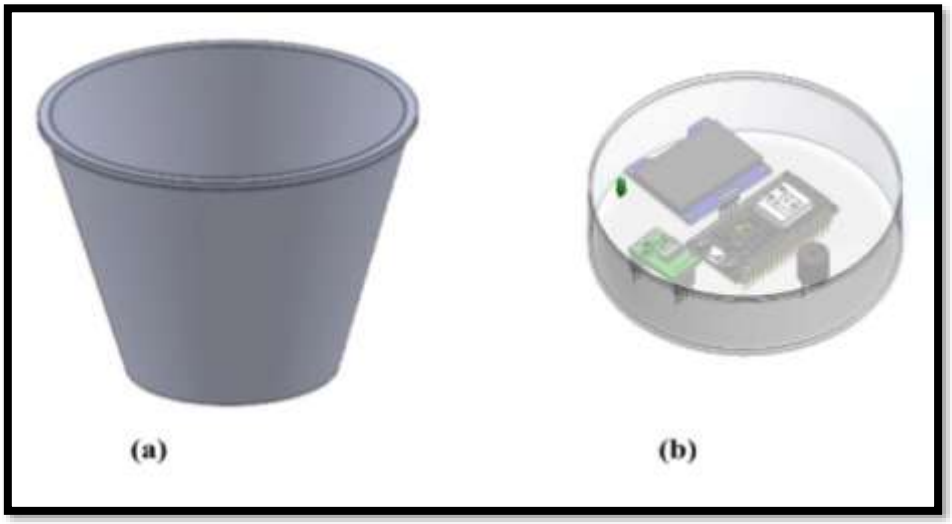

Figure 4. (a) Frustum-shaped conical cup designed in SolidWorks. (b) Casing of the complete system designed in SolidWorks.

The casing of the proposed system was designed in SolidWorks to ensure the protection and safety of all components. The LCD, HX711 module, ESP-32, green LED, and buzzer are enclosed within a sub-casing, as shown in Fig 4(b). This portable enclosure provides a convenient, handheld solution for farmers to check DAP quality without requiring any technical expertise. Its compact design allows easy transportation from one location to another. Moreover, casing minimizes the risk of moisture, dust, and accidental impacts, protecting the

sensitive electronic components and ensuring long-term durability and reliability under real farming conditions. The 3D printing process enables precise fabrication with customized dimensions to securely fit each component, enhancing the overall stability, sturdiness, and professional appearance of the device. The user-friendly design also allows farmers to place DAP samples easily without the risk of spillage or handling difficulties.

Some of the results, including Fig 5 below, are adapted from the author's previously presented conference paper [23]. Figure 5 presents the schematic diagram of the proposed system, which consists of the load cell HX711 module, ESP-32 microcontroller, buzzer, green LED, and LCD for density measurement and display. The load cell converts the applied force into a voltage signal, which is processed by the HX711 module to calculate the density of the DAP sample. The ESP-32 then compares the measured density with the true density of pure DAP and displays the result on the LCD, indicating whether the sample is pure or adulterated. The ESP-32, a microcontroller equipped with built-in Bluetooth and Wi-Fi connectivity, is commonly used in IoT-based projects to interface with sensors and execute programmed instructions [24, 25].

The ESP-32 microcontroller contains 30 pins. In the proposed system, pins 2 and 4 of the ESP-32 are connected to the load cell module, while pins 22 and 21 are connected to the LCD for result display. The buzzer is connected to pins 33 and 26 of the ESP-32. When the measured density of the DAP sample falls within the range of the true density of pure DAP, the LCDs "Pure DAP" and the green LED turn on as an indicator. Conversely, when the measured density deviates from the true value, the LCDs "Impure DAP," and the buzzer is activated as a warning signal. The schematic circuit of the proposed system is illustrated in Fig 5(a), while the printed circuit board (PCB) layout is shown in Fig 5(b). Both the schematic and PCB were designed using EasyEDA software [26]. The finalized PCB integrates all the electronic components, and the ESP-32 is programmed with the source code for initial device calibration and system operation.

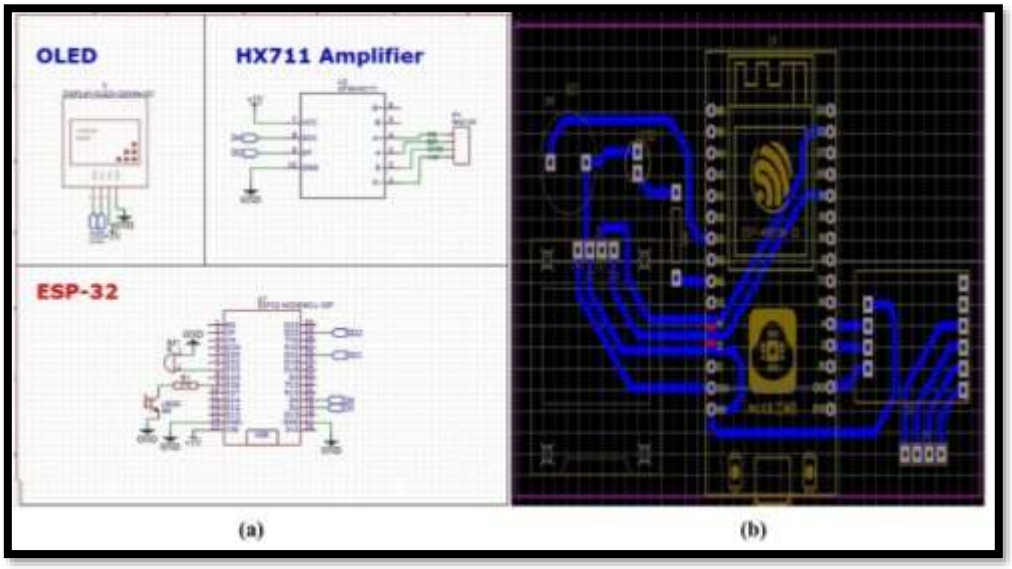

Figure 5. (a) Schematic circuit diagram of the proposed system. (b) Printed circuit board (PCB) layout of the system.

To give a clear overview of the research process, the main steps taken in this study are summarized below:

- A DAP sample was placed into a cone-shaped cup with a fixed volume, and its mass was measured to calculate density.
- The measured density was compared with the known true density of DAP.
- If both the values matched, DAP is pure and displayed on the OLED screen.

• If the measured value deviates from the true value, the DAP is impure.
• The CAD model of the casing and frustum cup designed in SolidWorks.
• The circuitry with ESP32 microcontroller and Load Cell HX711 designed in EasyEDA.

RESULTS AND DISCUSSION

After completing all system connections, the program was successfully uploaded to the ESP-32 microcontroller. As mentioned earlier, pure DAP has a fixed true density; therefore, to assess its quality, the density of the DAP sample was measured using the load cell (HX711) module. The frustum-shaped cup was filled with a DAP sample and placed on the load cell for density calculation, as shown in Fig 6(a). The measured mass of the sample was 206 g, and the calculated density was 1.37 g/cm³, obtained using the formula density = mass/volume. By comparing the measured density with the true density of pure DAP, it was determined that the sample was pure. The corresponding result indicating "Pure DAP" was displayed on the LCD, as shown in Fig 6(b).

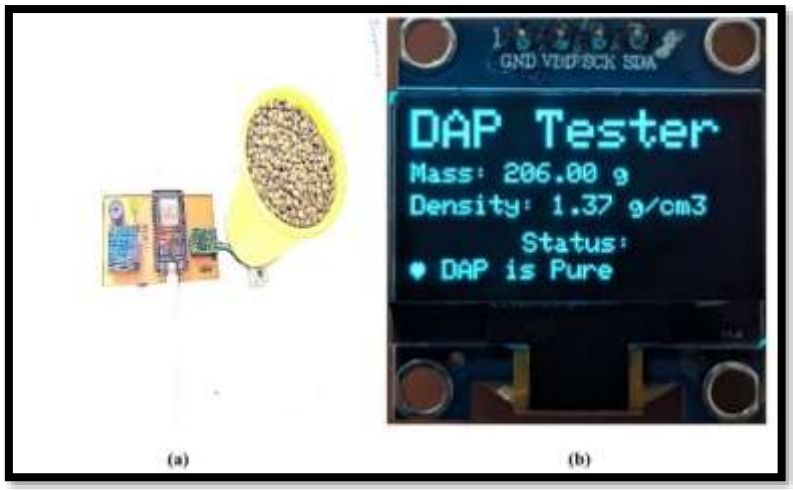

Figure 6. (a) Testing of a pure DAP sample. (b) LCD displaying the result of pure DAP.

Conversely, the impure DAP sample was also tested by placing it on the load cell, as shown in Fig 7(a). The measured mass of this sample was 398.54 g, resulting in a calculated density of 1.94 g/cm³, which deviates from the true density of pure DAP. Based on this difference, the system correctly identified the sample as impure, and the result "Impure DAP" was displayed on the LCD, as illustrated in Fig 7(b).

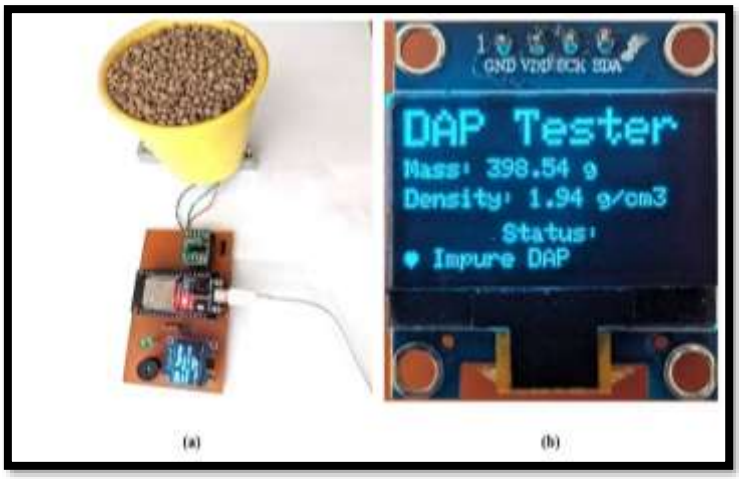

Figure 7. (a) Testing of an impure DAP sample. (b) LCD displaying the result of impure DAP.

As mentioned earlier, various methods are available to check the quality of DAP fertilizer; however, each method has certain limitations. The advantages and disadvantages of these methods are summarized in Table 1 below and their details are as follow.

The first method provided in table below is galvanometric method, that check the quality of DAP fertilizers of the basis of available content of phosphorus pentoxide (P2O5) in fertilizer. Although this method gives accurate results of phosphorus content in DAP fertilizer, but there are some limitations that include laboratory equipment, skilled personnel, chemical reagents and more time taking process. As a result, this method is not reliable for rapid field-based quality assessment of DAP fertilizer [17]. The second method discussed in table is X-rays fluorescence (XRF). This is non-destructive method used to determine the elemental composition of fertilizers. The sample of fertilizer is exposed to X-ray causing its constituent elements such as phosphorus, potassium, calcium to emit fluorescent radiation. The elemental concentrations are quantified by the emitted signals. Although XRF high accuracy and rapid analysis, the equipment is exorbitant and requires specialized calibration. These factors limit its use in low-cost quality assessment of DAP fertilizers [18]. The third method discussed in table is Near-Infrared (NIR) Spectroscopy. This method analyzes the reflected or absorbed near-infrared radiation to assess the fertilizer quality. This method gives approximate values of moisture content, nutrient concentration and other characteristics without destroying the sample. NIR methods allow quick and simultaneous results, however variations in sample composition and environmental conditions may vary measurement accuracy, making the method less suitable for low-cost quality assessment of DAP fertilizers [19]. The fourth method discussed in table is Physical Testing (moisture analysis). This method assesses the fertilizer quality based on physical properties such as granule strength, bulk density, shape, flowability, and particle size distribution. These factors are significant for storage, handling, transportation, and field application of fertilizers. Physical Testing is relatively simple and requires no advanced instruments but in contrary, the limiting factors include labor-intensity and may not specify the chemical nutrient composition of the fertilizer [27].
The proposed device is low-cost, user-friendly, and provides an accuracy of approximately 95%. This accuracy was determined by conducting multiple trials using different DAP fertilizer samples. Details of all trials and their respective accuracies are presented in Table 2 below. In the first trial, a pure DAP sample was tested, and its density was measured using the proposed device. The reference (true) density of pure DAP is 1380 kg/m³, while the device measured 1370 kg/m³, achieving 99% accuracy. In the second trial, a sample of NPK fertilizer, a possible adulterant, was tested. Its true density is 1970 kg/m³, and the device measured 1960 kg/m³, again achieving 99% accuracy. In the third trial, a DAP sample was tested with 93% accuracy, while in the fourth trial, a Single Super Phosphate (SSP) fertilizer sample with a true density of 2050 kg/m³ was measured by the device as 1900 kg/m³, corresponding to 92% accuracy.
Table 1. Comparison of the proposed device with existing methods.

S. No	**Method**	**Parameter**	**Accuracy %**	**Reference**
1	Chemical analysis (gravimetric)	P_2O_5 content (%)	93	[17]

2	X-ray fluorescence (XRF)	Elemental content (P, Ca, etc.)	94	[18]
3	Near-infrared spectroscopy (NIR)	Moisture and nutrient content	91	[19]
4	Physical testing (moisture analysis)	Particle size, moisture, strength	89	[27]
5	Density-based device (**Proposed study**)	Density-based quality checking	95	**Proposed study**

The proposed device is not only capable of determining the quality of DAP fertilizer but can also identify whether a given sample corresponds to NPK or SSP fertilizer, as these fertilizers have distinct true densities that can be accurately measured using the device. In the fifth trial, a mixed sample containing 55% pure DAP and 45% NPK as impurities was tested. The true density of this mixture was calculated using the formula (2) provided below, and the device measured its density with 93% accuracy, as shown in Table 2. Since the measured density deviated from the true density of pure DAP, the sample was classified as impure DAP. For accurate results, the sample mass must be sufficient to fill the frustum-shaped cup of fixed volume.

$$\rho_{True} = X_{NPK} \times \rho_{NPK} + (1 - X_{NPK}) \times \rho_{DAP} \qquad (2)$$

Substituting the values,

$$\rho_{True} = 0.45 \times (1970) + (1 - 0.45) \times (1380)$$
$$\rho_{True} = 1650\ kg/m^3$$

According to real-world observations, NPK and SSP fertilizers are the primary substances mixed or coated with pure DAP to make it impure. Therefore, in this study, the samples tested include pure DAP, NPK, SSP, and a mixture of DAP and NPK. However, according to the literature, other possible adulterants such as sand, salt, and similar materials can also be considered in future studies to further evaluate the device's performance and robustness.

Table 2. Result Comparison of Different Trials

Trial	Sample	True density (kg/m^3)	measure density (kg/m^3)	Error	Accuracy (%)
1	Pure DAP	1380	1370	-10	99
2	NPK	1970	1960	-10	99
3	Pure DAP	1380	1250	-130	93
4	SSP	2050	1900	-150	92
5	Pure DAP with 45% NPK as impurities	1650	1550	-100	93

CONCLUSIONS

The proposed DAP fertilizer quality-checking device was successfully developed and tested to measure the density of DAP fertilizer. Based on the measured density, the system determines whether the DAP sample is pure or adulterated by comparing it with the true density value. The results are displayed on an LCD screen, where a green LED indicates purity, and a buzzer alerts when adulteration is detected. The system is cost-effective, user-friendly, and specifically designed for farmers, enabling them to assess fertilizer quality without technical expertise. A compact casing was designed in SolidWorks and fabricated using a 3D printer to protect the components, while a cone-shaped cup of fixed volume was used for density measurement. The proposed system achieved an average accuracy of approximately 95% when validated with laboratory resources. Its affordability and simplicity make it a practical tool for farmers to avoid fraudulent fertilizer sales and ensure the use of high-quality DAP. Despite its promising results, the system has room for further enhancement. The current prototype primarily evaluates DAP quality in comparison with NPK and SSP fertilizers, which are common adulterants. However, according to the literature, other potential adulterants such as sand and salt can also affect fertilizer purity. Future studies may include these materials to improve the device's robustness and reliability. One of the most promising directions for future development is the integration of a mobile application to provide wireless connectivity via Bluetooth, Wi-Fi, or GSM. This would enable automatic data logging, storage, and visualization of measured density values on smartphones. Prior research has highlighted the role of mobile-based agricultural monitoring systems in improving decision-making and record-keeping within precision agriculture. Expanding the system's capability to test a wider range of fertilizers and soil additives is another important direction. Accuracy could be further improved through the incorporation of advanced sensors capable of limited chemical structure analysis. Moreover, the integration of Internet of Things (IoT) and machine learning (ML) technologies would allow the device to upload fertilizer quality data to a central cloud server in real time. This data-driven approach could enable large-scale fertilizer quality monitoring, assist policymakers in addressing adulteration

issues, and enhance supply chain transparency. In summary, the developed device demonstrates significant potential due to its high accuracy, affordability, and ease of use. By extending its functionality through IoT and mobile-based analytics, this system can evolve from a simple DAP quality checker into a smart agricultural tool, empowering farmers with digital resources to make informed decisions and safeguard against deceptive fertilizer practices.

ABSTRACT

The conservation of natural plant genetic resources and the evaluation of wild woody species adapted to environmental stress conditions as alternative rootstocks are important objectives in rootstock breeding. In this study, the early-stage graft compatibility of *Cotoneaster nummularia*, a species naturally distributed in Anatolia, with the apple cultivar Golden Delicious, pear cultivar Deveci, quince cultivar Eşme, and hawthorn cultivar Polat Efe was evaluated anatomically. Healthy and vigorously growing *C. nummularia* genotypes were selected as rootstocks, and dormant budding was performed in September 2025. Approximately 11 months after grafting, three samples were collected from the graft union of each combination. Longitudinal sections were evaluated for the graft union line, cambial and vascular continuity, necrotic tissues, and parenchymatous tissue formation. Visual differences in starch distribution were also assessed using a 1% iodine–potassium iodide (IKI) solution. Golden Delicious/*C. nummularia* showed vascular discontinuity, necrotic areas, irregular xylem orientation, and extensive parenchymatous tissue formation, indicating early-stage anatomical incompatibility. In Eşme/*C. nummularia*, anatomical union formation occurred, but scion growth ceased; this combination was therefore considered incompatible. Deveci/*C. nummularia* largely established cambial and vascular continuity, although the graft union trace remained visible in the wood tissue. Polat Efe/*C. nummularia* most closely resembled the self-grafted *C. nummularia*/*C. nummularia* control, particularly in regular cambial–vascular continuity and the near disappearance of the graft union line. These findings indicate high early-stage anatomical compatibility between *C. nummularia* and Polat Efe hawthorn. Long-term trials with additional hawthorn genotypes are required before *C. nummularia* can be recommended as a rootstock.

Keywords: *Cotoneaster nummularia*, rootstock breeding, graft compatibility, graft union, vascular continuity.

INTRODUCTION

Anatolia is one of the world's important regions in terms of plant genetic resources and biodiversity due to its diverse climatic zones and habitats (Kaya & Raynal, 2001; Ambarlı et al., 2016; Duman et al., 2024). Türkiye is reported to harbor approximately 12,000 plant taxa, of which nearly 32% are endemic (Duman et al., 2024). The ecological heterogeneity of Anatolia supports the coexistence of wild and cultivated plant forms and provides suitable habitats for numerous woody species of the Rosaceae family (Ercisli, 2004; Basbag et al., 2017). Long-term environmental selection can generate considerable genetic variation within natural populations, making them valuable sources of material for rootstock breeding (Ercisli, 2004). Genetic diversity related to geographic origin has been reported in *Prunus microcarpa* populations (Nas et al., 2011). In addition, naturally occurring *Prunus cerasifera* × *P. microcarpa* hybrids have been evaluated as potential rootstock materials (Uğur et al., 2021a). Therefore, the identification, conservation, and characterization of natural genetic resources are important for the development of new cultivars and rootstocks adapted to diverse environmental conditions (Ambarlı et al., 2016; Duman et al., 2024). Anatolia is home to wild genetic resources of several economically important Rosaceae genera, including Malus, Pyrus, Cydonia, Crataegus, Sorbus, Amygdalus, and Prunus (Ercisli, 2004). The potential use of wild Prunus species, including *Prunus domestica*, *P. cerasifera*, *P. divaricata*, *P. spinosa*, *P. microcarpa*, *P. scoparia*, *P. amygdalus*, and *P. arabica*, in rootstock breeding has also been investigated (Uğur, 2022; Uğur et al., 2023).

Rootstocks can influence scion vigor, precocity, yield, and fruit quality, as well as plant responses to different soil conditions, diseases, and abiotic stresses (Uğur et al., 2023; Ling et al., 2025). Wild species that naturally persist under adverse conditions such as drought, high temperature, salinity, high soil pH, and calcareous or nutrient-poor soils represent potentially valuable materials for rootstock breeding. Studies evaluating *Prunus scoparia* as a rootstock for almond under drought conditions (Abbasi et al., 2019) and reporting the effects of *P. microcarpa* on growth, yield, and nutrient uptake in apricot (Uğur, 2022; Uğur et al., 2021b) provide examples of the potential use of wild species in rootstock improvement.

This approach also supports the investigation of other wild members of the Rosaceae family as potential rootstock materials. One such species is *Cotoneaster nummularia* Fisch. & C.A.Mey. *C. nummularia* is a perennial wild species naturally occurring in Anatolia and has been reported to inhabit a wide range of environments, including dry slopes, limestone-derived soils, and eroded areas (Zengin et al., 2014; Basbag et al., 2017; Ravanbakhsh et al., 2018). This ecological distribution provides a rationale for experimentally investigating the species as a potential rootstock.

A substantial proportion of the research conducted on *C. nummularia* has focused on its ecological, phytosociological, and phytochemical characteristics. Zengin et al. (2014) reported the presence of various phenolic compounds in leaf and fruit extracts of naturally occurring *C. nummularia* from Anatolia. Although these findings do not directly demonstrate its suitability as a rootstock, they indicate that the species represents a biologically characterized wild genetic resource within the Rosaceae family. In contrast, experimental information regarding the potential use of *C. nummularia* as a rootstock for pome fruit species is currently lacking. Previous studies evaluating wild woody species as rootstocks (Nas et al., 2011; Abbasi et al., 2019; Uğur et al., 2021a; Uğur et al., 2021b; Uğur, 2022; Uğur et al., 2023; Ling et al., 2025) provide a scientific framework for investigating *C. nummularia* for this purpose.

Based on this knowledge gap, the present study aimed to evaluate the early-stage anatomical graft compatibility of naturally occurring *Cotoneaster nummularia* with Golden Delicious apple, Deveci pear, Eşme quince, and Polat Efe hawthorn. The study was conducted during 2025–2026 at the experimental grounds of Gaziantep University, Islahiye Vocational School, and in the laboratories of the Eastern Mediterranean Transitional Zone Agricultural Research Institute.

MATERİALS AND METHODS

Plant Material

The rootstock material consisted of naturally occurring *C. nummularia* genotypes growing on the campus of Gaziantep University, Islahiye Vocational School, located within the Eastern Mediterranean Transitional Zone. Commercially grown cultivars, namely Golden Delicious apple, Deveci pear, Eşme quince, and Polat Efe hawthorn, were used as scion material.

Methods

Survey and preparation of plants for grafting: A survey conducted in May 2025 identified six *C. nummularia* genotypes as potential rootstock candidates. Healthy individuals showing no visible disease symptoms and vigorous growth were selected. The selected genotypes were maintained under regular irrigation and cultural practices until September 2025. Eight branches suitable for grafting, each approximately 4–5 mm in diameter, were retained on each genotype.

Grafting and plant maintenance: In September 2025, dormant budding was performed on the selected *C. nummularia* rootstock candidates. Four rootstock–scion combinations were established: Golden Delicious apple/*C. nummularia*, Deveci pear/*C. nummularia*, Eşme quince/*C. nummularia*, and Polat Efe hawthorn/*C. nummularia*. A self-grafted *C. nummularia*/*C. nummularia* combination served as the anatomical control.

Irrigation and routine plant maintenance were continued after grafting. In March 2026, the grafted branches were cut back above the graft union to promote bud sprouting. Root suckers and vigorous watershoots were removed throughout the growing period, and routine irrigation and maintenance practices were continued from March to August 2026.

Collection of graft samples and anatomical examination: Approximately 11 months after grafting, three samples were collected from the graft union of each rootstock–scion combination and fixed in FAA solution (Sass, 1964). A total of 100 mL of FAA solution was prepared using 50 mL of 96% ethanol, 5 mL of glacial acetic acid, 10 mL of 37% formaldehyde, and 35 mL of distilled water. The samples were kept in the fixative for at least three days and were then transferred to 70% ethanol (Baş, 1998).

For macroscopic anatomical evaluation, longitudinal sections were prepared through the graft union, and the cut surfaces were smoothed using No. 0 waterproof sandpaper. A 1% iodine–potassium iodide (IKI) solution was applied to assess visual differences in starch distribution within the tissues. IKI staining intensity in the rootstock and scion tissues, the appearance of the graft union line, the structure of the bark and wood tissues, and the presence of necrotic tissue were evaluated together (Ünal, 1984; Ünal & Özçağıran, 1986; Watanabe & Nakazotomi, 1990; Tekintaş, 1991; Polat & Kaşka, 1992; Tekintaş & Dolgun, 1996; Kankaya et al., 1999).

Anatomical examinations were carried out in the laboratories of the Eastern Mediterranean Transitional Zone Agricultural Research Institute. Because the observations were qualitative and descriptive, no inferential statistical analysis was performed; the combinations were compared on the basis of the anatomical criteria described above.

RESULTS

Anatomical and IKI observations for all graft combinations are summarized in Table 1 and illustrated in Figures 1–5.

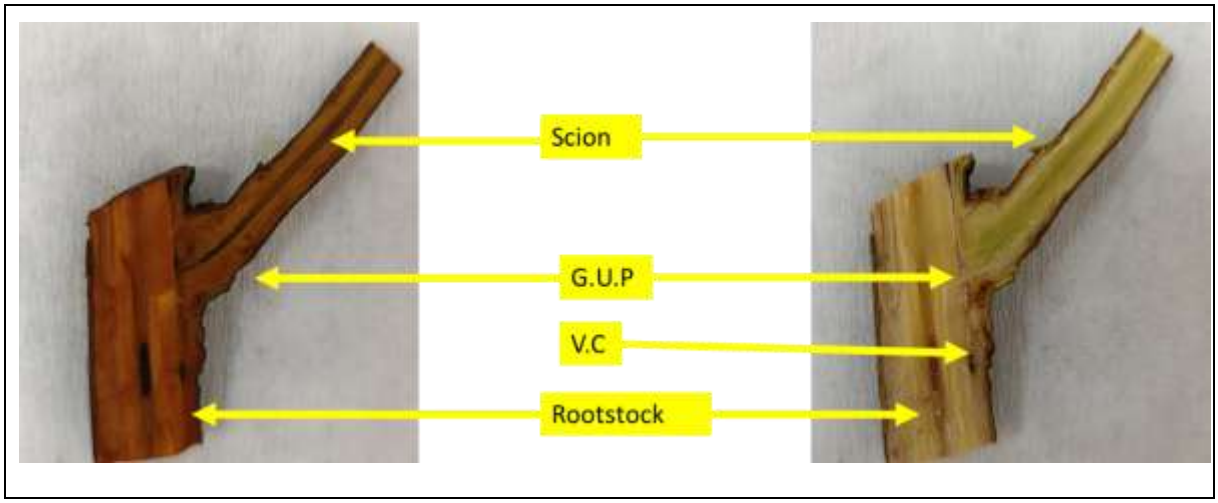

Figure 1. Anatomical images of the Golden Delicious apple/*C. nummularia* graft combination G.U.P.: graft union point; V.C.: vascular cambium

The Golden Delicious apple/*C. nummularia* graft union showed vascular discontinuity, bark thickening, necrosis, and changes in xylem orientation. Following IKI staining, the rootstock and scion tissues exhibited different staining intensities, with pronounced darkening along the graft union line. In the woody tissue beneath the bark, the union line was deep and clearly defined, while xylem continuity was weak. Limited vascular differentiation and the predominance of parenchymatous tissue indicated that complete anatomical integration had not yet been achieved during the early stage of graft union development.

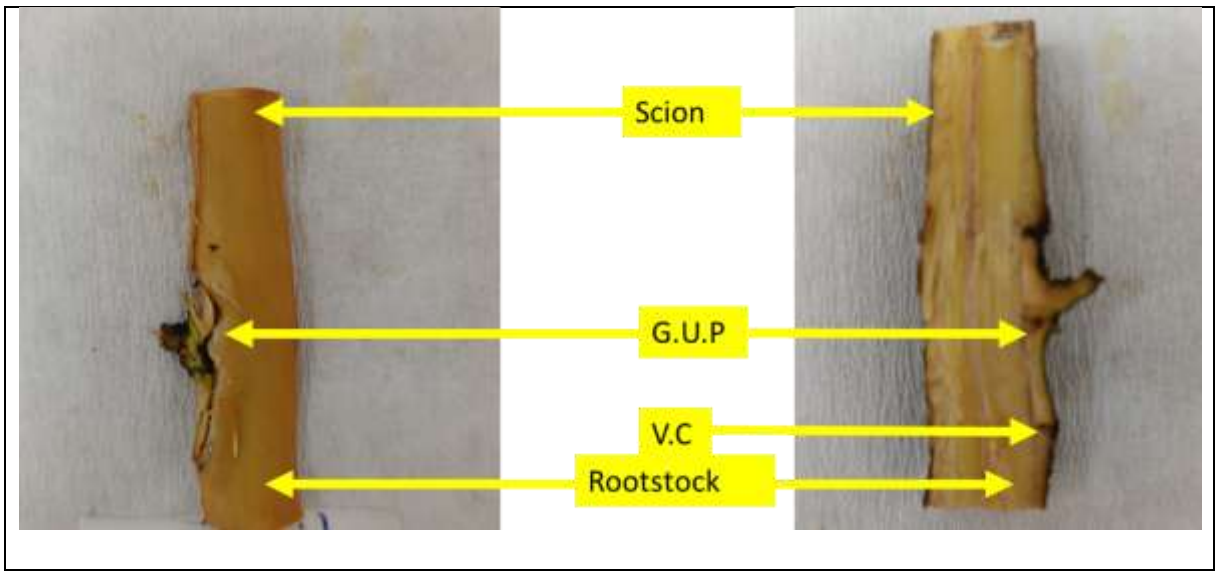

Figure 2. Anatomical images of the Eşme quince/*C. nummularia* graft combination

In the Eşme quince/*C. nummularia* combination, anatomical formation of the graft union was observed, but scion growth did not continue. This finding suggests that the initial formation of union tissue alone may not be sufficient for functional and long-term rootstock–scion compatibility. Because the method used did not directly measure nutrient or assimilate transport, no inference was made regarding the physiological mechanism underlying the growth failure. Based on the cessation of scion growth, the combination was considered incompatible at the early stage.

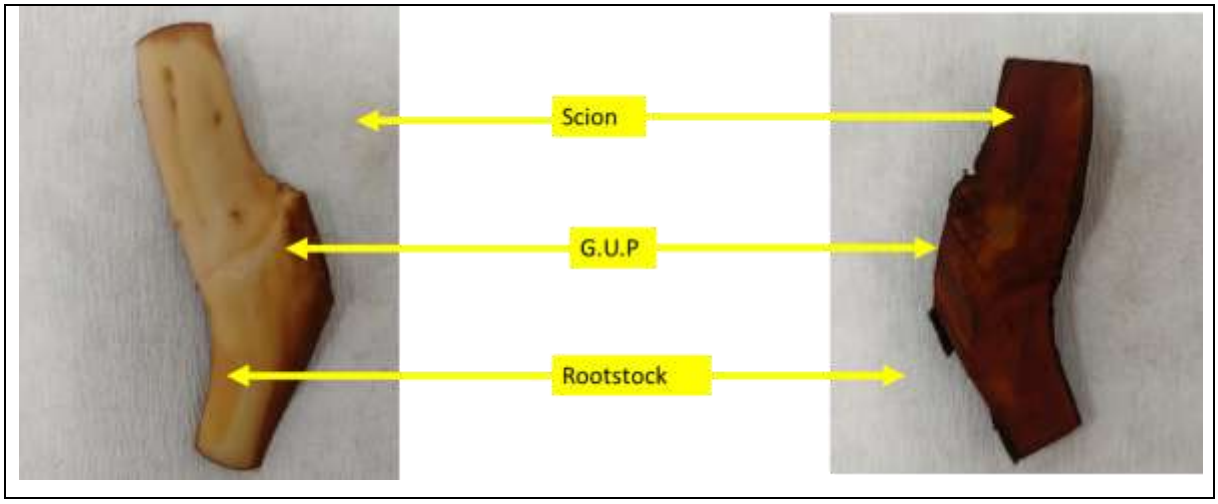

Figure 3. Anatomical images of the Deveci pear/*C. nummularia* graft combination

In the Deveci pear/*C. nummularia* combination, no obvious vascular discontinuity was observed at the graft union, and cambial continuity was largely maintained. Despite the change in orientation along the graft axis, the rootstock and scion tissues showed similar staining intensity after IKI treatment. This stained pattern suggested limited starch accumulation at the graft union; however, IKI staining does not provide a direct measure of assimilate or phloem transport. After removal of the bark, the graft union remained visible in the wood tissue as a shallow depression, indicating that the anatomical trace of the union had not completely disappeared.

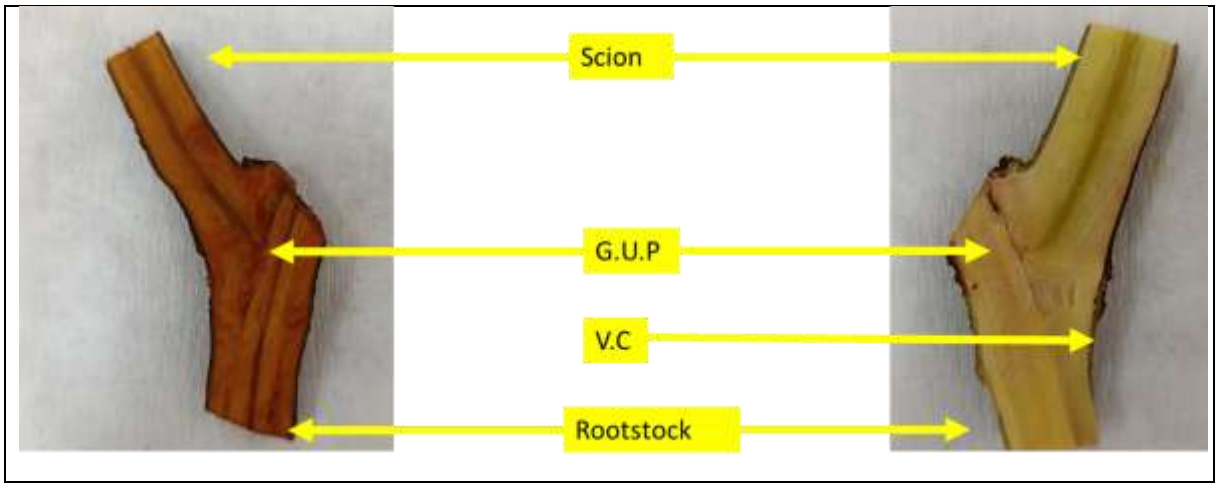

Figure 4. Anatomical images of the Polat Efe hawthorn/*C. nummularia* graft combination

In the Polat Efe hawthorn/*C. nummularia* combination, no obvious discontinuity was observed in the vascular tissues, and cambial continuity was well established at the graft union. Only a slight change in tissue orientation was observed along the graft axis. The rootstock and scion tissues showed similar staining intensity after IKI treatment, suggesting no marked local starch accumulation at the graft union. After removal of the bark, no distinct graft scar or depression was observed in the wood tissue, and the union line appeared smooth and continuous. These findings indicate a high degree of anatomical compatibility during the early stages of graft union development.

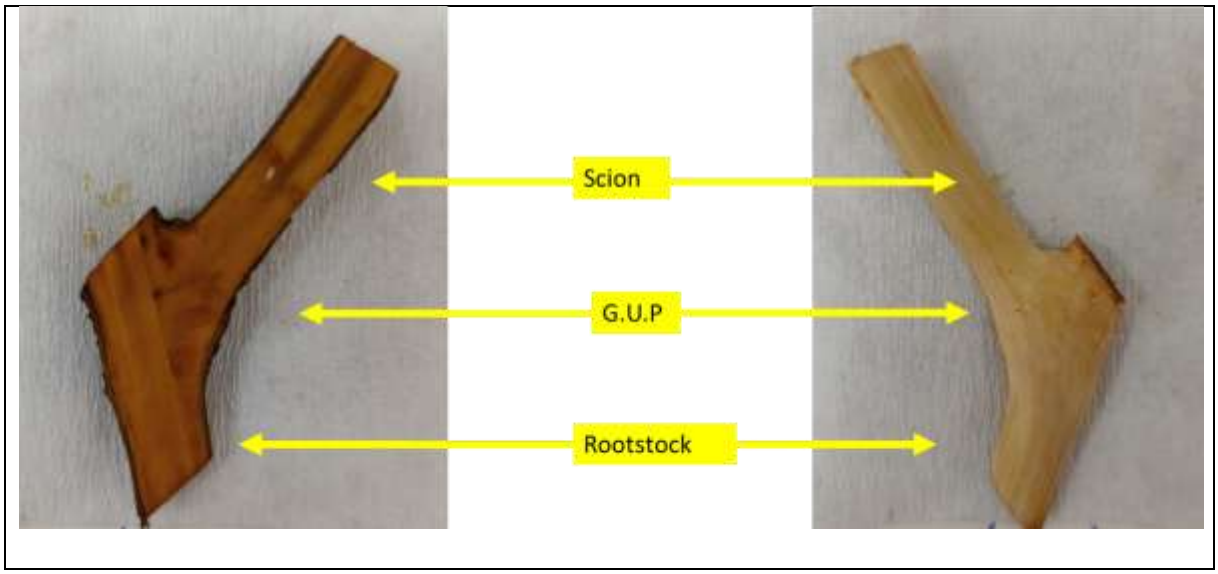

Figure 5. Anatomical images of the self-grafted *C. nummularia*/*C. nummularia* control combination

The *C. nummularia*/*C. nummularia* homograft combination was used as the control. No obvious discontinuity was observed in the vascular tissues at the graft union, and cambial continuity

was well established. Following IKI treatment, the rootstock and scion tissues exhibited similar staining intensity, suggesting no marked local starch accumulation. After removal of the bark, no depressed union line was evident in the wood tissue, and the surface appeared smooth. The close anatomical similarity between the Polat Efe hawthorn/*C. nummularia* combination and the control supports the high degree of early-stage graft compatibility observed in this combination.

DİSCUSSİON AND CONCLUSION

Successful graft compatibility should not be inferred solely from continued shoot growth. Stable union formation also requires callus development, differentiation of a new cambial layer, and re-establishment of functional vascular connections. Disrupted cambial development, insufficient vascular differentiation, and persistent undifferentiated parenchymatous or callus tissue at the graft union are recognized anatomical indicators of incompatibility (Uğur et al., 2023).

Although genetic relatedness may increase the probability of graft compatibility, compatibility is combination-specific and cannot be predicted solely from taxonomic proximity. In addition, some forms of localized or delayed incompatibility may not become evident during the first years after grafting (Ling et al., 2025). Therefore, the approximately 11-month observation period in this study represents only early-stage graft union development.

The Golden Delicious apple/*C. nummularia* combination showed vascular discontinuity, bark thickening, necrotic areas, altered xylem orientation, and abundant parenchymatous tissue at the graft union. These abnormalities indicate incomplete anatomical integration and are consistent with features reported for incompatible graft combinations (Uğur et al., 2023; Ling et al., 2025). IKI staining also differed between rootstock and scion tissues, with darkening along the graft union; however, because IKI staining does not directly quantify assimilate transport, this observation should be interpreted only as a qualitative indication of local starch distribution. Although Zengin et al. (2014) reported phenolic compounds in *C. nummularia*, their study did not examine graft unions, so the abnormalities observed here cannot be attributed directly to phenolic metabolism.

The Eşme quince/*C. nummularia* combination displayed a different form of graft failure. Anatomical union tissue developed, but scion growth did not continue. Thus, initial tissue union alone was insufficient to demonstrate functional compatibility. Because nutrient and assimilate

transport were not measured directly, the physiological cause of the growth failure could not be determined. This finding also illustrates why early anatomical continuity and subsequent scion performance should be evaluated together (Uğur et al., 2023; Ling et al., 2025).

In the Deveci pear/*C. nummularia* combination, cambial continuity was largely maintained and no obvious vascular discontinuity was detected, supporting early-stage anatomical compatibility. Rootstock and scion tissues showed similar IKI staining intensity, while the graft union remained visible as a shallow trace in the wood. Consequently, the combination should be regarded as promising at the early stage but still requires long-term evaluation for growth, mechanical stability, and delayed incompatibility (Uğur et al., 2023; Ling et al., 2025).

Among the heterograft combinations, Polat Efe hawthorn/*C. nummularia* showed the closest anatomical resemblance to the homograft control. Cambial continuity was well established, no obvious vascular discontinuity was observed, and no distinct graft scar or indentation remained on the wood surface. Similar IKI staining intensity in rootstock and scion tissues further supported a high degree of early-stage anatomical compatibility. This result, however, applies only to the Polat Efe genotype tested and should not be generalized to all hawthorn cultivars or genotypes (Nas et al., 2011; Abbasi et al., 2019; Uğur et al., 2021a).

The self-grafted *C. nummularia*/*C. nummularia* control showed the most uniform anatomical integration, with regular cambial continuity, no evident vascular discontinuity, similar IKI staining on both sides of the union, and no depressed graft line in the wood. Its close resemblance to the Polat Efe/*C. nummularia* combination strengthens the evidence for high early-stage compatibility in that heterograft.

Taken together, the combinations should not be forced into a single linear compatibility ranking because the Golden Delicious and Eşme combinations failed in different ways. Golden Delicious/*C. nummularia* showed clear anatomical incompatibility, whereas Eşme/*C. nummularia* formed union tissue but failed to sustain scion growth. Deveci/*C. nummularia* showed substantial anatomical continuity but retained a visible graft trace, while Polat Efe/*C. nummularia* most closely approached the homograft control. Both anatomical union characteristics and continued scion growth should therefore be considered when interpreting compatibility.

From a rootstock-breeding perspective, the close anatomical similarity between Polat Efe/*C. nummularia* and the control justifies further investigation of *C. nummularia* as a potential hawthorn rootstock. More broadly, evaluating wild woody genetic resources may help identify

stress-adapted material for sustainable rootstock breeding in Türkiye (Ercisli, 2004; Ambarlı et al., 2016; Duman et al., 2024). Nevertheless, the present findings are preliminary and do not establish species-level compatibility.

The principal limitations of this study were the approximately 11-month observation period, the descriptive sample design, the qualitative interpretation of IKI staining, and the absence of direct quantitative measurements of xylem and phloem function. Accordingly, the findings should be interpreted as early anatomical indicators rather than definitive evidence of long-term physiological compatibility.

Future studies should evaluate xylem and phloem continuity separately using histological methods and quantify traits such as callus thickness and vascular element number. Phenolic compounds should be analyzed in rootstock, graft-union, and scion tissues, and IKI-based observations should be validated by quantitative carbohydrate analyses. Long-term trials should also include a wider range of hawthorn genotypes and assess environmental adaptation, vegetative growth, yield, and fruit quality (Zengin et al., 2014; Uğur et al., 2023).

Table 1. Anatomical and IKI observations of the graft union in different rootstock–scion combinations

Combination	**Cambial/vascular continuity**	**Graft union line**	**Necrosis / excessive parenchyma**	**IKI appearance**	**Anatomical assessment**
C. nummularia / *C. nummularia*	Very good	Indistinct/smooth	Absent	Similar staining intensity	Control (reference anatomical appearance)
Polat Efe hawthorn / *C. nummularia*	Very good	Almost completely disappeared	Not evident	Similar staining intensity	High early-stage anatomical compatibility

Deveci pear / *C. nummularia*	Established	Visible graft union line; not completely disappeared	Not evident	Similar staining intensity	Compatible at the early stage; anatomical trace remains
Eşme quince / *C. nummularia*	Anatomical union observed; vascular function not confirmed	Details not specified	Not specified	Not specified	Union formed; scion growth did not continue (incompatible)
Golden Delicious apple / *C. nummularia*	Discontinuous/poor	Deep and distinct	Evident	Heterogeneous; darkening at the graft union	Clear early-stage anatomical incompatibility

ABSTRACT

Interest in herbal teas is steadily increasing due to their potential health benefits. In this study, fennel (*Foeniculum vulgare*), lemon balm (*Melissa officinalis* L.), hibiscus (*Hibiscus sabdariffa* L.), green tea (*Camellia sinensis* L.), freeze-dried Ottoman strawberries, and lavender (*Lavandula angustifolia*) were used to develop three functional herbal tea prototypes, and their antioxidant activities, FTIR spectral characteristics, and in vitro dissolution behaviours were evaluated. Three prototypes were prepared based on their targeted effects on the digestive system. Prototype 1 (P1), formulated with fennel (30%), lemon balm (24%), hibiscus (16%), green tea (14%), freeze-dried strawberry (12%), and lavender (4%), was designed to promote balanced digestion. Prototype 2 (P2) contained fennel (26%), lemon balm (20%), hibiscus (24%), green tea (12%), freeze-dried strawberry (14%), and lavender (4%) and was formulated to stimulate bowel activity. Prototype 3 (P3) was formulated with fennel (34%), lemon balm (30%), hibiscus (10%), green tea (10%), freeze-dried strawberry (12%), and lavender (4%), emphasising digestive comfort through increased proportions of fennel and lemon balm and reduced proportions of hibiscus and green tea. Fourier Transform Infrared Spectroscopy (FTIR) spectra revealed characteristic absorption bands associated with the diverse phytochemical and structural components of the plant mixtures. Antioxidant activity was evaluated using ABTS and DPPH radical-scavenging assays. P3 exhibited the strongest antioxidant performance among the three formulations, showing the highest ABTS radical-scavenging activity and the lowest IC_{50} value (9.65 and 9.71). The DPPH IC_{50} values were measured as 10.26, 9.73, and 9.71; and ABTS IC_{50} values were 10.26, 10.75 and 9.65, for P1,

P2, and P3, respectively. The Trolox-equivalent antioxidant capacity determined by the ABTS assay exceeded 90 μmol TE g^{-1} in all tested formulations. The SOTAX dissolution test demonstrated rapid and extensive in vitro release under simulated gastrointestinal pH conditions (pH 1.2, 4.5, and 6.8), with cumulative dissolution values approaching 99-100% after 30 min. Consequently, P3, in which the proportions of fennel and lemon balm were increased while those of hibiscus and green tea were reduced, emerged as the most promising formulation based on its antioxidant performance and dissolution behaviour. These findings suggest that combining plant-based ingredients in appropriate ratios may influence the functional characteristics of herbal tea blends. The results provide a basis for further studies involving simulated gastrointestinal digestion, bioaccessibility, and bioavailability of the bioactive compounds.

INTRODUCTION

Oxidative stress, characterized by an imbalance between the production of reactive oxygen species (ROS) and the antioxidant defense system, is implicated in the pathogenesis of numerous chronic diseases, including gastrointestinal disorders (Halliwell, 2012). ROS are highly reactive molecular species containing at least one unpaired electron, which enables them to readily interact with cellular components and initiate chain reactions that may impair normal

cellular functions and contribute to tissue damage (Phaniendra et al., 2015; Pooja et al., 2025). Consequently, the identification of effective dietary sources of antioxidants has received increasing attention in the context of disease prevention and health promotion.

Growing consumer interest in natural and functional products has increased the demand for plant-derived foods and beverages with antioxidant properties. Plant materials contain diverse secondary metabolites, particularly polyphenols, flavonoids, phenolic acids, and other phytochemicals, which can contribute to their antioxidant potential (Yeh and Yen, 2006; Holst and Williamson, 2008; Martins et al., 2016; Intrasook et al., 2024). Herbal teas and infusions are therefore of particular interest as convenient sources of bioactive compounds. Depending on the plant species and the solubility of its constituents, infusions can be prepared from various plant parts, including leaves, flowers, fruits, seeds, roots, and bark. The extraction of bioactive compounds is strongly influenced by preparation conditions, particularly temperature and infusion time. Campanella et al. (2003) reported that a 5-min hot-water infusion provided optimal extraction of antioxidant compounds from both conventional and green tea; prolonged infusion and subsequent cooling may promote precipitation or micelle formation, potentially reducing the measurable antioxidant capacity and polyphenol content of the extract. The biological activity of plant-derived antioxidants is determined not only by their individual concentrations but also by their interactions within complex plant matrices. When different plant materials are combined, their bioactive constituents may exhibit additive, synergistic, or antagonistic interactions, resulting in antioxidant activity that cannot necessarily be predicted from the activity of the individual components. Thus, changing the relative proportions of the same plant materials may substantially modify the overall antioxidant capacity of the resulting infusion. Such interactions are particularly relevant for multifunctional herbal tea formulations, in which plants with complementary phytochemical profiles may be combined to target different physiological functions (Seeram, 2008).

The potential health effects of herbal teas are also influenced by the bioaccessibility and bioavailability of their phytochemicals. Although many plant-derived compounds demonstrate substantial antioxidant activity *in vitro,* their biological effects following ingestion depend on digestion, metabolism, absorption, and individual physiological factors (Heim et al., 2002; Espín et al., 2007; Holst and Williamson, 2008). Some compounds may be absorbed in their original form, whereas others undergo extensive metabolic transformation before exerting biological activity. Therefore, antioxidant capacity should be interpreted within the broader

context of the composition and potential bioavailability of the phytochemicals present in the formulation.

Several plant materials are particularly relevant to the development of antioxidant-rich herbal tea formulations. *Melissa officinalis* L. (lemon balm) contains rosmarinic acid and flavonoids and has been associated with antioxidant and antispasmodic properties (Barros et al., 2013; Ülgen et al., 2023). *Foeniculum vulgare* (fennel) contains characteristic volatile constituents such as anethole and fenchone and is traditionally used for digestive and carminative purposes (Rahimi and Ardekani, 2013). *Hibiscus sabdariffa* L. (roselle) is rich in anthocyanins and protocatechuic acid and exhibits substantial radical-scavenging activity (Da-Costa-Rocha et al., 2014). *Camellia sinensis* L. (green tea) is a major dietary source of catechins, particularly epigallocatechin gallate, which contributes substantially to its antioxidant activity (Khan and Mukhtar, 2007). Strawberry (*Fragaria* spp.) is also a significant source of phenolic compounds and vitamin C, and freeze-drying can help preserve these compounds and the fruit's sensory characteristics (Giampieri et al., 2012). *Lavandula angustifolia* (lavender), traditionally used in herbal preparations and beverages, contains phenolic and volatile constituents that may contribute to its antioxidant and sensory properties (Cavanagh and Wilkinson, 2002; Batiha et al., 2023).

Despite the well-documented antioxidant potential of individual plant materials, the effects of combinations of multiple botanical products at different proportions remain insufficiently characterized. In particular, information on how formulation ratios influence the radical-scavenging capacity of multifunctional herbal tea blends is limited. Understanding these effects may facilitate the development of functional tea formulations with optimised antioxidant properties. Therefore, the present study aimed to develop and evaluate functional herbal tea prototypes formulated from six plant matrices: *Foeniculum vulgare, Melissa officinalis* L., *Hibiscus sabdariffa* L., *Camellia sinensis* L., a freeze-dried strawberry preparation, and *Lavandula angustifolia*, combined at different proportions to target specific gastrointestinal functions. The prototypes were designed to represent three functional concepts: balanced digestion, intestinal activation, and gastric soothing. Their antioxidant capacities were evaluated using the ABTS and DPPH radical-scavenging assays, while FTIR analysis was performed for molecular characacterization and an *in vitro* dissolution test was conducted using a SOTAX dissolution system. The study further aimed to compare the effects of formulation ratios on antioxidant activity and dissolution behaviour and to identify the blend composition providing the highest antioxidant activity.

MATERIALS AND METHODS

2.1. Plant Materials and Prototype Formulations

Five plant materials were purchased from the Spice Bazaar (Mısır Çarşısı), Istanbul, Türkiye, and used to prepare three different functional herbal tea prototypes: fennel (*Foeniculum vulgare*), lemon balm (*Melissa officinalis* L.), hibiscus (*Hibiscus sabdariffa* L.), green tea (*Camellia sinensis* L.), and lavender (*Lavandula angustifolia*). Black strawberry, hairy strawberry, and Ottoman strawberry collected from Zonguldak and freeze-dried for 48 hours. The plant materials were blended at different proportions to develop three prototypes according to their targeted effects on the digestive system as demonstrated in Figure 1. Prototype 1 (P1) (balanced digestion) was formulated with fennel (30%), lemon balm (24%), hibiscus (16%), green tea (14%), freeze-dried strawberry 12%), and lavender (4%). Prototype 2 (P2) (intestinal activation/motility) contained fennel (26%), lemon balm (20%), hibiscus (24%), green tea (12%), freeze-dried strawberry (14%), and lavender (4%). Prototype 3 (P3) (gastric soothing) was formulated with fennel (34%), lemon balm (30%), freeze-dried strawberry (12%), hibiscus (10%), green tea (10%), and lavender (4%).

The prototypes were designed according to their targeted effects on the digestive system and developed with the inspiration of studies by Cho et al. (2026) and Teterovska et al. (2025). P1 was intended to support balanced digestion and reduce gas and bloating, P2 to support intestinall activity and motility, and P3 to provide a soothing effect on the stomach.

Figure 1. Visual appearance of the developed herbal tea prototypes (P1, P2, and P3, respectively).

2.2. Determination of Antioxidant Activity

The DPPH free-radical scavenging activity of the herbal tea mixture samples was determined based on the method described by Wang et al. (2012). Briefly, 0.1 mL of each sample solution was mixed with 3.9 mL of methanolic 64 µM DPPH solution. Following incubation in the dark, the absorbance was measured spectrophotometrically at 517 nm. The remaining DPPH concentration and overall antiradical capacity were quantified using a Trolox standard calibration curve prepared over a concentration range of 0-200 µg/mL. The IC_{50} value, defined as the sample concentration required to scavenge 50% of the initial DPPH radicals, was calculated accordingly. The percentage of DPPH inhibition was calculated using the Equation 1:

$$DPPH\ \ Scavenging\ Activity = 1 - \frac{Asample}{Acontrol} x100 \quad (1)$$

In the control assay, methanol was used instead of the sample solution.

2.3. Identification and Quantification of Phenolic Compounds

Phenolic compounds in the herbal tea infusions were identified and quantified using a Shimadzu HPLC system (Shimadzu, Japan) equipped with binary gradient pumps, an autosampler, and a diode array detector. Prior to analysis, samples were filtered through a 45 µm membrane filter and transferred into HPLC vials. Chromatographic separation was performed on a reversed-phase C18 column using acetonitrile (solvent A) and 0.75% (v/v) aqueous formic acid (solvent B) as the mobile phase. The flow rate was 1.0 mL min^{-1} and the injection volume was 10 µL. Detection at 220 nm was used for lutein, apigenin, hesperidin, and hydroxycinnamic acid; 306 nm for quercetin and quercetin-3-galactoside; and 330 nm for caftaric acid, ferulic acid, and chlorogenic acid. Phenolic compounds were identified by comparison of their retention times and UV-Vis spectral characteristics with analytical reference standards. Quantification was performed using external calibration curves over a concentration range of 10-50 µg mL^{-1}, with high linearity (R^2 = 1.000). The concentrations were calculated from the corresponding calibration curves and expressed as µg g^{-1} of sample.

2.4. FTIR Spectroscopy

Spectroscopic characterization of the herbal tea mixture samples was performed using FTIR spectrometer (Thermo Scientific, Nicolet iS5, Waltham, USA). High-resolution spectra were acquired over the wavenumber range of 500-4000 cm^{-1} by 37 scans at a spectral resolution of 4 cm^{-1}. Spectral processing and baseline evaluation was performed using OMNIC 9.0 software.

2.5. *In Vitro* Dissolution Test

The *in vitro* dissolution behavior of the herbal tea mixture samples was evaluated using a Sotax AT-MD dissolution system (Sotax AG, Switzerland) in accordance with the United States Pharmacopeia (USP 42-NF 37). The dissolution test was performed at a paddle rotation speed of 100 rpm and a temperature of 36.5°C. Three dissolution media were used: HCI solution at pH 1.2, acetate buffer at pH 4.5, and phosphate buffer at pH 6.8. For each condition, 100 mL of dissolution medium was prepared.

For the dissolution analysis, 5 mL of each sample was transferred into a 100 mL volumetric flask and diluted to volume with the dissolution medium, followed by thorough mixing. After 30 min, 5 mL of the sample solution was withdrawn and placed in an ultrasonic bath for 1 min and then allowed to cool. Subsequently, 1 mL of the sample solution was transferred into a separate 10 mL volumetric flask, diluted to volume with dissolution medium, and thoroughly mixed. A sodium chloride saline solution (10 mg) was used to prepare the blank solution. The pH values of the dissolution media were measured using a pH meter. The absorbance of the samples was measured against the blank solution using a UV-Vis spectrophotometer over the wavelength range of 200-400 nm, with a wavelength accuracy of ±0.1 nm, in accordance with USP 42-NF 37.

3. RESULTS AND DISCUSSION

3.1. Antioxidant Activity of the Herbal Tea Prototypes

The ABTS radical-scavenging profiles of P1, P2, and P3 are presented in Figures 2. P1 exhibited a relatively regular increase in radical-scavenging activity with increasing sample concentration (Figure 2A), indicating a consistent antioxidant response across the tested concentration range. P2 showed a similar concentration-dependent response, although its antioxidant performance remained relatively close to that of P1 (Figure 2B). Among the three formulations, P3 exhibited the most pronounced ABTS radical-scavenging response, with the highest antioxidant performance across the tested concentrations (Figure 2C). The overall Trolox-equivalent antioxidant capacity of all prototypes exceeded 90 μmol TE g^{-1}, indicating a

substantial antioxidant potential of the developed herbal tea blends. IC_{50} values for P1, P2, and P3 samples were 10.26, 10.75 and 9.65, respectively. The superior performance of P3 is particularly noteworthy because its formulation contained lower proportions of green tea and hibiscus than P1 and P2, while the proportions of fennel and lemon balm were increased. Green tea and hibiscus are generally recognized as important sources of catechins and anthocyanins, respectively. Therefore, the higher antioxidant response of P3 suggests that the activity of a multi-component herbal blend cannot be predicted solely from the proportion of a single plant with high individual antioxidant capacity.

Instead, the observed response may reflect interactions among phenolic compounds originating from different botanical sources. Such interactions may be additive, synergistic, or antagonistic depending on the composition and relative proportions of the components. In P3, the increased contribution of *M. officinalis* and *F. vulgare* may have contributed to the enhanced antioxidant response through their phenolic constituents, including rosmarinic acid and flavonoids in lemon balm and phenolic compounds in fennel. However, the present results do not establish a specific molecular mechanism of synergy and should therefore be interpreted as evidence of a formulation-dependent antioxidant effect rather than direct proof of synergism.

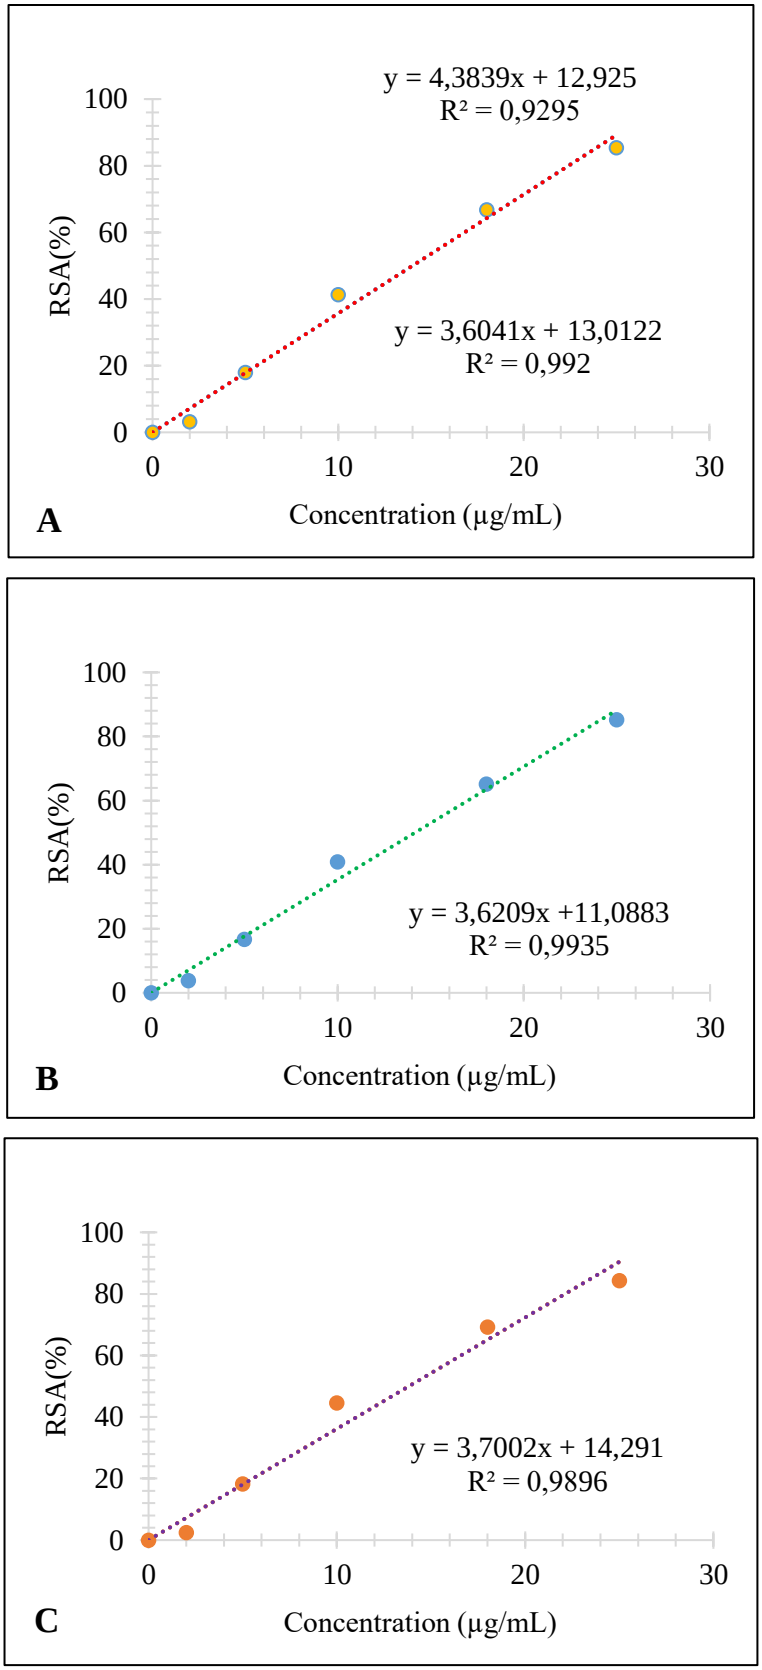

Figure 2. ABTS radical-scavenging activity curve of P1 (A), P2 (B), P3 (C) samples.

The DPPH assay provided complementary information on the radical-scavenging efficiency of the prototypes. Consistent with the ABTS results, P3 exhibited the strongest DPPH radical-scavenging performance among the formulations. The IC_{50} values were measured as 10.26, 9.73, and 9.71 for P1, P2, and P3, respectively. Because a lower IC_{50} value indicates a greater radical-scavenging efficiency, P3 showed the highest efficiency, followed closely by P2 and P1.

Although the differences in IC_{50} values were relatively small, the consistent ranking of P3 as the most effective formulation in both ABTS and DPPH assays strengthens the evidence that its specific botanical composition provided a more favorable antioxidant profile. The similarity between P1 and P2 further suggests that moderate changes in the proportions of individual ingredients did not substantially alter their overall radical-scavenging efficiency. The IC_{50} profiles of the three prototypes are presented in Figures 3.

The antioxidant capacity of the developed formulations was also consistent with previous observations for commercial herbal teas. Apak et al. (2006) reported substantial antioxidant capacities among commercially available tea products, including green tea. The antioxidant responses observed in the present study therefore support the potential of appropriately formulated herbal tea blends as sources of dietary antioxidants. The superior antioxidant performance of P3 is particularly noteworthy because the formulation contained lower proportions of green tea and hibiscus, despite the well-established antioxidant potential of these materials. Green tea is rich in catechins, including epigallocatechin gallate, whereas *H. sabdariffa* is characterized by anthocyanins and other phenolic compounds with radical-scavenging activity (Da-Costa-Rocha et al., 2014; Khan and Mukhtar, 2007). The higher antioxidant response of P3 therefore suggests that the antioxidant activity of a botanical mixture cannot be predicted solely from the concentration of the plant material generally recognized as having the strongest individual antioxidant activity.

Instead, interactions among phytochemicals originating from different plant materials may contribute to the overall response. Such interactions can be synergistic, additive, or antagonistic, depending on the composition and relative proportions of the components (Seeram, 2008). In P3, the increased contribution of *M. officinalis* and *F. vulgare* may have contributed to the observed antioxidant response. *M. officinalis* contains rosmarinic acid and flavonoid derivatives, whereas *F. vulgare* contains phenolic compounds and characteristic volatile constituents such as anethole and fenchone (Barros et al., 2013; Rahimi and Ardekani, 2013).

Their combined contribution may have enhanced the radical-scavenging capacity of the formulation. However, the present data do not allow a specific molecular mechanism of synergy to be established, and further component-specific interaction studies would be required to confirm this interpretation.

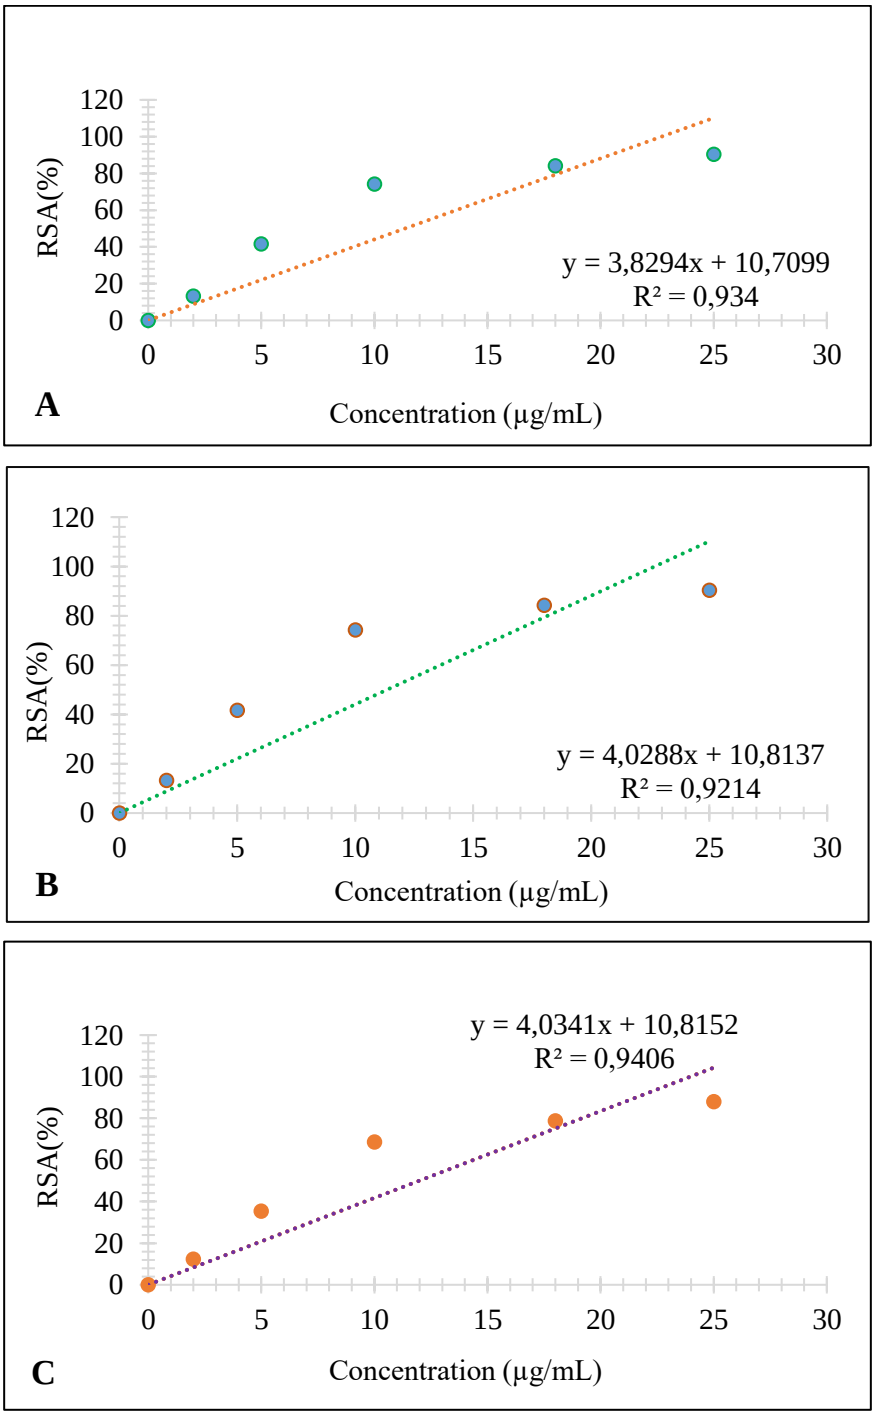

Figure 3. DPPH radical-scavenging activity curve of P1 (A), P2 (B), P3 (C) samples.

Although the prototypes differed in the relative proportions of the six botanical ingredients, all formulations exhibited substantial antioxidant activity. The IC_{50} differences among the prototypes indicate that the antioxidant potential of the blends was influenced not only by the presence of individual antioxidant-rich plants but also by their relative proportions.

3.2. Identification and Quantification of Phenolic Compounds

HPLC-DAD analysis was performed to characterise and quantify the individual phenolic compounds present in the three herbal tea prototypes. The phenolic compounds were identified and quantified by comparing their chromatographic characteristics with those of phenolic reference standards. The HPLC-DAD chromatogram of the phenolic reference standard used for compound identification and quantification is presented in Figure 4.

HPLC-DAD analysis identified ten phenolic compounds in the three herbal tea prototypes (P1, P2, and P3), comprising six phenolic acids, three flavonols, and one flavone (**Table 2**). Chlorogenic acid was the most abundant phenolic compound detected in all three prototypes, followed by ferulic acid and hydroxycinnamic acid. Among the remaining phenolic acids, caffeic, vanillic, and syringic acids were detected at comparatively lower concentrations. Within the flavonoid group, quercetin was the predominant flavonol, followed by kaempferol and myricetin, while apigenin was the only flavone detected. Overall, the phenolic profiles of the three prototypes were dominated by phenolic acids, particularly chlorogenic acid and ferulic acid, whereas flavonols and flavones were present at substantially lower levels.

Among the other phenolic acids, vanillic acid ranged from 825.40 to 835.30 µg/g, caffeic acid from 889.45 to 892.50 µg/g, syringic acid from 664.81 to 712.45 µg/g, and hydroxycinnamic acid from 1038.65 to 1042.11 µg/g across the three prototypes. The concentrations of the detected flavonols ranged from 188.35 to 215.80 µg/g for quercetin, 75.30 to 91.25 µg/g for kaempferol, and 28.60 to 45.70 µg/g for myricetin. Apigenin, the detected flavone, ranged from 99.80 to 125.80 µg/g among the prototypes.

P1 contained 1852.02 ± 0.01 µg/g chlorogenic acid, 825.40 ± 0.15 µg/g vanillic acid, and 892.30 ± 0.12 µg/g caffeic acid. The highest concentration of chlorogenic acid was observed in P1, whereas the lowest concentration was detected in P3. Hydroxycinnamic acid showed only minor variation among the prototypes, with the highest concentration observed in P3 and the

lowest in P2. In contrast, the individual phenolic compounds showed different distribution patterns among the prototypes, indicating that the relative proportions of the botanical ingredients influenced the phenolic composition of the resulting herbal tea formulations.

The predominance of chlorogenic and ferulic acids across the prototypes may have contributed to their antioxidant properties, given the recognized radical-scavenging capacity of phenolic acids. However, the differences in antioxidant activity among the prototypes cannot be attributed to a single phenolic compound. Rather, the overall antioxidant response may reflect the combined contribution and interactions of multiple phenolic constituents, including phenolic acids, flavonols, and flavones. This observation is consistent with the antioxidant results obtained from the ABTS and DPPH assays and further supports the importance of optimizing the relative proportions of individual botanical materials in multifunctional herbal tea formulations.

Table 1. Phenolic contents of the functional herbal tea prototypes (mean ± SD).

	Compounds (µg/g)	**P1**	**P2**	**P3**
Phenolic acids	Chlorogenic acid	1852.02 ±0.01	1836.53 ±0.24	1783.1±0.42
	Hydroxycinnamic acid	1042.9±0.18	1038.65±0.20	1042.11±0.05
	Vanilic acid	825.4 ±0.15	830.74 ±0.42	835.3 ±0.8
	Caffeic acid	892.30 ±0.12	889.45 ±0.32	892.5±0.14
	Syringic acid	664.81 ±0.05	675.45 ±0.28	712.45 ±0.25
	Ferulic acid	1211.09±0.32	1230.26±0.25	1227.46±0.48
Flavonols	Quercetin	188.35±0.09	195.3±0.11	215.8±0.28
	Kaempferol	88.15 ±0.02	91.25 ±0.05	75.3 ±0.05
	Myricetin	28.60 ±0.01	45.7 ±0.02	39.9 ±0.02
Flavons	Apigenin	99.8±0.08	125.8±0.13	115.5±0.19

3.4. FTIR Characterization

FTIR spectroscopy was used to characterize the major functional groups present in the herbal tea formulations. The spectra showed characteristic absorption bands associated with aliphatic, phenolic, aromatic, carbonyl, and carbohydrate-containing constituents of the plant matrices (Figure 4).

Absorption bands observed at approximately 3012 and 2908 cm^{-1}, together with bands around 2801 and 2783 cm^{-1}, were associated with C–H stretching vibrations of aliphatic CH_2 and CH_3 groups. The broad region between approximately 3100 and 2750 cm^{-1} may also include C–H stretching vibrations associated with phenolic and other aromatic constituents. The spectral region between 1900 and 1100 cm^{-1} corresponded predominantly to the fingerprint region of the plant matrices and included stretching and bending vibrations associated with C=C, C–O–H, and C–O–C groups. Absorption bands in the 1600–1350 cm^{-1} region were consistent with aromatic and phenolic structures, including C–O-related vibrations associated with phenolic acids. A band occurring approximately between 1700 and 1655 cm^{-1} may be associated with carbonyl (C=O) stretching, including esterified components such as pectic substances. Additional bands around 1480 and 1410 cm^{-1} may be related to C–H deformation and other vibrations of aromatic and aliphatic constituents. The region between approximately 1410 and 750 cm^{-1} showed several characteristic bands attributable to organic acids, polysaccharides, and other plant-derived components.

The fingerprint region between approximately 1300 and 850 cm^{-1} contained bands potentially associated with C–O and C–C stretching vibrations of flavonoids, glycosides, anthocyanins, and polysaccharides. Bands in the 800–710 cm^{-1} region may additionally be related to C–O stretching and O–C–H bending vibrations. Overall, the FTIR spectra confirmed the presence of diverse oxygenated and aromatic functional groups consistent with the complex phytochemical composition of the herbal tea mixtures.

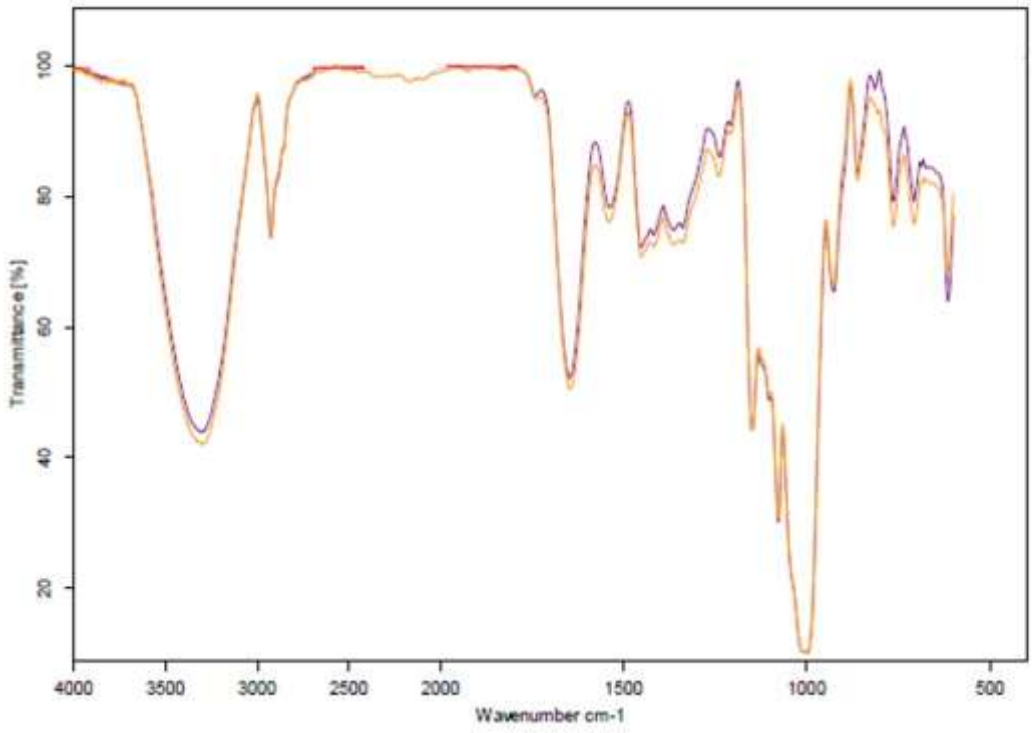

Figure 4. FTIR spectra of the herbal tea formulations.

3.5. *In Vitro* Dissolution Test

The *in vitro* dissolution behavior of the pilot herbal tea mixtures was evaluated under different gastrointestinal pH conditions. The formulations demonstrated rapid release, with cumulative dissolution generally exceeding 80% by 20 min and approaching a plateau within approximately 15 min.

At pH 1.2, the control formulation showed cumulative dissolution values of 68.0 ± 2.4%, 79.8 ± 3.1%, 89.0 ± 2.9%, and 98.8 ± 2.0% at 5, 10, 15, and 30 min, respectively. The corresponding 30-min values for batches 1-3 were 99.9 ± 1.2%, 100.0 ± 0.5%, and 100.0 ± 1.0%, respectively. At pH 4.5, the control reached 90.5 ± 2.0% dissolution at 15 min and 99.5 ± 2.0% at 30 min. The corresponding 30-min dissolution values for batches 1-3 were 99.7 ± 1.2%, 99.4 ± 1.9%, and 99.9 ± 1.3%, respectively. A similar pattern was observed at pH 6.8. The control reached 90.2 ± 3.0% at 15 min and 98.8 ± 2.0% at 30 min, whereas the three batches reached approximately 99-100% dissolution at 30 min. These results indicate that the tested formulations exhibited rapid and extensive dissolution across the simulated gastrointestinal pH conditions.

Table 2. Mean cumulative dissolution (%) ± RSD (%) of the herbal tea mixture batches at different gastrointestinal pH conditions.

Dissolution Medium	Sample	Mean Cumulative Dissolution (%) ± RSD (%)			
		5 min	10 min	15 min	30 min
Hydrochloric acid (pH 1.2)					
	Control	68.0±2.4	79.8±3.1	89.0±2.9	98.8±2.0
	P1	70.1±1.2	82.5±1.8	92.9±2.0	99.9±1.2
	P2	72.0±0.5	85.1±1.6	95.5±0.4	100.0±0.5
	P3	72.6±2.0	85.5±2.2	94.0±1.6	100.0±1.0
Acetate buffer (pH 4.5)					
	Control	67.0±3.0	78.0±2.5	90.5±2.0	99.5±2.0
	P1	70.5±1.8	79.5±1.1	92.0±1.5	99.7±1.2
	P2	71.5±1.5	80.5±2.2	93.9±1.1	99.4±1.9
	P3	73.0±2.7	82.0±2.3	92.5±2.5	99.9±1.3
Phosphate buffer (pH 6.8)					
	Control	68.0±2.5	77.5±2.0	90.2±3.0	98.8±2.0
	P1	71.5±2.0	80.0±2.6	95.0±1.2	99.0±1.10
	P2	69.5±1.4	85.2±1.4	93.2±1.2	100.0±0.2
	P3	70.0±1.5	83.8±1.0	95.8±0.6	99.9±0.4

The relatively low RSD values observed at the different sampling times indicate good repeatability of the dissolution profiles. The convergence of dissolution values toward approximately 99-100% at 30 min further suggests that the major soluble constituents of the formulations were efficiently released under the tested conditions. However, dissolution should be interpreted as an indicator of ***in vitro*** **release**, rather than direct evidence of bioavailability. Although rapid dissolution may facilitate subsequent absorption, actual bioavailability depends on additional processes, including gastrointestinal stability, enzymatic transformation, intestinal permeability, metabolism, and systemic disposition. Therefore, the high dissolution observed in the present study demonstrates favorable in vitro release characteristics but does not by itself establish *in vivo* bioavailability.

CONCLUSION

This study demonstrated that the formulation ratio of six botanical materials significantly influenced the phenolic composition and antioxidant properties of the developed herbal tea prototypes. Among the formulations, P3 showed the most promising overall antioxidant

performance, characterized by a comparatively higher phenolic contribution and lower IC_{50} value, together with strong ABTS and DPPH radical-scavenging activity (R^2 = 0.990-0.994 for ABTS and R^2 = 0.929-0.941 for DPPH). The high correlations observed between TPC and antioxidant activity further highlighted the contribution of phenolic compounds to the antioxidant capacity of the formulations. HPLC analysis identified chlorogenic and ferulic acids as the predominant phenolic constituents, while FTIR analysis confirmed the presence of characteristic functional groups associated with the complex phytochemical composition of the plant mixtures. In addition, the formulations exhibited rapid and extensive *in vitro* dissolution, reaching approximately 99-100% cumulative release at 30 min under the tested gastrointestinal pH conditions. Overall, these findings indicate that optimizing the relative proportions of botanical ingredients can enhance antioxidant performance without simply increasing the amount of individual plant materials, supporting P3 as a promising candidate for further functional dried capsule tea or nutraceutical development. Nevertheless, simulated gastrointestinal digestion and Caco-2 cell models should be employed in future studies to evaluate the stability, bioaccessibility, and intestinal uptake of the bioactive compounds. Comprehensive sensory and consumer acceptance studies, besides pilot- and industrial-scale validation, are also recommended to assess the practical applicability and commercialization potential of the optimized formulation for further studies.

ABSTRACT

The application of microbial fertilizers on plants has gained increasing importance as a sustainable strategy to enhance crop stress tolerance and plant productivity under challenging deficit irrigation conditions. This study aimed to evaluate the effects of various mycorrhiza-based microbial fertilizer formulations on the growth performance of broad-leaved basil (*Ocimum basilicum* L.) grown in a sandy-loam calcareous soil. The study focused on how these microbial amendments influence plant resilience across four deficit irrigation levels: full irrigation (SS100) and three deficit irrigation regimes (SS80, SS60, and SS40). The results indicated that deficit irrigation conditions severely restricted vegetative growth parameters in unfertilized control groups. However, microbial fertilization significantly alleviated the adverse effects of drought stress. Basil plants treated with mycorrhizal formulations, particularly dual or combined microbial treatments, exhibited notable improvements in plant growth dynamics. Key parameters including plant height, root collar diameter, and total leaf number were positively affected by the microbial amendments even under high water deficit. Additionally, plants treated with microbial fertilizers recorded significantly higher chlorophyll levels (SPAD values), demonstrating sustained photosynthetic efficiency under stress. At harvest, a substantial increase in fresh biomass accumulation was observed in mycorrhiza-treated plots compared to the control group, highlighting the role of these symbiotic microorganisms in optimizing root surface area and nutrient uptake. Overall, mycorrhiza-based applications emerged as highly effective inputs for mitigating drought-induced limitations in basil cultivation.

Keywords: Mycorrhiza, Biostimulants, Drought tolerance, Sustainable agriculture

INTRODUCTION

The rapidly increasing global population, dwindling freshwater resources, and irregular rainfall patterns triggered by global climate change are among the most significant ecological problems threatening agricultural production. In particular, in semi-arid climate zones such as the Mediterranean Basin (e.g., the southern coasts of Türkiye), plants frequently face water scarcity (drought) stress throughout their growing seasons (IPCC, 2021). Drought stress leads to a decrease in cell turgor pressure, stomatal closure, accumulation of reactive oxygen species (ROS) causing oxidative damage, and consequently a significant reduction in photosynthesis, nutrient uptake, and ultimately biomass and economic yield in plants (Augé, 2001; Dimkpa et al., 2009).

Basil (*Ocimum basilicum* L.), belonging to the Lamiaceae family, is a high-value annual plant with wide applications in the food, pharmaceutical, and cosmetic industries, classified as a medicinal and aromatic plant. Basil plants have significant economic importance due to their volatile oils, phenolic compounds, and antioxidants. However, the plant is highly sensitive to soil moisture deficiency during its vegetative growth period (Daza-Torres et al., 2017). In basil plants grown under water scarcity, the leaf area index decreases, fresh herb yield decreases, and the market value of the plant diminishes. Therefore, developing alternative, environmentally friendly agronomic strategies that will ensure the sustainability of basil production and increase abiotic stress tolerance under deficit irrigation conditions is critically important.

Intensive chemical fertilization, used in traditional agriculture to increase yields, leads to salinity accumulation in the soil, groundwater pollution, and disruption of the soil microbiota. In recent years, the use of microbial fertilizers (biostimulants) such as Arbuscular Mycorrhizal Fungi (AMF) and Plant Growth Promoting Rhizobacteria (PGPR) as alternatives to these chemical inputs has attracted great interest in terms of agricultural sustainability (Calvo et al., 2014; Backer et al., 2018). AMF forms extraradical hyphae networks by establishing a symbiotic relationship with plant roots; these hyphae take up and transport low-mobility nutrients such as water and phosphorus from soil pores that the plant's normal root system cannot reach (Ruiz-Lozano et al., 2012). At the same time, mycorrhiza and beneficial rhizobacteria improve root architecture by promoting indole acetic acid (IAA) synthesis in the plant and provide osmotic protection against water stress by increasing antioxidant enzyme activities (Bharti et al., 2016).

The main objective of this study is to comparatively determine the effects of different mycorrhiza-derived microbial fertilizer formulations on parameters reflecting the agricultural characteristics of Large-Leaf Basil (*Ocimum basilicum* L.) grown under restricted irrigation conditions. The primary reason for focusing on basil in this study is the lack of comprehensive literature on the specific morpho-physiological responses of combined microbial fertilizer applications at different water stress levels, despite the high economic value of the species. The study is based on the hypothesis that microbial symbiosis can compensate for yield losses under restricted irrigation by increasing water use efficiency.

MATERIAL AND METHODS

Research Area and Soil Characteristics

This study was conducted in the autumn of 2025 in the Research and Application Greenhouse of the Faculty of Agriculture, Akdeniz University (36° 53' 33" N, 30° 38' 52" altitude 50m). According to meteorological data collected throughout the experiment, the average daily temperature of the area was 16.0 °C, the average daily sunshine duration was 6-7 hours, the average daily open surface evaporation was 2.5 mm to 3.0 mm/day, the average daily rainfall was 4.6 mm, the average daily wind speed was 2.9 m/s, and the average relative humidity was 64%. The greenhouse floor was covered with black plastic mulch, and the greenhouse had top and side ventilation systems.

The experiment was carried out under controlled conditions with natural sunlight, under a homogeneous temperature and relative humidity regime throughout the growing period. The growing medium used in the experiment was obtained soil from a depth of 0-30 cm from the Aksu Application Area of Akdeniz University. This soil is classified as "Typic Xerofluvent" based on its physical and chemical properties, formed on alluvial parent material called the "Tehnelli Series" (Sarı et al., 2009).

Analysis of the potting soil revealed a slightly alkaline pH (pH 7.9), low electrical conductivity (salinity), high lime content, cation exchange capacity (CEC) ranging from 18.9-19.3 meq/100g, and a sandy-loam texture (Table 1). Overall, the soil has a low organic matter content (1.6%), a high bulk density (1.40 g/cm³), and a low water-holding capacity (available water 8.96%) due to its composition. These physical characteristics indicate that the soil is prone to rapid water loss and provides an ideal testing environment for drought stress trials.

Table 1. Soil physical and chemical properties

Parameter	Content
pH	7.9
EC (dS/m)	0.38
Total N (%)	0.09
Available P (mg/kg)	8.4
CEC (me/100g)	18.9
Exchangeable Na (me/100g)	0.1
Exchangeable K (me/100g)	0.3
Exchangeable Ca (me/100g)	18.5
Exchangeable Mg (me/100g)	2.4
Lime (%)	30.5
Organic matter (%)	1.6
Sand (%)	44.3
Loam (%)	39.1
Clay (%)	16.6

Plant Material and Applications

In the experiment, commercially standardized large-leaf basil (*Ocimum basilicum* L. cv. Vilmorin) seedlings were used as plant material. The experiment was established using a Randomized Complete Block Design in a factorial arrangement, with 5 different fertilizer applications x 4 different irrigation levels x 3 replications, totaling 60 pots (one plant per pot). The pots were placed in a north-south direction, taking care to avoid placing the same applications side by side to minimize the shading effect (edge effect). Details regarding mycorrhiza-based microbial fertilization and other fertilization treatments in the experiment are given in Table 2.

Table 2. Fertilizer materials and their contents applied to potting soil in the experiment

Application	Content
MG+A	Application of the microbial preparation called Krishiza (contains arbuscular mycorrhizal fungus and microorganism spores)
MG+B	Application of the microbial fertilizer called Indigo (contains arbuscular mycorrhizal fungus and microorganism spores)
MG+A+B	Combined (dual) application of Krishiza and Indigo preparations
OG+	Application of standard chemical fertilizer (does not contain microbial inoculant)
OG-MG-	Negative control group without mycorrhiza or chemical fertilizer application

Irrigation Regime

Irrigation was applied to all trial subjects when 40% of the available water capacity of the soil was consumed based on the water requirements of the basil plant (Allen et al., 1998; Daza-Torres et al., 2017). Irrigation procedures were determined by the gravimetric (weighing) method based on the field capacity and wilting point data of the pots, and 4 different irrigation levels were created (Table 3).

Table 3. Water restriction rates applied to basil plants in the experiment

Irrigation level	Content
SS100	Full Irrigation (No Stress) where 100% of the plant's water needs are met
SS80	Slightly Restricted Irrigation (80% of the water lost is replenished)
SS60	Moderately Restricted Irrigation (60% of the water lost is replenished)
SS40	Severely Restricted Irrigation (40% of the water lost is replenished) (Heavy water stress)

The water levels in the pots were checked at regular intervals using a precision balance, and the amount of moisture lost was measured, with water added to the pots according to their group size. In addition, a standard liquid chemical fertilization (fertigation) program was applied to all pots in equal volumes throughout the experiment to meet the plants' basic nutrient needs.

Experimental Procedure and Measurements

Following the preparation of soil, filling it into pots (September 24), and bringing it to field capacity, seedlings were planted on October 10 after being treated with microbial preparations

using the root dipping (inoculation) method. During the growing season, hoeing, disease/pest (entomological) controls, and specific treatments (October 23-30) were carried out. Phenological readings were taken at 5 different measurement times (Time points 1-5; e.g., October 20, November 14, November 25, etc.) during the vegetation period.

Plant height (cm): Measured from the soil surface to the apical bud using a ruler. Root collar diameter (mm): Measured just above the soil surface with a digital caliper. Plant crown width (cm): Determined by measuring the distance between the two widest points of the plant. Number of leaves (pieces/plant): Determined by counting the number of fully opened non-chlorotic functional leaves. Chlorophyll content (SPAD): Measured from fully developed leaves at the mid/upper nodes of the plant using a SPAD-502 (Konica Minolta) portable chlorophyll meter. Fresh weight (g/plant): Above-ground biomass of plants was determined by weighing with a precision balance (0.01 g) at the last harvest on December 12th.

Statistical Analyses

The obtained data were statistically evaluated using the SPSS (Version 23.0) software package. The main effects and interactions of the Application (AAP), Irrigation Level (IL), and Measurement Time (MT) factors on growth parameters were tested at a 5% significance level ($P<0.05$) using a three-way factorial analysis of variance (ANOVA) with Type III sums of squares. Statistically significant differences were separated using the Least Significant Difference (LSD) test.

RESULTS

The effects of different microbial fertilizer applications (MFA), limited irrigation levels (LI), and measurement time (MT) on plant growth parameters were investigated. It was determined that the applications (MFA) had a highly significant effect ($P<0.001$) on root collar diameter, leaf number, chlorophyll content, and fresh weight, and a significant effect ($P<0.01$) on plant height and crown width. In addition to the main factors, the Application × Irrigation Level (MFAxLI) interaction was found to be statistically significant only in root collar diameter ($P<0.05$) (Table 4).

Root Collar Diameter and Plant Height

Root collar diameter (RCD) in plants is a critical parameter reflecting the capacity of vascular bundles for water and nutrient transport. According to the research findings, the highest RCD values were obtained from the MG+A+B (5.55 mm) and MG+A (5.48 mm) plots containing mycorrhiza and microbial treatment, and these treatments were statistically in the same "a" group (Table 4). The lowest root collar diameter was observed in the OG-MG-control group (4.72 mm, "c" group) without any fertilizer/microbial application. When examined according to irrigation levels; full irrigation (SS100) provided the highest diameter development with 5.36 mm, while severe water stress (SS40) reduced this value to 4.97 mm (P<0.05).

Similarly, plant height values were significantly affected by the MFA. MG+A+B (39.33 cm), MG+A (38.43 cm), and MG+B (38.43 cm) applications statistically significantly increased plant height compared to the OG+ (35.51 cm) and OG-MG- control groups (35.11 cm) without microbial inoculant. Regarding the irrigation regimes, a fluctuating trend was observed where the highest vegetative height was noted under moderate water restriction (SS60 with 38.72 cm) and full irrigation (SS100 with 38.38 cm), whereas severe water stress (SS40) suppressed the average plant height to 35.73 cm (Table 4).

Plant Crown Width and Number of Leaves

Plant crown width and leaf number are directly related to the plant's net assimilation area (photosynthetic surface). Analysis data show that mycorrhizal applications increase crown width. MG+A application (26.38 cm) ranked first in group "a", while the OG-MG-control group (22.21 cm) remained in group "c". Although the effect of irrigation level on crown width was not statistically significant (NS), the highest numerical values were measured at SS60 (24.50 cm) and SS80 (24.50 cm) levels (Table 4).

In terms of total leaf number, the MG+A (58.93 leaves/plant) and MG+A+B (58.65 leaves/plant) combinations increased leaf formation by approximately 40% compared to the control group (42.28 leaves/plant) (P<0.001). As expected, the measurement time factor showed a linear increase correlated with plant phenology; the average leaf number, which was 8.23 in the 1st measurement, reached 112.13 leaves/plant in the 5th measurement before harvest. The MFA×MT interaction on leaf number was also found to be significant (P<0.001) (Table 4); this demonstrates that microbial fertilizers stimulate leaf organogenesis much faster in later growth stages compared to the control group.

Chlorophyll Content (SPAD Values)

SPAD values, which represent chlorophyll concentration, showed quite interesting responses to microbial fertilization and water restriction factors. While the average SPAD value in control plants (OG-MG-) was 38.28, MG+A (41.72) and MG+A+B (41.50) applications statistically increased chlorophyll levels (P<0.001) and were placed in group "a" (Table 4).

A much more striking finding emerged in the differences between irrigation levels (SS). While the average SPAD value was 39.37 under full irrigation (SS100) conditions without water stress, this value increased to 42.02 at the SS40 level with severe water restriction and to 41.91 at the SS60 level (P<0.001). Specifically, this physiological response indicates that the severity of water restriction increased the amount of chlorophyll per unit area in the leaves.

Plant Weight (Biomass)

Harvest fresh weight (biomass), the most fundamental indicator of agricultural success in basil cultivation, was the parameter that most clearly reflected the effect of microbial fertilizers (P<0.001). At the end of the experiment, the average fresh weight of the MG+A application, which contains mycorrhiza and beneficial bacteria alone, was measured as 102.50 g. This was followed by the MG+A+B combined application with 91.25 g. In contrast, the average fresh weight in the OG-MG- control group, which received only inorganic base fertilization and no microbial support, was only 49.16 g. This explicitly indicates that the mycorrhizal formulation (MG+A) increased the plant fresh biomass by 108% (more than double) compared to the control group in the overall average. Interestingly, the statistical analysis revealed that the deficit irrigation levels did not exert a significant main effect (NS) on the total fresh weight, implying that the robust root infrastructure promoted by microbial inoculation effectively buffered potential biomass losses across different water availability levels (Table 4).

DISCUSSION

The findings clearly demonstrate the supportive effects of beneficial microorganisms (AMFs) applied to the soil on plant morphology and biomass. The calcareous, low-organic-matter, and

sandy-loam soil used in the experiment has low water-holding capacity, making the plants susceptible to water stress. The findings support the idea that microbial fertilizers activate tolerance mechanisms despite these challenging soil characteristics and irrigation limitations.

In the study, mycorrhizal (MG+A) and combined microbial fertilizer (MG+A+B) applications significantly increased the height, root collar diameter, and leaf number of basil plants compared to the control group. Mycorrhizal fungi establish a symbiotic relationship by settling in the root cortex cells of the plant. Through their hyphal networks (extraradical mycelium), they transfer water and nutrients with slow diffusion (especially phosphorus, zinc, and copper) from micro-pores inaccessible to the roots to the plant (Dimkpa et al., 2009; Calvo et al., 2014). This observed promotion in plant height and root collar diameter can be explained by improved plant nutrition and consequently increased meristematic cell division. Similar studies on basil plants (Copetta et al., 2006) also confirm that AMF inoculation optimizes vegetative parameters. The fact that combined application (MG+A+B) yields result as successful as single applications is a result of the synergistic interaction between these combined applications; because such applications can promote the germination of mycorrhizal spores and the root infection rate (Barea et al., 1992).

One of the most striking results of the study is that increased water restriction (SS60 and SS40) statistically increases the amount of chlorophyll (SPAD value) in basil plants compared to the SS100 level. Water stress generally causes the degradation of photosynthetic pigments (chlorosis). This phenomenon is primarily driven by the 'concentration effect' under drought stress. To minimize transpirational water loss, plants restrict leaf cell expansion. Consequently, the reduction in total leaf area combined with increased leaf thickness elevates the relative chlorophyll density per unit surface area, directly reflected in higher SPAD indices (Rouphael et al., 2012). The higher SPAD values (41.72) in plants treated with microbial fertilizer compared to the control group (38.28) are related to the fact that beneficial microorganisms facilitate the uptake of essential elements for chlorophyll biosynthesis, such as nitrogen (N) and magnesium (Mg), thus ensuring that the photosynthetic apparatus remains more robust against stress.

The fresh weight findings, the most important outcome of the experiment, proved that microbial fertilizers are an indispensable tool for maintaining plant production under water stress. The fact that the biomass amount in the control plots was almost half that of the plants treated with microbial inoculant shows how much water stress conditions suppress the metabolism of uninoculated plants. Mycorrhizal plants (especially the MG+A formulation) can maintain cellular turgor even at low soil moisture levels and continue carbon assimilation (biomass formation) by increasing the expression of "aquaporin" genes, which regulate water flow into the plant body through the roots, and by optimizing stomatal conductivity (Ruiz-Lozano et al., 2012).

CONCLUSION

The results of this study, conducted on basil (*Ocimum basilicum* L.) grown under limited irrigation conditions (drought stress) in calcareous soils with low organic matter and poor water

retention capacity typical of the Mediterranean Basin, can be summarized as follows: Mycorrhiza-based microbial fertilizer applications (especially MG+A and MG+A+B combinations) statistically increased plant height, root collar diameter, and crown width (P<0.001) compared to the control group grown under conventional cultivation, resulting in a stronger and more structurally resistant plant architecture. The number of leaves, an indicator of the vegetative capacity of the plants, was approximately 40% higher in pots inoculated with microbial fertilizers compared to the control group. Severe water restriction (SS40) caused a concentration effect by concentrating chlorophyll content per unit leaf area. Microbial fertilizers supported photosynthetic capacity by maintaining chlorophyll integrity at a higher level against this physiological pressure of stress. Regarding agricultural yield, the most critical finding was that Mycorrhiza (MG+A) application increased the fresh biomass of basil by 108% compared to control crops in limited irrigation scenarios. In conclusion, against the backdrop of global climate change scenarios where drought increasingly limits agricultural productivity, transitioning from intensive chemical inputs to integrated mycorrhizal formulations stands out as a high-efficiency, agronomically viable, and ecologically sustainable strategy to secure crop yields. Further studies could investigate how this microbial symbiosis regulates water stress genes at the molecular (transcriptomic) level and its effects on the essential oil profile, which determines the economic importance of basil, under field conditions.

ACKNOWLEDGEMENTS

In this study, the phase of conducting pot experiments under modern greenhouse conditions was supported by Dean’s Office of the Faculty of Agriculture at Akdeniz University.

ABSTRACT

Propolis, often referred to as "bee glue," is a resinous substance collected by honey bees from plant buds, exudates, and bark, and mixed with beeswax and salivary enzymes. It plays a vital role in hive hygiene and structural integrity, and has gained global recognition for its diverse biological properties, including antioxidant, antimicrobial, anti-inflammatory, and anticancer activities. As worldwide demand for natural health products continues to rise, propolis has emerged as a commercially valuable hive product. However, its chemical composition and yield are highly variable and influenced by several factors, including bee genetics, local flora, environmental conditions, and hive design. This variability poses significant challenges for standardisation and quality control, and highlights the need for region-specific studies. The present study was undertaken to evaluate the effects of two key factors, hive floor type (open vs. closed bottom) and honey bee breed (native Iranian vs. Carnica), on the quantitative production and qualitative characteristics of propolis in the geographical region of Bostanabad, Iran. A total of 32 colonies were standardised and evenly assigned to four experimental groups: (1) closed-bottom hives with native bees, (2) open-bottom hives with native bees, (3) closed-bottom hives with Carnica bees, and (4) open-bottom hives with Carnica bees. Propolis was collected using plastic traps with 3-mm mesh grids over a two-month period under uniform management conditions. Harvested samples were weighed, and their physicochemical properties, including moisture, ash content, pH, total phenolic content, total flavonoid content, antioxidant activity (DPPH radical-scavenging assay), soluble and insoluble solid fractions, and mineral element profiles, were analysed using standard laboratory methods. The results revealed significant differences in propolis yield among the treatments. The highest production (61.25 g per colony) was recorded in closed-bottom hives housing native Iranian bees, whereas the lowest yield (47.87 g) was obtained from open-bottom hives with Carnica bees ($p < 0.05$). This suggests that both genetic predisposition and hive microclimate influence resin-collecting behaviour. Interestingly, total phenolic content, flavonoid content, DPPH scavenging activity, ash percentage, and moisture content did not differ significantly across treatments ($p > 0.05$), indicating that these quality attributes were relatively stable under the study conditions. In contrast, the proportion of soluble solids was highest in native-bee colonies kept in closed-bottom hives, which may reflect subtle differences in resin origin or processing. The pH

of propolis from native bees was consistently lower than that from Carnica bees, pointing to breed-related chemical variation. Mineral analysis showed that closed-bottom hives with native bees yielded propolis with higher concentrations of calcium, phosphorus, copper, magnesium, manganese, and chromium compared to other groups ($p < 0.05$). These minerals are nutritionally and biologically relevant, contributing to propolis's overall bioactivity. Taken together, these findings demonstrate that both hive type and bee breed significantly affect the quantity and certain quality parameters of propolis. The superior performance of native Iranian bees in closed-bottom hives may reflect better adaptation to local environmental conditions and resource availability. From a practical perspective, this study provides valuable evidence for local beekeepers and producers seeking to optimise propolis yield and quality. It also underscores the importance of region-specific management strategies and the need for further research on seasonal variation, harvesting methods, and the chemical characterisation of active compounds. Ultimately, this work contributes to the broader goal of developing sustainable, high-value propolis production systems that support both apicultural livelihoods and the growing natural health product industry.

Keywords: Propolis; honey bee breed; hive type; antioxidant activity; phenolic compounds; mineral elements; propolis yield; Apis mellifera; Carnica bee; native Iranian bee; beekeeping management

1. INTRODUCTION

Propolis is a resinous hive product collected by honey bees from plant buds, exudates, bark, and other plant-derived sources and subsequently modified with beeswax and bee secretions. Within the colony, it serves as an important component of the social defense system by contributing to hive sealing, structural maintenance, and the inhibition of microbial growth. Beyond its biological role in the colony, propolis has attracted considerable scientific and commercial interest because of its diverse biological activities, including antioxidant, antimicrobial, anti-inflammatory, and other health-promoting properties (Bankova et al., 2000; Fokt et al., 2010; Anjum et al., 2019). Consequently, propolis is increasingly considered a valuable secondary hive product with potential applications in pharmaceutical, food, nutraceutical, and cosmetic industries.

The chemical composition and biological properties of propolis are highly variable. Unlike honey and royal jelly, whose major constituents are largely derived from the bees themselves, propolis is strongly dependent on the botanical resources available to foraging colonies. Plant species, geographical location, climate, season, and availability of resinous materials can therefore result in substantial differences in the chemical profile of propolis. More than hundreds of chemical constituents have been identified in propolis, with polyphenols, flavonoids, phenolic acids, terpenoids, and other plant-derived compounds contributing to its biological activity (Bankova et al., 2006; Kasote et al., 2022). This considerable chemical diversity is one of the major challenges in establishing consistent quality criteria for propolis and limits the direct comparison of samples originating from different geographical regions.

In addition to environmental and botanical factors, characteristics of the honey bee colony may influence both the quantity and composition of collected propolis. Honey bee genotypes and races differ in their propolis-hoarding behavior and in their ability or tendency to collect plant resins. Evidence from different honey bee populations indicates that genetic and morphometric characteristics can be associated with differences in propolis-collecting capability (Koo & Park, 1997; Kekeçoğlu et al., 2020). Such differences may be particularly important when comparing locally adapted honey bee populations with introduced or selected genotypes under the same environmental conditions. The behavioral response of bees to resin availability and their ability to identify and transport suitable resinous materials may consequently affect the amount and characteristics of propolis accumulated within a colony.

Hive design is another potentially important management factor affecting propolis collection. The physical structure of the hive can modify the microenvironment of the colony and may influence the number and location of gaps or surfaces that bees attempt to seal with propolis. Experimental evidence has shown that modifications of hive interiors can alter propolis-hoarding behavior, while differences among hive designs have also been associated with variation in propolis production and quality (Hodges et al., 2019; Kiziltas & Erkan, 2020). Thus, optimizing hive design may provide a relatively simple management strategy for increasing the recovery of propolis as a commercial hive product. However, the response to a particular hive design may depend on the genetic characteristics of the colonies and the environmental conditions under which they are maintained.

Despite the increasing interest in propolis as a high-value apicultural product, information concerning the interaction between honey bee genotype and hive design under the environmental conditions of Iran remains limited. In particular, comparative information on propolis production by native Iranian honey bees and Carnica bees maintained in different hive-bottom configurations is scarce. Because native bees may be better adapted to local environmental conditions and available plant resources, their propolis-collecting behavior may differ from that of introduced or selected bee genotypes. At the same time, the use of closed- or open-bottom hives may modify colony conditions and consequently influence resin collection. Therefore, the present study was conducted to evaluate the effects of honey bee genotype and hive bottom type on the production and selected physicochemical and functional characteristics of propolis under the environmental conditions of Bostanabad, northwestern Iran. Native Iranian and Carnica honey bee colonies were maintained in wooden hives with either closed or open bottoms under standardized management conditions. The study was designed to determine whether these two practical factors could influence propolis yield and selected quality attributes and thereby provide useful information for improving propolis production in local beekeeping systems.

2. MATERIALS AND METHODS

2.1. Experimental design and propolis collection

The experiment was conducted using 32 honey bee colonies representing two honey bee genotypes: native Iranian honey bees (*Apis mellifera*) and Carnica bees (F1 hybrid). Colonies were randomly assigned to four experimental treatments according to honey bee genotype and

hive bottom type: native bees in closed-bottom hives, native bees in open-bottom hives, Carnica bees in closed-bottom hives, and Carnica bees in open-bottom hives. Each treatment included eight colonies. Before the beginning of the experiment, colonies were standardized to six frames of adult bees and five brood frames and maintained under similar management conditions.

Propolis was collected using plastic propolis traps equipped with 3-mm grids. The traps were installed in the experimental colonies and left in place for two months. At the end of the collection period, the propolis from each colony was removed, weighed, and recorded as propolis yield (g colony^{-1}). Samples intended for laboratory analyses were transferred to the laboratory, stored at −19 °C, and subsequently processed for physicochemical and biochemical analyses.

2.2. Propolis extraction

For analyses of phenolic compounds, flavonoids, and antioxidant activity, raw propolis samples were powdered and extracted with 80% ethanol. Briefly, 100 g of powdered raw propolis was mixed with 200 mL of 80% ethanol and shaken for 48 h at room temperature. The extract was filtered to remove residual wax and insoluble materials, kept at −10 °C for 24 h, and subsequently concentrated using a rotary evaporator at 45 °C. The concentrated extracts were stored in dark glass containers until analysis.

2.3. Physicochemical and antioxidant analyses

Selected physicochemical characteristics of the raw propolis samples were determined, including moisture, ash, pH, and soluble and insoluble solid fractions. Soluble and insoluble solids were determined by extracting 1 g of powdered propolis with 250 mL of 80% ethanol, followed by stirring, filtration, and weighing of the insoluble fraction. The soluble fraction was calculated from the difference between the initial sample weight and the insoluble fraction. Propolis pH was determined using a pH meter after preparation of the sample solution, with calibration performed using standard buffer solutions. Ash content was determined by drying the sample followed by incineration at 550 °C until a constant ash residue was obtained.

Total flavonoid content was determined using the aluminum chloride colorimetric method, with quercetin used as the reference standard. Absorbance was measured at 415 nm and results were expressed as quercetin equivalents. Total phenolic content was determined using the Folin–Ciocalteu colorimetric method, with gallic acid used as the reference standard, and expressed as mg gallic acid equivalents per gram of sample.

Antioxidant activity was evaluated using the DPPH radical-scavenging assay. Propolis extract was reacted with a methanolic DPPH solution and incubated for 30 min in the dark at room temperature. Absorbance was measured at 517 nm using a spectrophotometer. Radical-scavenging activity was calculated as the percentage inhibition of DPPH radicals relative to the control.

2.4. Mineral analysis

The mineral composition of propolis samples was determined to characterize differences in selected mineral elements among the experimental treatments. The concentrations of calcium, phosphorus, magnesium, iron, copper, manganese, zinc, sodium, potassium, and chromium were evaluated and expressed on a concentration basis. Selected additional elements, including nickel, lead, and aluminum, were also determined as part of the mineral profile.

2.5. Statistical analysis

Data were analyzed using the General Linear Model (GLM) procedure of SAS. The experimental treatments were considered as the statistical factor, and treatment means were compared using Duncan's multiple range test. Differences were considered statistically significant at $P < 0.05$. The statistical model was:

$$Y_{ij} = \mu + T_j + e_{ij}$$

where $Y_{ij}$is the observed value, $\mu$is the overall mean, $T_j$is the effect of treatment, and $e_{ij}$is the experimental error.

3. RESULTS AND DISCUSSION

3.1. Propolis yield

Propolis yield differed significantly among the four experimental treatments ($P = 0.037$). Native Iranian honey bee colonies maintained in closed-bottom hives produced the greatest amount of propolis (61.25 g colony^{-1}), whereas the lowest yield was obtained from Carnica colonies maintained in open-bottom hives (47.87 g colony^{-1}). Native bees in open-bottom hives and Carnica bees in closed-bottom hives showed intermediate values of 56.62 and 53.62 g colony^{-1}, respectively (Table 1).

The greater propolis production observed in native colonies, particularly under the closed-bottom hive condition, suggests that both colony genotype and hive environment may influence resin-hoarding behavior. The relatively higher production by native bees may partly reflect adaptation to the local environment and the plant resources available in the study area. Previous studies have similarly reported differences in propolis-collecting ability among honey bee races and ecotypes, indicating that genetic characteristics can contribute to variation in resin collection (Koo and Park, 1997; Kekeçoğlu et al., 2020). Differences among hive designs have also been reported, supporting the possibility that hive structure can modify the conditions that stimulate bees to deposit and accumulate propolis (Kiziltas and Erkan, 2020).

The magnitude of the observed differences should nevertheless be interpreted within the specific environmental and management conditions of the present study. Propolis production is influenced by several factors, including botanical resources, geographical location, season, colony characteristics, and collection method. Therefore, the superior performance of native bees in the present experiment should not be generalized to all regions or seasons. Rather, it provides evidence that the choice of bee genotype and hive configuration can be relevant considerations when propolis production is an important objective of beekeeping.

3.2. Physicochemical characteristics of propolis

Moisture and ash contents were not significantly affected by the experimental treatments ($P > 0.05$). Moisture ranged from 1.25 to 1.85%, while ash content ranged from approximately 1.05 to 1.89%. These values indicate relatively low moisture and ash contents across all treatments and suggest that the basic physicochemical characteristics of the collected raw propolis were relatively consistent under the conditions of the experiment.

The pH values ranged from 5.46 to 5.73. Although the statistical analysis did not indicate a significant treatment effect ($P = 0.2279$), propolis obtained from native bee colonies showed numerically lower pH values than propolis collected from Carnica colonies. This numerical difference may indicate some variation in the chemical characteristics of propolis associated

with bee genotype; however, the absence of statistical significance means that this observation should be considered cautiously. Previous research has indicated that propolis pH can vary according to geographical origin, botanical sources, and other factors affecting its chemical composition.

A significant difference was observed in the soluble fraction of propolis (P = 0.0089). The highest soluble-solid content was recorded in propolis from native bees maintained in closed-bottom hives (24.23%), whereas the lowest value occurred in native bees maintained in open-bottom hives (22.87%). The corresponding insoluble fractions showed the reverse pattern. Total solids remained high and relatively consistent among treatments, ranging from approximately 98.15 to 98.74%.

The variation in soluble and insoluble fractions may reflect differences in the type and relative proportions of plant-derived resins collected by the colonies. Propolis composition is strongly dependent on botanical and geographical origin, while bee genotype and hive conditions may influence resin-collection preferences and the material ultimately deposited in the hive. Similar variability in the physicochemical composition of propolis from different bee populations and hive conditions has been reported previously. Thus, the higher soluble fraction observed in the native-bee/closed-bottom treatment may represent a potentially useful quality-related characteristic, although chemical profiling of individual compounds would be required to establish its biological significance.

3.3. Phenolic compounds and antioxidant activity

In contrast to propolis yield and soluble solids, the principal antioxidant-related characteristics evaluated in this study were relatively stable among treatments. Total flavonoid content ranged from 0.93 to 1.28 mg quercetin equivalents g^{-1}, total phenolic content ranged from approximately 326 to 345 mg gallic acid equivalents g^{-1}, and DPPH radical-scavenging activity ranged from approximately 85.6 to 89.4%. None of these parameters differed significantly among the experimental treatments ($P > 0.05$).

The absence of significant differences in these parameters despite the clear difference in propolis yield is noteworthy. It suggests that, under the environmental conditions and collection period of this experiment, the factors affecting the quantity of propolis collected did not produce a corresponding change in its overall phenolic and antioxidant characteristics. The phenolic content of propolis is generally strongly associated with botanical origin, and substantial differences among geographical regions have been reported. Therefore, the relatively similar phenolic and antioxidant profiles observed among the four treatments may indicate that colonies had access to a broadly similar pool of resin-producing plants during the experimental period.

The results also emphasize an important distinction between propolis quantity and quality. Increasing the amount of propolis collected does not necessarily imply an increase in total phenolic concentration or antioxidant activity. For practical propolis production, both yield and chemical characteristics should therefore be considered when evaluating the effect of beekeeping management practices.

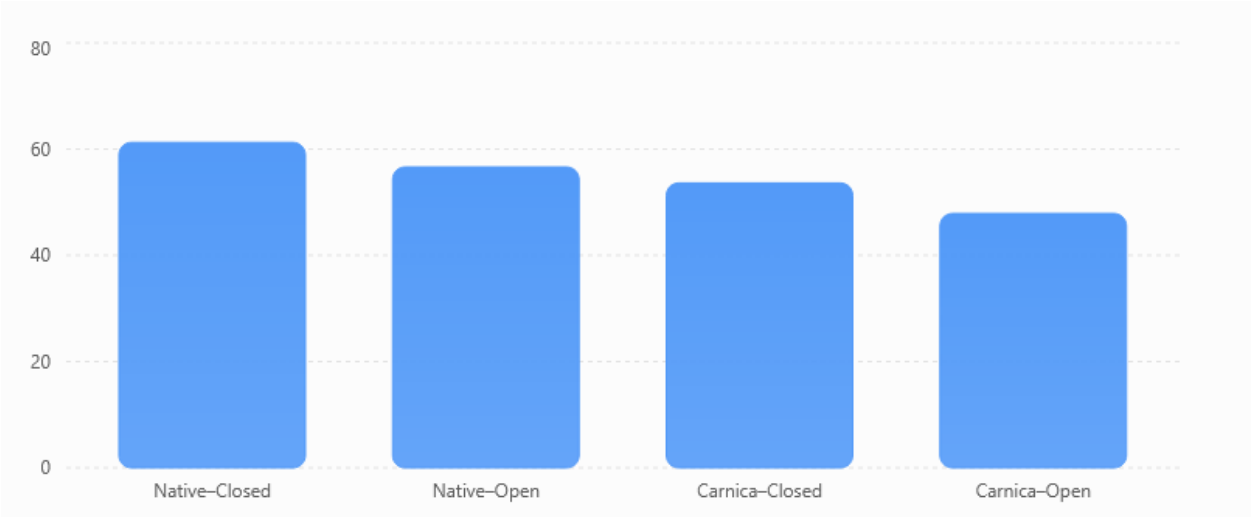

Figure 1. Propolis yield of native Iranian and Carnica honey bee colonies maintained in closed- and open-bottom hives. Values represent treatment means; the treatment effect was significant ($P = 0.037$).

3.4. Mineral composition

Mineral analysis demonstrated clearer treatment-related differences than those observed for phenolic and antioxidant characteristics. Propolis obtained from native bee colonies maintained in closed-bottom hives generally contained higher concentrations of several measured mineral elements than samples from the other treatments. In particular, calcium, phosphorus, copper, magnesium, manganese, iron, zinc, sodium, potassium, and chromium showed higher numerical concentrations in this treatment, with several of these differences reaching statistical significance.

The differences in mineral composition may be related to the botanical sources of the resins collected by the bees, as mineral profiles can vary among propolis samples according to geographical and environmental conditions. Trace and major elements have previously been investigated as potential indicators of the origin and characteristics of propolis. The greater concentrations observed in propolis from native colonies in closed-bottom hives therefore suggest that this treatment may have influenced either the source of collected resin or the relative incorporation of mineral-containing materials into the final propolis.

However, the mineral findings should not be interpreted as evidence that higher mineral concentrations necessarily indicate superior biological quality. Some elements may contribute to the nutritional or functional profile of propolis, whereas potentially toxic elements such as lead require separate consideration in quality-control studies. The present results primarily demonstrate that mineral composition was more responsive to the experimental treatments than the broad antioxidant indicators measured in this study.

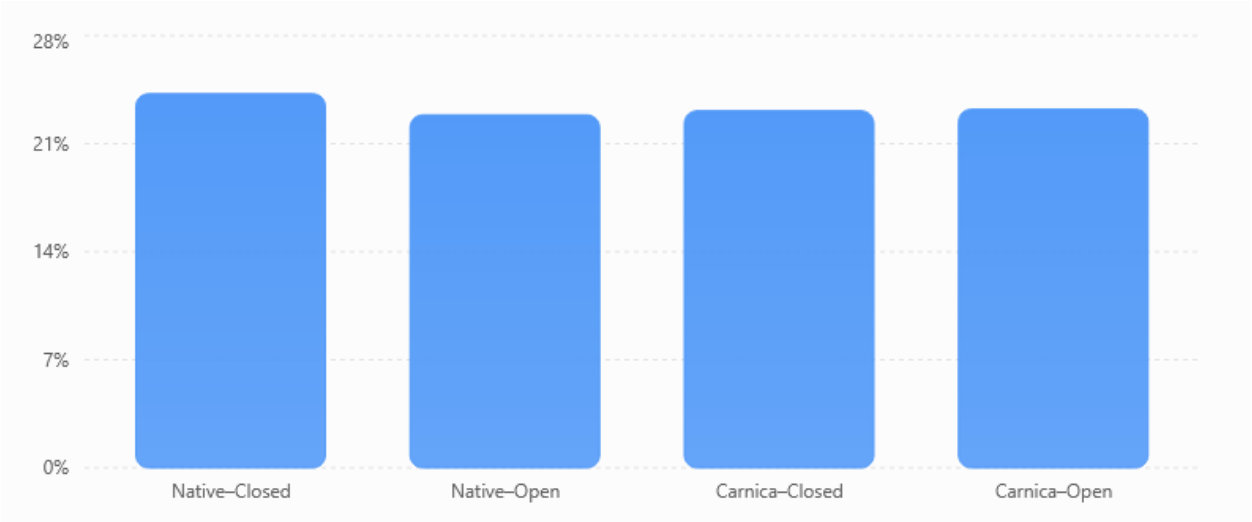

Figure 2. Soluble-solid fraction of propolis collected from native Iranian and Carnica honey bee colonies maintained in closed- and open-bottom hives. Treatment differences were significant ($P = 0.0089$).

CONCLUSION

The present study demonstrated that honey bee genotype and hive bottom design can influence propolis production under the environmental conditions of northwestern Iran. Native Iranian honey bee colonies maintained in closed-bottom hives produced the highest amount of propolis, whereas Carnica colonies in open-bottom hives showed the lowest production. In contrast, moisture, ash content, total phenolic content, total flavonoid content, and DPPH radical-scavenging activity were relatively stable among the experimental treatments. A significant difference was observed in the soluble fraction of propolis, while the mineral profile also showed treatment-related variation, particularly in propolis obtained from native colonies maintained in closed-bottom hives. These findings indicate that increasing propolis yield does not necessarily result in proportional changes in its broad phenolic or antioxidant characteristics. From a practical perspective, the use of native Iranian bees in closed-bottom hives appears promising for improving propolis yield under the conditions evaluated in this study. Nevertheless, these findings should be interpreted within the specific geographical and seasonal context of the experiment. Further studies covering different seasons, locations, botanical resources, and longer collection periods are warranted to determine the consistency of these effects and to identify the specific chemical compounds responsible for differences in propolis quality.

ABSTRACT

Climate change represents one of the major challenges facing agricultural production in the Mediterranean region, where increasing temperatures, irregular precipitation, recurrent droughts, and water scarcity are expected to substantially affect crop productivity and product quality. The Turkish Republic of Northern Cyprus (TRNC), characterized by a Mediterranean climate and limited freshwater resources, is particularly vulnerable to these changes. Agriculture in the region includes important perennial and annual crops such as citrus, cereals, vegetables, grapes, olives, carob, and forage crops, many of which are highly sensitive to changes in temperature and water availability. This review evaluates the potential and observed impacts of climate change on agricultural production in the TRNC, with particular emphasis on crop yield and product quality. The review examines changes in temperature and precipitation patterns, increasing drought and evapotranspiration, water scarcity, soil salinity, and the potential changes in pest and disease pressure and their effects on agricultural systems. Particular attention is given to the effects of climate-related stresses on yield components and quality parameters, including fruit size, total soluble solids, titratable acidity, grain yield and protein content, nutritional quality, and postharvest characteristics. The role of irrigation management, soil and water conservation, improved fertilization, drought- and heat-tolerant cultivars, treated wastewater, precision agriculture, and other climate-smart agricultural practices in reducing climate-related risks is also discussed. The review highlights the need for long-term climate and agricultural production datasets, crop-specific climate impact assessments, and locally adapted adaptation strategies. Developing climate-resilient agricultural systems will be essential for maintaining sustainable production, protecting product quality, improving water-use efficiency, and strengthening food security in the TRNC under future climate conditions.

Keywords: Climate change, Crop quality, Mediterranean agriculture, Water scarcity

INTRODUCTION

Climatic changes are increasingly impacting agricultural systems worldwide, including through changes in temperature, precipitation, atmospheric water demand, extreme weather events, soil moisture, and water availability. Climatic variability, especially in agriculture, is sensitive, as crop development and growth are directly associated with climatic conditions at specific phenological stages. The Mediterranean region is one of the most climate-changed areas in the world, with warming and water scarcity intensifying, and its freshwater resources already scarce. The Intergovernmental Panel on Climate Change (IPCC) classifies the Mediterranean basin as a region where heatwaves are expected to become more frequent and persistent, accompanied by increasing drought and water scarcity and associated risks to agriculture and other climate-sensitive sectors (Ali et al., 2022). The recent regional assessment (Zittis et al., 2022) shows that the Eastern Mediterranean and the Middle East are warming faster than the global average, and that drying trends are expected to intensify in the twenty-first century, regardless of the emission scenario adopted.

Islands are particularly vulnerable since they rely heavily on Mediterranean agriculture. Agricultural systems are mostly island-based and are typically constrained by land and freshwater resources and by their ability to relocate production geographically when needed. Cyprus is an unusual example to illustrate this. Irrigation is a key feature of the island's agriculture, and times of drought and water scarcity have been a recurring problem; agriculture is the main user of the island's water resources, with an estimated 75% of the total abstraction being used in this sector, despite the increasing demand for water from domestic and tourism activities. According to FAO, olives, citrus, grapes, potatoes and other Mediterranean crops are key agricultural products in Cyprus, and the sector is highly reliant on irrigation.

While the environmental challenges are similar to those of the island as a whole, in some respects, they are more severe in the TRNC, given its limited supply of large-scale desalination and inter-basin water-transfer infrastructure. Drought and salinisation have been recognised as chronic issues in Northern Cyprus, and the need for irrigation efficiency and crop-water management has been highlighted via dedicated research. For instance, Kahramanoğlu et al. (2020) investigated the water footprints and irrigation-use efficiency of the most important crops in Northern Cyprus. They reported that the selection of crops and the allocation of water resources need to be reconsidered to ensure that agricultural water use is environmentally, economically, and nutritionally sustainable.

Long-term meteorological data also show that Northern Cyprus is becoming more drought-prone. Payab and Türker (2018) studied the temporal and spatial features of drought events in the region using different SPI time scales. They determined that drought has been a frequent and worsening event in recent decades, and that there is a regional pattern of rainfall distribution. A follow-up study, which compared several widely used drought indices (DIs) for Northern Cyprus, found that the indices are highly correlated with each other and are all equally effective at measuring the effect of drought on the yield of rain-fed wheat and barley (Payab & Türker, 2019). Recently, Payab and Türker (2025) used the Reconnaissance Drought Index (RDI) and the CROPWAT crop-simulation model to estimate the impact of drought severity on the yield of rainfed wheat, barley, and olive in Northern Cyprus from 1977 to 2013, reporting a mean loss of roughly 37% for wheat, 28% for barley, and 49% for olive under drought

conditions. This loss became more apparent as drought severity increased. It is important because production is influenced not just by the average climatic state but also by the frequency, duration, timing, and intensity of droughts, and because soil water-holding capacity has been shown to have a nearly linear effect on yield loss.

Projected climate change at the larger scale suggests further warming and decreased precipitation. In the 2031-2060 period, under the RCP4.5 and RCP8.5 emission scenarios, projected seasonal warming and decrease in annual precipitation, especially in summer rainfall, are significant (Papadaskalopoulou et al., 2020). The changes are highly relevant to Northern Cyprus, as many of the region's most important crops have the highest water requirements during spring and summer, which are the periods when the largest precipitation reductions are projected.

An analysis of climate change impacts on the production of major crops in Cyprus using coupled climate and crop models revealed that future warming and reduced precipitation are likely to significantly affect wheat, barley, tomato, potato, grape, and olive production (Markou et al., 2020). The study highlighted the vulnerability of crops with a summer growing season, such as tomato, grapevine, and olive. It suggested a list of adaptation measures for each crop that remain applicable in Northern Cyprus.

While the current literature offers good guidance, there is still a lack of research on how climate change will impact agricultural production, yield, and quality together, especially in Northern Cyprus. Most studies have focused on water use, drought indices, and single crops. In contrast, relatively few studies combine climatic trends with yield components, product quality, soil processes, pest and disease pressure, and adaptation options in one place, grounded in the local context.

This review, therefore, aims to provide a synthesis of the existing scientific literature on the impact of climate change on agricultural production in Northern Cyprus. Since limited experimental data are available for specific Northern Cyprus crops and quality parameters, studies relevant to the area are included to the extent that their results are likely to be applicable. The review also guides areas for further research and policy directions for establishing locally appropriate adaptation strategies to climate change.

REVIEW METHODOLOGY

Review Approach

The paper is written in a narrative scientific review style, drawing on peer-reviewed literature, scientific reports, and relevant institutional sources. Relevant literature was identified and assessed for relevance to Cyprus, Northern Cyprus, and similar Mediterranean agricultural systems regarding climate change, agricultural production, crop yield, product quality, water resources, drought, salinity, pests and diseases, and climate adaptation in Cyprus. Searches were carried out in the major scientific databases and in the platforms of the publishers, with targeted searches for recent studies (2021–2026) focusing on drought trends in Northern Cyprus, crop-

specific responses to drought, water management under drought conditions, and climate-smart agricultural practices.

The following priorities were applied, in order: (1) peer-reviewed studies that explicitly referred to Northern Cyprus; (2) studies that covered all of Cyprus; (3) studies that covered the entire Mediterranean region but had a clear link to growing conditions in the Eastern Mediterranean; (4) recent studies that dealt with the adaptation of agriculture and water management; and (5) international assessments, such as the IPCC, FAO and European Environment Agency. Where evidence was not available on a Northern Cyprus-specific basis, evidence from comparable semi-arid Mediterranean environments was used with caution to provide scientific context, explicitly noting its transferability rather than assuming it.

Scope of the Review

The review is centred around six interrelated themes: climatic changes; agricultural production; crop yield; product quality; soil and water constraints; and adaptation and climate-smart agricultural practices. The main crops considered are those that, for the most part, take up most of the cultivated land and add value in Northern Cyprus, including cereals (wheat and barley), citrus, potatoes and vegetables, grapes, olives, carob, figs, and forage crops.

Agricultural and Climatic Context of Northern Cyprus

The climate of Northern Cyprus is Mediterranean, with hot, dry summers and relatively mild, wet winters. This climate results in good growing conditions for most Mediterranean crops but also significant water management requirements over the growing season, as nearly all rainfall falls outside the critical crop water uptake window.

The spatial variability of agricultural production is due to varying soil characteristics, topography, precipitation, groundwater resources, irrigation systems, and coastal location. Wheat and barley are important rainfed crops, mainly grown on the Mesaoria plain. Horticultural and perennial fruit crops, on the other hand, typically rely on supplemental or complete groundwater and reservoir irrigation.

The agro-system is thus very sensitive to the interaction between temperature and water availability. Increasing temperatures under moderate conditions may not necessarily lead to severe impacts if an adequate water supply is available. However, if warming is coupled with reduced rainfall, both atmospheric evaporative demand and crop water requirements may rise, placing greater stress on limited water resources.

Studies specifically targeting Northern Cyprus indicate that drought and salinisation have been significant constraints on agriculture for decades (Payab & Türker, 2018). The limited availability of freshwater makes irrigation efficiency particularly important. Kahramanoğlu et al. (2020) found significant variations in irrigation requirements and in economic and nutritional productivity per unit of water used. Their results indicate that making the water requirements of crops explicit in a crop plan can significantly reduce pressure on agricultural water resources without necessitating a decrease in cropped area.

This problem is likely to become more important under climate change because water availability and crop water demand may change simultaneously. Conventional agricultural planning, which is often based on historical climatic averages, may therefore be less effective for anticipating these combined changes.

Observed and Projected Climate Change

Increasing Temperature

One of the primary climate variables that influences crop production is temperature. Plants respond to temperature in characteristic ways, with the highest growth rates occurring within an optimal temperature range and declining above and below it. Photosynthesis, development, respiration, flowering and fertilisation can also be reduced above and below the optimum temperatures, as can the grain- or fruit-filling period.

Future warming projections for Cyprus show significant warming (Figure 1). The projected seasonal mean temperature changes for 2031-2060 from the ADAPT2CLIMA assessment were higher in comparison to the 1971-2000 reference period, with approximately 2°C warming in winter and 3°C in summer for RCP4.5 and 4°C warming in winter and 6°C in summer for RCP8.5 (Markou et al., 2020). The warming trend is also consistent with regional projections for the Eastern Mediterranean, which show that warming is generally greater than the global average and that the incidence of extreme heat events is increasing (Zittis et al., 2022).

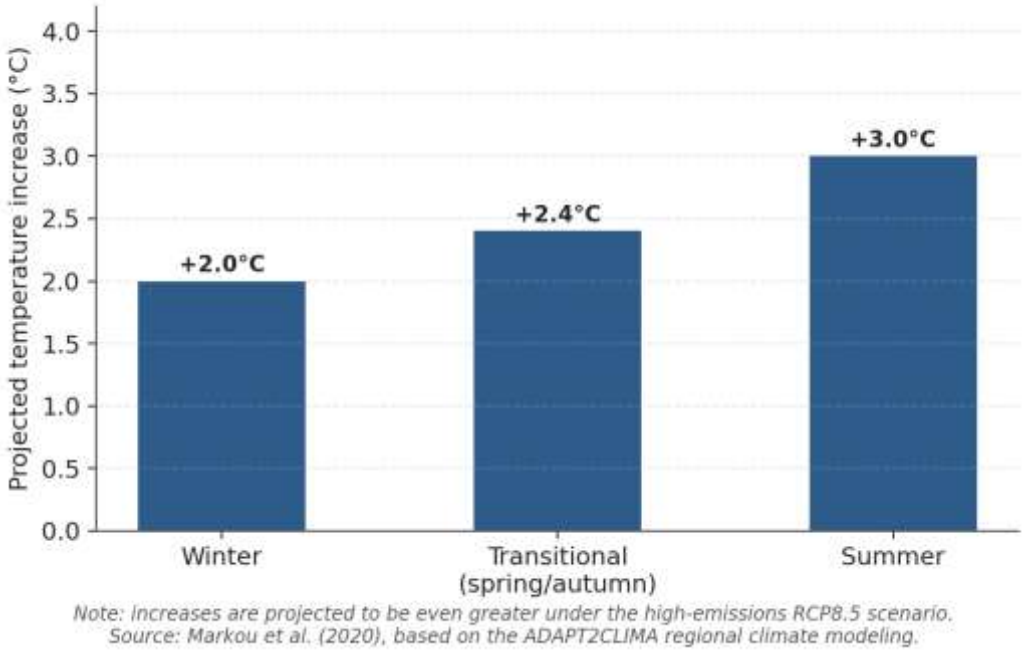

Figure 1. *Projected seasonal mean temperature increase in Cyprus, 2031–2060 vs 1971–2000, under RCP4.5 (Markou et al., 2020).*

The increase in temperature is especially relevant for Northern Cyprus, as the temperatures are already close to or surpassing critical physiological limits for several crops during summer. As a result, further temperature increases could lead to increased heat stress, especially at

flowering, fruit development, grain filling, and grain maturity, when even brief periods of extreme heat can cause disproportionate yield and quality losses.

Changes in Precipitation

Another significant concern is projected changes in precipitation. Cyprus climate projections show decreases in annual precipitation under both RCP4.5 and RCP8.5, especially in summer (Figure 2). In summer, precipitation reductions are around 20–30% under the RCP8.5 scenario across most of the island, with larger reductions in some areas (Papadaskalopoulou et al., 2020).

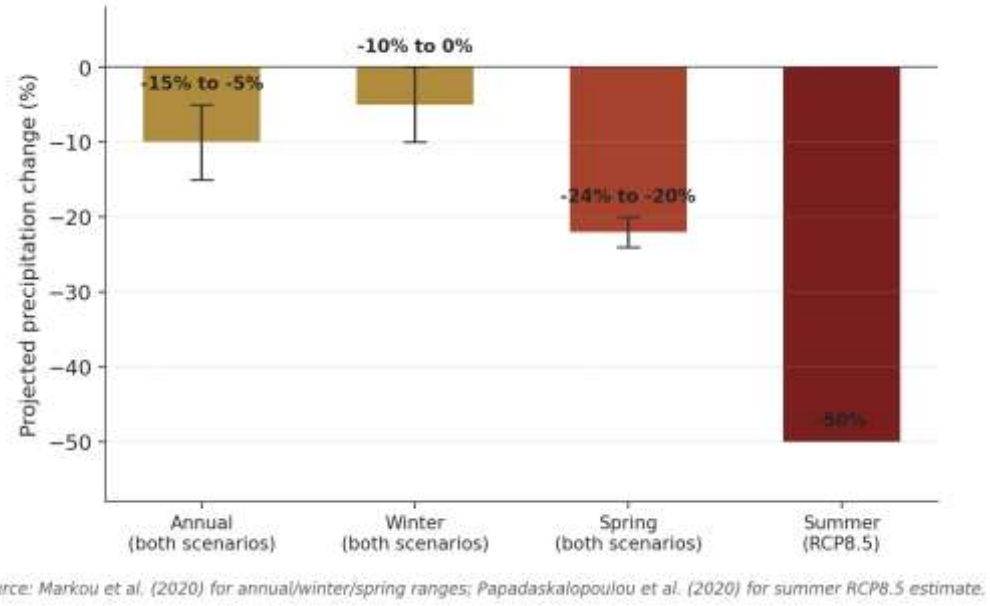

Figure 2. Projected seasonal precipitation change in Cyprus, 2031–2060 vs 1971–2000 (Markou et al., 2020; Papadaskalopoulou et al., 2020).

The increased temperature and reduced rainfall are more significant than either factor alone. A decrease in precipitation reduces soil-water availability, and an increase in temperature raises evapotranspiration; this can create a significant water deficit during a peak crop water-demand period and therefore compress the time available to draw water from soil-water or irrigated sources (Table 1).

Table 1. Summary of projected climate change indicators for Cyprus, 2031–2060, relative to 1971–2000.

Indicator	RCP4.5	RCP8.5
Winter temperature	+2.0°C	Greater than RCP4.5 (not separately quantified in source)
Transitional-season temperature	+2.4°C	Greater than RCP4.5 (not separately quantified in source)
Summer temperature	+3.0°C	Greater than RCP4.5 (not separately quantified in source)
Annual precipitation	−5% to −15%	−5% to −15% (similar range to RCP4.5)
Winter precipitation	Up to −10%	Up to −10% (similar range to RCP4.5)
Spring precipitation	20% to −24%	20% to −24% (similar range to RCP4.5)
Summer precipitation	Not separately quantified in the source	Up to −50% (the largest seasonal decrease of any scenario/season)

Increasing Drought

Drought is perhaps the most direct climate-related agricultural risk in Northern Cyprus (Figure 3). Historical drought records indicate that droughts have become more frequent and severe in the region over the last few decades (Payab & Türker, 2018, 2019; Payab & Türker, 2025, as summarised in Türker & Payab, 2023).

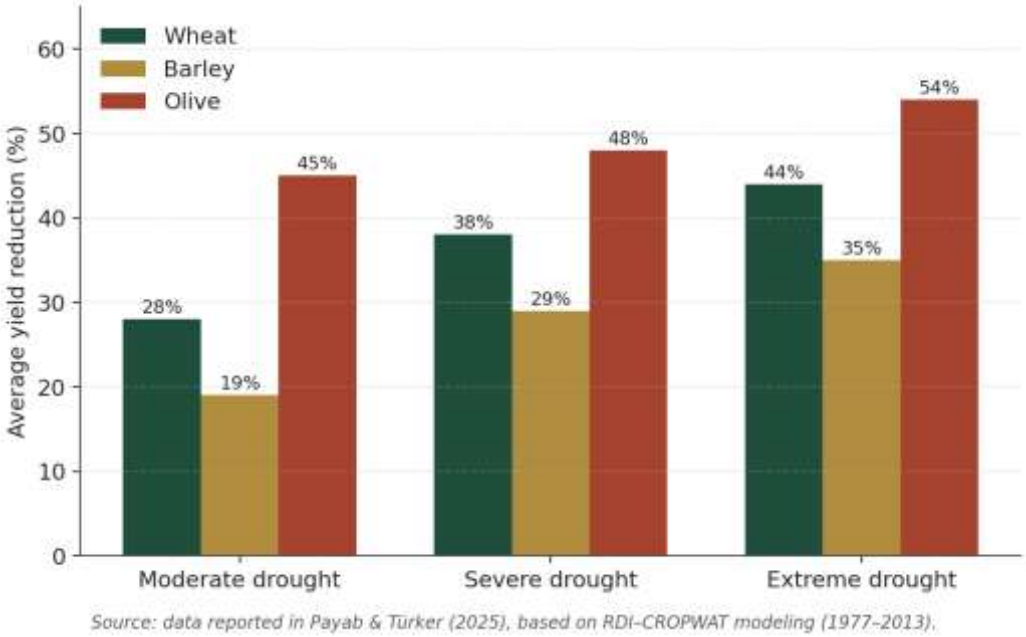

Figure 3. Drought-related yield reduction in rainfed wheat, barley, and olive in Northern Cyprus, by drought severity level (Payab & Türker, 2025).

Agriculture is affected by drought in multiple ways, including soil moisture, groundwater recharge, reservoir storage, irrigation water availability, salinity risk, nutrient uptake, photosynthesis, premature leaf senescence, and fruit and grain development. The quantitative

evidence from CROPWAT based modelling in Northern Cyprus is very direct in this sense: reductions in average yield were estimated to be around 37% under drought conditions for wheat, 28% for barley and 49% for olive, with the severity of the drought showing a rapid increase along with drought severity, and soil water-holding capacity acting as a significant moderation factor (Payab & Türker, 2025). Such impacts can be especially strong when drought occurs during hot periods of the year, which may be more likely under anticipated future climate conditions.

Evapotranspiration and Crop Water Demand

Climate change is not only causing decreased rainfall but also increasing the water requirement of the atmosphere. Higher temperatures also increase potential evapotranspiration and, consequently, crop water demand, increasing the amount of water required to maintain production.

These include remote-sensing techniques for estimating crop evapotranspiration and irrigation needs for citrus, olives, and potatoes within a smart farming water management framework, which has been developed in recent research in Cyprus (Neophytides et al., 2024). The need to optimise irrigation water use is highlighted because the total water demand of these crops may exceed reservoir inflow, especially during dry irrigation seasons.

The discovery has implications for Northern Cyprus. The increasing variability in precipitation with rising temperatures and the greater need for irrigation water may make history-based irrigation plans ever less reliable, making evapotranspiration-based, near-real-time irrigation scheduling an increasingly useful management tool, not just an added luxury.

Effects of Climate Change on Agricultural Production

Agricultural production can be impacted by climate change in various ways. Direct effects include heat stress, drought, flooding, and alterations in growing-season length and timing. Indirect effects include water shortages, salinity, changes in pest and disease pressure, soil degradation, changes in production costs, and changes in input requirements. The overall impact on a particular farm or crop, however, depends on the interaction among climate, crop, soil, management, and socioeconomic factors. Hence, the evidence for particular crops, described in the subsequent sections, is vital for supporting the interpretation of general climate trends into farm-specific agricultural guidance.

Effects on Cereals

Wheat and barley are important cereal crops in Cyprus. They are especially significant in the field of food security, as cereals constitute a large share of the cultivated area on the island and are mostly grown under rainfed conditions in Northern Cyprus.

Drought and high temperatures are a threat to cereals. The effects of water stress include reduced tiller survival, increased spike formation, decreased grain number, decreased grain filling, decreased thousand-kernel weight, and ultimately decreased final grain yield. Heat stress during flowering can affect pollen viability and fertilisation, while heat during grain filling can accelerate grain maturation and shorten grain-filling time. The impact of these effects in

Northern Cyprus is well documented, as modelled reductions in yield under drought conditions are on the order of about 37% for wheat and about 28% for barley, and about 44% and 35% for wheat and barley, respectively, under extreme drought (Payab & Türker, 2025).

Over the last few years, evidence from around the world has emerged that heat stress can affect both yield and grain quality in wheat. A 2026 meta-analysis of 95 studies and 1,976 observations worldwide revealed that heat stress had a significant negative effect on thousand kernel weight and starch concentration and significant positive effects on protein and wet gluten concentration, while the effects of these responses were found to vary systematically with the timing, duration and intensity of heat exposure (Liu et al., 2026). For drought, a complementary meta-analysis yielded the same conclusion: the effect of drought on wheat yield and grain protein content (GPC) is highly moderated by the environmental context, defined by soil type, prior water status, and cultivar (Wan et al., 2022).

Wheat protein concentration can also be affected by drought. However, it is not always valid to assume that a decrease in protein concentration is equivalent to better nutritional or processing quality, since any increase in protein concentration may be offset by decreases in grain size and starch concentration. Processing quality depends on the balance among protein, starch, and gluten fractions, not on protein concentration alone.

This is because, in Northern Cyprus, higher temperatures and reduced rainfall could pose both challenges: reduced yields, primarily due to water deficiency during tillering and grain filling, and altered grain composition due to heat stress during these developmental periods.

Effects on Potato and Vegetable Production

Potato and vegetable production is highly dependent on adequate water availability. Potatoes are especially sensitive to temperature and soil-water stress during tuber initiation and bulking, when brief water deficits can cause greater yield loss.

Water stress can decrease the number of tubers, tuber size, marketable yield, uniformity, dry matter content, and post-harvest quality. The high temperature may also have a direct impact on tuber formation and has a positive relationship with the incidence of internal heat necrosis and secondary growth as physiological disorders.

High temperatures and water shortages are also detrimental to vegetable crops such as tomato, lettuce, eggplant, watermelon, and melon. Tomato and potato crops were among the most water-intensive and economically valuable crops identified as in need of specific adaptation measures as a result of a climate assessment in Cyprus (Markou et al., 2020).

Horticultural crops typically have higher production costs and greater irrigation requirements than many rainfed crops. Therefore, yield losses are more likely to result in farm-level economic losses than similar percentage losses in extensive rainfed cereals.

Effects on Citrus Production

Citrus is one of the significant groups of perennial crops in Cyprus. Citrus production is generally year-round. It therefore has a relatively high water requirement, which must be

available throughout the year, especially during fruit development, and is not easily adapted to alternative planting dates if the water year turns out to be poor.

Climate change could affect citrus production through higher evapotranspiration, drought stress, smaller fruit, earlier fruit drop, sunburn, changes in maturation time, changes in soluble solids and acidity, and greater irrigation needs. Fruit growth may be affected by water stress due to the critical nature of water supply during certain fruit development stages, and the high susceptibility of fruit and canopy to sunburn and physiological stress due to severe heat.

With perennial crops, adaptation over 10 years or more is required, as there is no possibility of simply replanting and adjusting each year to climate variability. Therefore, rootstock choice, irrigation water-use efficiency, mulching, soil-water conservation, canopy management, and cultivar selection are among the factors that are very important for maintaining productivity under changing conditions.

Effects on Grapevines and Grape Quality

The sensitivity of grapevines to changes in temperature and water availability is especially high, as climate strongly influences phenology and fruit composition. With increased temperatures, bud formation, flowering, veraison, sugar ripening, maturation, and harvest may occur faster, sometimes with shorter intervals.

This rate of increase often leads to earlier harvests and changes in the sugar-to-organic acid ratio. In wine grapes, global warming is consistently associated with higher soluble solids content, lower acidity, and lower anthocyanin concentration. This mix may result in wines of higher alcohol content, different colour, and reduced aromatic balance, which can pose difficulties in maintaining the regional style. Recent literature reviews of Mediterranean viticulture (2020-2023) agree that climate is the main driver of grape and wine quality in the region and that global warming is causing a general increase in soluble solids and a decrease in anthocyanin and acid levels in a broad spectrum of varieties and locations.

Grape yield and quality are also influenced by water availability. Well-timed moderate water stress can sometimes enhance some quality parameters, e.g., the concentration of phenolic compounds. In contrast, excessive or poorly timed water stress decreases berry size and yield, photosynthetic activity, and, over consecutive seasons, plant longevity. Field trials comparing productive and morphological traits under rain-fed conditions with those under irrigated conditions highlight a yield–quality trade-off: a reduction in yield and deterioration in quality parameters in certain instances. In contrast, some quality parameters, such as colour and astringency, may increase under limited water availability, as observed in wine-grape genotypes cultivated in the Mediterranean region.

For Northern Cyprus, local grapevine cultivars and practices appear well adapted to Mediterranean conditions, but they may become increasingly vulnerable as temperatures and drought intensity exceed historical levels. In other parts of the Mediterranean, phenological modelling indicates the potential for veraison and harvest several weeks earlier under high-emissions scenarios by mid-century. In the absence of adaptation, this change would also be anticipated in the Eastern Mediterranean vineyards.

Adaptation options may include the use of drought-hardy cultivars and rootstock, deficit irrigation (where scientifically sound and planned for); canopy management (shading, forced bud regeneration, which slows ripening); soil mulching; planting density changes; modified pruning; and modified vineyard microclimate management—some of which are effective in similar dryland Mediterranean winegrowing areas.

Effects on Olive Production

Olive trees are considered relatively drought-resistant among fruit trees. However, drought tolerance is not drought immunity and, as the recent Mediterranean-wide experience indicates, even this relatively hardy plant is being heavily stressed by climate change.

Extended periods of water deficit, excessive temperatures, irregular flowering and fruiting, diminished fruit set, smaller fruit size, alternate bearing, changes in the oil content of the fruit, and increased infestation can affect olive production. Increased temperatures and water scarcity are expected to alter the geographic distribution of areas suitable for olive cultivation, decrease yields in the warmest and driest regions, and necessitate the use of adapted cultivars, deficit irrigation, and potentially modified orchard management to sustain productivity over the mid-term (Fraga et al., 2020).

This vulnerability is also reflected in recent harvest outcomes around the Mediterranean: four years of high temperatures and drought in Spain, Italy, Greece and Tunisia (2021-2024) resulted in significant reductions in olive oil production and skyrocketing prices, and survey data showed that the proportion of growers reporting drought and high temperatures as harvest-limiting factors increased significantly from previous years. Furthermore, a long-term (8,000 years) palaeoecological analysis of olive pollen records indicates that the productivity of olive trees in the Eastern Mediterranean is ultimately determined by the level of photosynthetic activity, which is determined by the interaction of temperature, precipitation timing and radiation balance, and not for example by temperature alone (Kaniewski et al., 2025); thus, the future trajectory of olive productivity in the Eastern Mediterranean will depend on the combined trajectory of water stress and solar radiation and not on the trajectory of temperature alone.

According to modelled evidence, for Northern Cyprus in particular, this is the case for olive since average yield losses under drought have been estimated to be about 49%, which is higher than those modelled for wheat and barley, and more than 50% under severe and extreme drought conditions (Payab & Türker, 2025). This discovery is in stark contrast to the general public perception of olives as relatively hardy under drought conditions. It indicates that in Northern Cyprus, soil and rainfall distributions may increase the susceptibility of olive orchards to drought.

Thus, future climate conditions may not necessarily threaten the viability of olive trees in Northern Cyprus, However, water management, cultivar and rootstock choice, and orchard-level adaptations are likely to be required to ensure the trees yield high amounts of high-quality oil, while maintaining high productivity and oil quality will require appropriate adaptation measures.

Effects on Carob, Fig, and Other Perennial Crops

Carob and fig are less susceptible to dry Mediterranean conditions and may require less irrigation than more intensive horticultural crops. In the study carried out in the Northern region of Cyprus, irrigation water consumption for carob and fig was among the lowest among the other crops studied (Kahramanoğlu et al., 2020).

This will have significant implications for future agricultural planning. Due to water scarcity, attention could be given to species such as carob and fig, which have relatively high economic or nutritional value, but relatively low water requirements, thus suggesting these species as possible contributors to a more water-friendly crop mix for the territory.

However, water use should not be the sole criterion for crop diversification. The other factors that can be taken into account are the market demand, suitability of the land, farm income, biodiversity, nutritional value, processing opportunities, and tolerance to climate change; a transition to low-water crops that do not have market access or processing infrastructure would move the risk from water balance to farm income.

Climate Change and Product Quality

Climate change impacts on agriculture need to be assessed beyond yields. Product quality is also crucial because it affects market value, consumer acceptance, processing capacity, storage life, and exportability, all of which are crucial for the long-term economic sustainability of Northern Cyprus agriculture, which is heavily dependent on export markets for citrus, potatoes, and other horticultural products.

Fruit size, colour, firmness, soluble solids, titratable acidity, sugar/acid ratio, antioxidant content, phenolic compounds, oil composition, grain protein content, grain starch content, thousand-kernel weight, and post-harvest shelf life may all be affected by climate-related changes.

Fruit Size

Fruit expansion is closely related to water availability. Drought stress may limit cell growth and, thus, fruit size. Fruit size is especially important for fruit intended for commercial markets, such as citrus, grapes and other horticultural crops, because undersized fruit may be considered in a completely different category for premium export grades than it would be for other grades, and may not be saleable for those grades.

Total Soluble Solids

Sugar buildup in fruits may be affected by temperature and water availability. Some fruit crops may be affected by moderate water stress, which may increase soluble solids content as water is diluted. The relationship is not necessarily linear, because severe stress can reduce photosynthesis and total carbohydrate production.

Therefore, an increase in soluble solids is not always a good indicator of climate change. Product quality is multi-dimensional, and whenever a product improvement is achieved in one quality dimension, it is often counterbalanced by a decrease in another.

Titratable Acidity

In many fruits, the degradation of organic acids can be hastened by high temperatures. Excessive heat in grapes can therefore result in higher sugar content and lower acidity, which may alter fruit and wine quality and necessitate adjustments in winemaking (such as acidification) that were not required before.

Grain Quality

This evidence reinforces the importance of considering both yield and end-use quality when assessing climate impacts on wheat.

This illustrates why future climate assessments should consider both yield and quality: a wheat crop that maintains yield but loses milling or baking quality may still represent an economic loss for producers and processors.

Water Scarcity and Irrigation

One of the main issues in agriculture in Northern Cyprus is water scarcity. The problem extends beyond the absolute availability of water and involves rainfall variability, groundwater extraction, reservoir storage, irrigation efficiency, evaporation, salinity, competing domestic demands, tourism, and the allocation of irrigation water during dry years.

Research on Northern Cyprus highlights the need for increased irrigation efficiency and water footprint management as immediate measures that the sector can leverage (Kahramanoğlu et al., 2020). The complementary work carried out on a Cyprus-wide scale demonstrated that the use of remote sensing for evapotranspiration monitoring can make a real contribution to improved irrigation scheduling accuracy for citrus, olive, and potato crops, compared to traditional calendar-based methods (Neophytides et al., 2024).

So the best solution for adaptation will not be a single technology. Instead, water management should include: (1) the accurate assessment of crop water requirement, (2) efficient irrigation systems, (3) soil-moisture monitoring, (4) suitable irrigation scheduling, (5) water productivity-informed crop selection, (6) use of drought-tolerant cultivars, (7) water harvesting, (8) wastewater reuse, (9) groundwater protection, and (10) digital monitoring throughout the value chain.

Soil Salinity and Water Quality

When preferred freshwater sources are unavailable, water scarcity can lead to reliance on less suitable sources, such as treated wastewater and saline groundwater, especially during prolonged dry spells.

Seawater intrusion is particularly a problem in Mediterranean coastal regions due to excessive groundwater drainage. Research conducted in Cyprus has shown that saline irrigation water can have negative impacts on soil resources. At the same time, moderate salinity can cause significant and even long-lasting soil problems (Kathijotes & Panayiotou, 2013).

Soil salinity causes salinity stress to crops by decreasing the root's water-absorbing capacity and by causing ion toxicity and nutrient imbalance in the soil, even though, in a volumetric sense, the water appears sufficient.

Climate change may exacerbate the salinity issue due to changes in rainfall, which lead to less natural freshwater recharge; greater evaporation would result in salt concentration in soil and remaining water bodies; drought-induced groundwater dependence would cause groundwater to be pumped at higher rates, increasing the salinity of wells; the total demand for irrigation would increase; and seawater intrusion would be more likely in vulnerable coastal aquifers, as groundwater levels are lowered during drought.

So, climate adaptation requires water-quality management in addition to water quantity; a plan that could provide adequate irrigation water but would let salt levels increase to the detriment of the crops would just be changing one type of stress for another.

Treated Wastewater as an Adaptation Strategy

Treated wastewater can be a valuable supplementary water source for agriculture. Potential benefits include reduced dependence on freshwater, a relatively stable water source during drought, nutrient recycling, and broader circular water management.

Reliance on wastewater reuse, however, requires careful management, as salinity, sodium, pathogens, nutrients, and other contaminants can be problematic if not properly managed. The results in Cyprus show that the use of saline wastewater for irrigation can lead to a measurable impact on soil resources over time; therefore, treated wastewater is not a risk-free alternative to freshwater (Kathijotes & Panayiotou, 2013).

Thus, wastewater reuse in Northern Cyprus should be implemented under appropriate treatment standards and regular water-quality monitoring, together with crop-specific irrigation requirements, salinity management, soil monitoring during the growing season, and suitable irrigation techniques. These measures may include subsurface drip irrigation to minimise contact between edible plant parts and wastewater and blending with freshwater when necessary to maintain salinity below crop-specific thresholds.

Treated wastewater should therefore not be regarded as the sole replacement for freshwater, but rather as an integral part of integrated water management, and its development in Northern Cyprus should not take the place of investments in measures that lead to freshwater savings.

Pest and Disease Pressure

Climatic changes may impact pests and diseases through changes in temperature, humidity, host susceptibility, and pest development rates, many of which are not simply predicted by changes in temperature alone.

Increased temperatures may lead to faster development and more generations per season of insects, change the geographic distribution of insects, boost overwintering survival, and affect interactions between the insects and host plants more broadly. Meanwhile, any changes in

precipitation and humidity can influence disease pressure from fungi and bacteria either positively or negatively, depending on the organism causing the disease.

The relationship is complex: warmer, drier weather may reduce the growth of some pathogens and increase the growth of others; extreme weather events can cause physiological stress on plants, making them more vulnerable to secondary pests and diseases, even if the primary climate driver is not directly affecting the pest. This compound effect was also observed in the documented experience of the 2023 harvest in the Mediterranean olive region, where heat and drought stress clashed with increased pest emergence, further affecting olive production.

As such, in the context of Cyprus climate adaptation research, increasing pest pressure and declining plant health are considered important issues in agriculture that require special monitoring (Markou et al., 2020). For Northern Cyprus, locally relevant monitoring systems are necessary to identify the risks posed by pests and diseases that are actually rising, given the region's agroclimatic peculiarities, because information from Mediterranean-scale trends cannot be extrapolated to Northern Cyprus. Farmer observation data should be systematically collected alongside meteorological and agricultural surveillance data to build this evidence base over time.

Climate Change and Crop Phenology

Important crop development stages may be altered by climate change. With warmer temperatures, flowering could be earlier, fruiting could be sooner, the grain-filling period may be shortened, harvest may be earlier, crop-pollinator synchronisation may be disrupted, and exposure to late-season heat events that occurred rarely during flowering/fruit set may be higher.

Changes in phenology are particularly significant for perennial crops, like grapes, citrus and olives, whose management schedules, workforce planning and even export logistics are based on historically consistent phenological periods. For instance, advancements in grape maturity due to earlier ripening may shift the balance between sugar accumulation and acid retention, as shown in several Mediterranean vineyards, where veraison and harvest dates have already shifted significantly over the last few decades. Likewise, cereal development can be accelerated, which could negatively impact grain filling under heat and drought stress and grain weight, as described in Section 6.

Hence, phenological monitoring should be incorporated into climate adaptation research in Northern Cyprus as an early, sensitive indicator of climate impacts and to support management decisions before yield and quality reductions are observed.

Climate-Smart Agricultural Adaptation

Climate adaptation should not only seek to sustain existing agricultural production, but also to strengthen the overall production system to withstand climate risks, as historical norms have been optimised for a climate that is no longer applicable.

Improved Irrigation Management

Efficient irrigation is among the most critical adaptation options at hand. Water losses (and salinity) can be minimised with drip irrigation systems, which deliver water to the root zone; however, the efficiency of the delivery system critically depends on irrigation scheduling, even if the system is efficient itself, because over-irrigation can cause water losses and salinity.

The use of remote sensing and evapotranspiration monitoring can enable more accurate irrigation decisions. Recent studies conducted on Cyprus demonstrated the potential of remote sensing to estimate crop evapotranspiration and optimise irrigation water demand for citrus, olives, and potatoes within an integrated smart-farming framework (Neophytides et al., 2024).

Soil-Water Conservation

Water loss from soil management can be reduced through mulching, conservation tillage, organic amendments, cover crops, retaining residues, improving soil structure, and rainwater harvesting. These practices can increase infiltration, decrease evaporation, and improve soil-water retention, thereby increasing the time that stored soil water is available to the crop between rains and/or irrigation.

Drought- and Heat-Tolerant Cultivars

Genetic adaptation is particularly significant because cultivar differences in response to heat and water stress are large. Breeding and cultivar selection should focus on drought tolerance, heat tolerance, efficient water use, yield stability, disease resistance, adaptation to local soils, and yield potential under historical average conditions.

For perennial crops, rootstock choice can be another mechanism that significantly affects drought tolerance and water-use efficiency without changing the cultivar of the fruit scion or fruit quality traits.

Crop Diversification

Diversifying crops can help reduce dependence on a few climate-sensitive crops. An analysis of the net primary productivity (NPP) of different cropping systems in Cyprus with the aid of machine-learning techniques and Earth-observation data revealed that diversification generally resulted in a small improvement of the NPP by around 2.8% across the country, especially under warmer and drier climatic scenarios, indicating that diversified cropping systems may be more resilient to the climate pathway that Cyprus is projected to experience (Giannarakis et al., 2023).

Diversification might thus be a promising option for Northern Cyprus, if the appropriate market access and processing facilities are available and crop selection is economically and agronomically viable.

Precision Agriculture

Precision agriculture can improve resource-use efficiency when sensing, monitoring, and decision-support tools are integrated into a coherent management system rather than applied independently.

These systems can detect problems before they become visually apparent and enable more efficient irrigation and fertilization, shifting management from reactive to proactive and data-driven.

Protected Cultivation

Some extreme weather can be minimised in greenhouses and protected crops. They can also be associated with increased cooling and irrigation needs in extreme heat; however, protected cultivation is not a solution for every climatic situation and requires adaptation to a warming climate.

Thus, using a protected cultivation system that is resistant to climate change should be based on the integrated use of ventilation, shading, efficient cooling, water recycling, climate-controlled irrigation, and energy-efficient technologies – not as individual features.

Crop-Specific Adaptation Priorities

The evidence reviewed above is summarised in Table 2, which highlights the major climate risks, likely impacts, and priority adaptation measures for extension and policy planning.

Table 2. Crop-specific climate risks, likely impacts, and priority adaptation measures in Northern Cyprus.

Crop / group	Major climate risks	Likely impacts	Priority adaptation
Wheat	Heat, drought	Lower grain number and weight (avg. ≈–37% yield under drought); altered protein/starch balance	Early/appropriate sowing, drought-tolerant cultivars, efficient fertilization
Barley	Drought, heat	Reduced biomass and grain yield (avg. ≈–28% under drought)	Drought-tolerant varieties, optimized planting date
Potato	Heat, water shortage	Reduced tuber formation, size, and marketable yield	Efficient irrigation, heat-tolerant varieties, soil mulching
Tomato	Heat, drought	Reduced fruit set, yield, and quality	Protected cultivation, irrigation scheduling, heat-tolerant varieties
Citrus	Water shortage, heat, salinity	Smaller fruit, physiological stress, altered soluble solids/acidity	Drip irrigation, rootstock selection, salinity management
Grapes	Heat, drought	Earlier maturation, smaller berries, higher sugar/lower acidity	Cultivar/rootstock selection, canopy management, strategic irrigation
Olive	Heat, drought	Reduced fruit set and yield (avg. ≈–49% under drought — the most drought-sensitive of the modeled crops)	Efficient irrigation, drought-tolerant cultivars, orchard-level water management
Carob	Drought	Generally, more resilient; productivity may still decline under severe stress	Crop diversification and soil-water conservation

Fig	Drought and heat	Fruit size and quality changes	Efficient water management, cultivar selection
Forage crops	Heat, drought	Lower biomass and feed quality	Drought-tolerant species and improved irrigation

Economic and Food-Security Implications

The effects of climate change on farms are far-reaching and extend beyond the individual farm. Lower yields can lead to rising food prices, lower farm income, greater reliance on imports, and the jeopardization of rural livelihoods, all of which can build on a series of poor seasons.

This is especially relevant on islands, where the share of food imports could rise rapidly as local agriculture becomes less reliable, and where alternative options for importing food are limited during regional shortages. Climate-induced production shocks in the Mediterranean, with significant impacts in Spain, Italy and Greece due to drought and heat, provide a clear example of how extreme drought and heat can drive a price shock that globalises the Mediterranean and quickly impacts other importing and producing regions in the basin.

In Northern Cyprus, where the majority of farmers are smallholders, economic viability is an important aspect of adaptation. No economically viable and technically viable approach will be of much practical value if it has not been proven to be agronomically beneficial. Agricultural policies, therefore, could focus on financial incentives, modernisation of irrigation through subsidisation, farmer training, dissemination of climate information, crop insurance, research and extension services, access to precision farming technologies, and improved water governance – all as a package, not separately.

CONCLUSION

Northern Cyprus is facing a serious and increasing threat to agricultural sustainability from climate change. The Mediterranean climate, scarcity of fresh water resources, reliance on irrigation, and the current problems of drought and salinity make the area vulnerable to future climate change.

There is evidence that Northern Cyprus is already under severe drought stress, and climate models predict further warming in Cyprus and less rainfall. Recent drought analysis has shown that drought severity and frequency have been increasing over the past few decades in Northern Cyprus (Payab & Türker, 2018, 2019), and quantitative crop-simulation evidence has estimated substantial yield reductions under drought conditions in the region (average of around 37% for wheat, 28% for barley and 49% for olive under drought conditions; Payab & Türker, 2025). Climate projections for Cyprus indicate significant additional warming and reduced precipitation, especially in summer (Papadaskalopoulou et al., 2020; Zittis et al., 2022).

Agriculture impacts are expected to be significant. Heat and drought stress may lead to additional yield losses and modifications in grain composition in cereal crops. Increasing irrigation needs and heat stress may limit potato and vegetable production.

Most importantly, climate change impacts not only the amount of agricultural yields but also their quality. Fruit size, soluble solids, acidity, grain protein, starch concentration, and post-harvest characteristics may affect market value and food quality. Recent global evidence on wheat shows that heat stress can affect both grain weight and the chemical composition of wheat simultaneously (Liu et al., 2026), with repercussions for Northern Cyprus wheat production.

In this context, water management should be at the core of agricultural adaptation in Northern Cyprus. The studies show that significant differences exist in water use efficiency and requirements for various crops when irrigated in Northern Cyprus, indicating that improved crop planning can help minimise water scarcity (Kahramanoğlu et al., 2020). More recent studies in Cyprus also show the potential of remote sensing and evapotranspiration-based methods to enhance irrigation management for citrus, olive, and potato production (Neophytides et al., 2024).

Finally, the review highlights the need for additional local studies in Northern Cyprus. Future research could combine long-term climate data with crop yield and grain quality data and explore the economic feasibility of other adaptation options. Thus, developing climate-resilient agriculture in Northern Cyprus is important not only for environmental reasons but also for food security, rural livelihoods, sustainable water management, and the long-term economic viability of the agriculture sector.

ABSTRACT

The male effect is considered one of the most efficient natural methods for stimulating ovarian activity and synchronizing estrus in goats, representing a practical alternative to hormonal protocols in extensive and semi-extensive production systems. The present study was conducted to evaluate the influence of the male effect on estrus response in Carpathian goats raised under two contrasting climatic conditions in Romania. A total of 100 clinically healthy adult females were equally distributed between a dry and a humid climatic area and assigned to control and experimental groups. In the experimental groups, females were completely isolated from bucks for 60 days before the breeding season, after which one buck was introduced for every 25 females. Estrus was monitored daily for 15 days following buck introduction and both the proportion of females exhibiting estrus and the interval between buck introduction and estrus onset were recorded. The application of the male effect significantly improved reproductive performance in both climatic areas. In the dry area, the proportion of females exhibiting estrus increased from 68% in the control group to 92% in the experimental group, while in the humid area it increased from 72% to 96%. In addition, a considerably higher proportion of females expressed estrus within the first five days after buck introduction, demonstrating a more synchronized reproductive response. Although reproductive performance was slightly higher in the humid area, the male effect proved highly effective under both environmental conditions, indicating that climatic factors may influence the intensity, but not the efficiency, of the reproductive response. The results demonstrate that the male effect is a simple, low-cost and hormone-free reproductive management strategy capable of improving estrus synchronization in Carpathian goats and can be successfully applied under different climatic conditions to increase the efficiency of breeding management.

Keywords: goats, estrus, male, effect, reproductive

INTRODUCTION

Reproductive performance is an important component of goat production because it influences herd replacement, the organization of mating and kidding and the continuity of milk and meat production. Goats are generally classified as seasonally polyestrous animals, although the onset and duration of reproductive activity vary according to breed, latitude, photoperiod, physiological status, nutrition and production system (Luo et al., 2019; Souza-Fabjan et al., 2021; Šavorić et al., 2024). At temperate latitudes, the annual variation in day length is the main environmental factor controlling reproductive seasonality, while climatic conditions and forage availability may further modify the reproductive response.

The seasonal pattern of reproduction can limit the organization of breeding programmes and the planned distribution of kidding throughout the year. Hormonal protocols based on progestogens, prostaglandins and gonadotropins are commonly used to induce or synchronize estrus. Although these treatments can provide a controlled reproductive response, their application requires additional animal handling and increases production costs. Repeated hormonal treatments may also reduce estrus response and reproductive performance through endocrine and immune changes (Sun et al., 2024). For these reasons, increasing attention has been directed towards non-hormonal methods that can be more easily integrated into extensive and semi-extensive production systems.

The male effect is a natural reproductive management method based on the introduction of bucks after a period of separation from females. Contact with a sexually active male can stimulate luteinizing hormone secretion, follicular development, ovulation and estrous behaviour in females with reduced or absent ovarian activity (Chemineau, 1987; Delgadillo et al., 2009). The response is initiated mainly by olfactory signals but is reinforced by visual, auditory and behavioural stimuli. Consequently, complete separation before buck introduction is generally recommended to increase the response of females when contact is re-established.

The effectiveness of the male effect depends on several factors associated with both females and males. In females, live weight, body condition, previous reproductive activity and nutritional status can influence the proportion of animals that ovulate or exhibit estrus after buck introduction (Gallego-Calvo et al., 2015, 2018). In males, sexual activity, age, feeding level, photoperiodic treatment and the intensity of behavioural interactions with females may modify the reproductive response. Delgadillo et al. (2020) found that undernutrition reduced body weight, testicular size and odour intensity in bucks and increased the interval between buck introduction and the onset of estrous behaviour in females. Subsequent research showed that nutritional supplementation improved the sexual response of bucks managed under semi-extensive conditions and increased their ability to stimulate reproductive activity in females (Delgadillo et al., 2021).

The sexual activity of males may also affect the proportion of females that show estrus and ovulation. Photoperiod-treated bucks can improve estrus expression and reproductive performance, particularly in breeds characterized by pronounced reproductive seasonality (Zarazaga et al., 2021). However, high testosterone concentrations at the time of buck introduction do not appear to be an essential condition for inducing ovarian activity, suggesting that the response results from the combined action of several behavioural and physiological signals (Zarazaga et al., 2022).

The male-to-female ratio is another factor that may affect the degree of contact between animals and the intensity of stimulation. Ratios ranging from one buck per five females to one buck per 20 females have produced stronger reproductive responses than lower male availability, such as one buck per 30 females (Zarazaga et al., 2018). Nevertheless, climatic and management conditions may modify these responses. Alves et al. (2014) obtained high estrus rates in Anglo-Nubian goats during both dry and rainy periods, although some reproductive indicators were more favourable during the rainy season. These differences may be associated with changes in feed availability, nutritional status and environmental stress.

Climatic conditions can influence reproduction directly through temperature and humidity and indirectly through their effects on pasture growth and feed quality. Although goats are considered well adapted to a wide range of environments, prolonged exposure to high temperatures can alter endocrine function, feed intake and reproductive performance (Danso et al., 2024). In extensive and semi-extensive systems, dry conditions may also reduce the availability and nutritional value of forage, whereas more favourable rainfall can support a more stable supply of feed. The reproductive response to the male effect should therefore be evaluated in relation to the environmental and management conditions in which the animals are raised.

The Carpathian goat is widely raised in Romania, particularly in traditional production systems; however, information regarding its estrous response following the controlled introduction of bucks remains limited. Moreover, few studies have compared the effectiveness of the same male-effect protocol in Carpathian goats maintained under contrasting climatic conditions.

Therefore, the present study aimed to evaluate the influence of the male effect on estrus response in Carpathian goats raised in a dry and a humid climatic area of Romania. The proportion of females that showed estrus during the first 15 days and the distribution of estrus onset after buck introduction were compared to determine whether climatic conditions were associated with differences in the intensity and synchronization of the reproductive response.

MATERIALS AND METHODS

The study was conducted between August and September 2025 on two goat farms located in regions of Romania with contrasting climatic conditions. The first farm was situated in a dry region of south-eastern Romania, characterized by higher mean annual temperatures, reduced annual precipitation and frequent periods of water deficit during the growing season. The second farm was located in a more humid northern region, characterized by moderate temperatures, higher precipitation and conditions favorable for vegetation growth and pasture availability.

The climatic characterization of the two regions was based on mean annual temperature, mean temperature during the breeding season, annual precipitation, relative humidity and the mean annual number of rainy days. In the dry region, the mean annual temperature was 12.5°C, the mean temperature during the breeding season was 18.6°C, annual precipitation was 420 mm, relative humidity was 63% and the mean annual number of rainy days was 85. In the humid region, the corresponding values were 9.8°C, 15.2°C, 720 mm, 76% and 125 days, respectively. Climatic data were obtained from the Romanian National Meteorological Administration (ANM, https://www.meteoromania.ro/clima/).

A total of 100 clinically healthy adult Carpathian females were included in the study, with 50 females selected from each farm. Within each climatic region, the animals were divided into a control group and an experimental group, each consisting of 25 females. Therefore, the control group included 50 females, with 25 animals from each region, while the experimental group consisted of another 50 females distributed in the same manner. All animals were maintained under the usual feeding and management conditions of the farms throughout the study.

The females in the control groups were managed according to the usual reproductive practices of each farm. They were not subjected to a prior period of separation from males and therefore did not undergo the protocol based on male presence. Reproductive activity proceeded under the routine conditions of the farms and these groups served as the basis for comparison when evaluating the influence of male presence on estrus expression.

The females in the experimental groups were completely isolated from males for 60 days before the beginning of the breeding period. During this interval, all direct and indirect contact between females and males was prevented, including visual, olfactory and auditory contact. At the end of the isolation period, one breeding male was introduced into each experimental group of 25

females, corresponding to a male-to-female ratio of 1:25. The day of male introduction was designated as Day 0 and the males remained with the females throughout the 15 day observation period. Monitoring of the control and experimental groups began on the same date in each climatic region.

Estrous behavior was monitored daily for 15 consecutive days. Females were considered to be in estrus when they showed behavioral signs of sexual receptivity and accepted mounting by the male. The number of females that showed estrus was recorded individually for each group. Estrus response was calculated as the number of females that showed estrus divided by the total number of females in the respective group and multiplied by 100.

To assess the distribution and degree of synchronization of the reproductive response, the interval between the beginning of the observation period and the first detection of estrus was recorded for each female. According to the time of estrus onset, the females were classified into three intervals: 1-5 days, 6-10 days and 11-15 days.

The numbers and proportions of females that showed estrus were calculated for each group and climatic region. Differences between the control and experimental groups were assessed using Pearson's chi-square test. The same test was applied to compare the proportions of females that showed estrus within the three observation intervals. Statistical significance was established at $P < 0.05$ and the results were expressed as numbers of females and percentages.

RESULTS AND DISCUSSION

The proportion of females that showed estrus within the first 15 days after male introduction was used to evaluate the reproductive response in the two climatic regions (Table 1).

Table 1. Estrus response of Carpathian females according to climatic region and group

Climatic Area	**Group**	**n**	**Females in estrus**	**%**	**P-value**
Dry Area	Control	25	17	68,00	P=0,034
	Experimental	25	23	92,00	
Humid Area	Control	25	18	72,00	P=0,022
	Experimental	25	24	96,00	

The presence of the male stimulated estrus expression in Carpathian females in both regions. In the dry region, the proportion of females that showed estrus increased from 68.00% in the control group to 92.00% in the experimental group, representing an increase of 24.00 percentage points. In the humid region, the corresponding proportion increased from 72.00% to 96.00%, resulting in the same increase of 24.00 percentage points.

Statistical analysis revealed significant differences between the control and experimental groups in both the dry region ($P = 0.034$) and the humid region ($P = 0.022$), confirming the influence of male presence on estrus expression.

The reproductive response was numerically slightly higher in the humid region, where 96.00% of the experimental females showed estrus, compared with 92.00% in the dry region. Nevertheless, the increase relative to the control group was identical in both regions. Therefore, male presence produced a clear reproductive response under both climatic conditions (Figure 1).

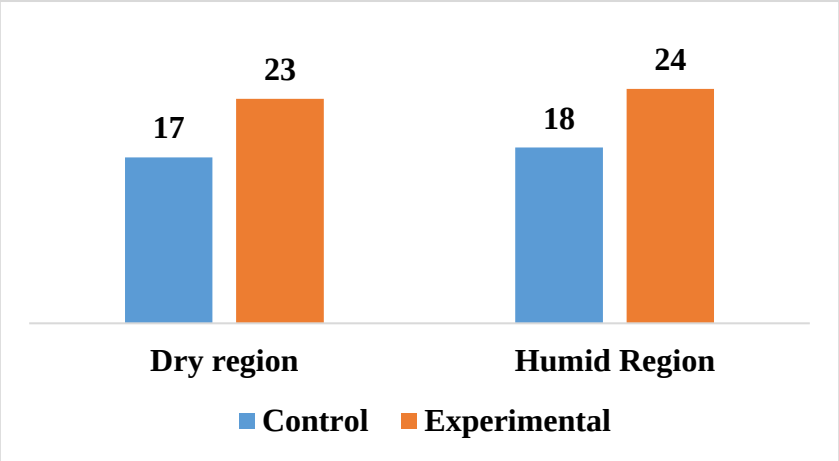

Figure 1. Distribution of estrus expression during the first 15 days following male introduction

In addition to the proportion of females that showed estrus, the time interval between male introduction and estrus onset was analyzed to assess the degree of synchronization of reproductive activity.

Estrus expression was concentrated mainly within the first five days after male introduction. In the dry region, the proportion of females that showed estrus during the 1-5 day interval increased from 20.00% in the control group to 56.00% in the experimental group. In the humid region, the corresponding values increased from 28.00% to 68.00%.

The proportions of females that showed estrus during the 6-10 day and 11-15 day intervals were lower in the experimental groups than in the control groups. This distribution indicates that male introduction promoted an earlier and more synchronized reproductive response. Highly significant differences were recorded for the 1-5 day interval in both the dry region ($P = 0.009$) and the humid region ($P = 0.004$). Differences between groups during the 6-10 day and 11-15 day intervals were not statistically significant ($P > 0.05$) (Table 2).

Table 2. Distribution of females that showed estrus according to the time interval following male introduction

Climatic Region	**Group**	**n**	**1-5 days**	**%**	**6-10 days**	**%**	**11-15 days**	**%**
Dry Area	Control	25	5	20,00	7	28,00	5	20,00
	Experimental	25	14	56,00	6	24,00	3	12,00
P-value			**0,009**		**0,754**		**0,439**	
Humid Area	Control	25	7	28,00	6	24,00	5	20,00
	Experimental	25	17	68,00	5	20,00	2	8,00
P-value			**0,004**		**0,733**		**0,218**	

Note: n - number of females.

The introduction of males after a 60 day separation period increased both the proportion of females that showed estrus and the concentration of estrus onset within the first five days. These findings are consistent with the neuroendocrine mechanism described by Chemineau (1987) and subsequently detailed by Delgadillo et al. (2009). According to this mechanism, olfactory, visual, auditory and behavioral stimuli emitted by the male activate the hypothalamic-pituitary-ovarian axis, promoting luteinizing hormone secretion, follicular development and ovulation.

The earlier concentration of estrus expression observed in the experimental groups is also supported by Augusto et al. (2020). In prepubertal Saanen goats, exposure to a sexually active male resulted in estrous behavior occurring two weeks earlier than in females maintained without male stimulation. These authors recorded estrus in 70.00% of the stimulated animals, compared with 44.00% in the control group. Although the breed, age and experimental design differed from those of the present study, both studies indicate that sociosexual stimulation can increase the proportion of responsive females and promote an earlier estrous response.

The slightly higher numerical response recorded in the humid region may be associated with differences in environmental and nutritional conditions. A more consistent availability of feed resources in regions with higher rainfall may contribute to maintaining a favorable body condition and metabolic status. By contrast, water deficit and variations in the availability and quality of vegetation in dry regions may reduce the energy and protein intake required for normal reproductive activity. However, because each climatic region was represented by one farm, the observed differences cannot be attributed exclusively to climatic conditions.

These findings are supported by Danso et al. (2024), who reported that although goats have a strong capacity to adapt to high temperatures, prolonged exposure to heat stress may cause endocrine and metabolic changes that negatively affect reproductive performance. High temperatures and reduced feed availability can influence reproductive activity in both females and males.

The results are also comparable to those reported by Alves et al. (2014), who evaluated the male effect in Anglo-Nubian goats during dry and rainy seasons. Their findings demonstrated that this method can be applied successfully under different climatic conditions, although some reproductive indicators were more favorable during the rainy season. Similarly, the present study recorded a slightly earlier and more concentrated estrus response in the humid region.

The high estrus response observed in the present study is also consistent with the findings of Viana Neto et al. (2015), who reported that 94.50% of dairy goats showed estrus following biostimulation through the male effect during rainy and dry seasons. This value was intermediate between the 92.00% recorded in the dry region and the 96.00% recorded in the humid region in the present study. Despite differences in breed and management conditions, the similarity between these values demonstrates that controlled male introduction can produce a high estrus response under contrasting environmental conditions.

From a practical perspective, male presence represents an effective method for reproductive management on goat farms in Romania, where many herds are raised under extensive or semi-extensive systems and the use of hormonal treatments may be limited by their cost. The method can contribute to a more efficient organization of the breeding season and facilitate the grouping of kidding events without the use of hormonal protocols. Its effectiveness may be supported by ensuring appropriate nutritional conditions and adapting reproductive management to the environmental characteristics of each region.

CONCLUSIONS

The male effect was effective in stimulating and synchronizing reproductive activity in Carpathian goats in both climatic regions. Following male introduction after a 60 day separation period, the proportion of females that showed estrus within the first 15 days increased from 68.00% to 92.00% in the dry region and from 72.00% to 96.00% in the humid region.

The protocol also promoted an earlier onset of estrus. During the first five days following male introduction, the proportion of females that showed estrus increased from 20.00% to 56.00% in the dry region and from 28.00% to 68.00% in the humid region, indicating more effective synchronization of reproductive activity in the experimental groups.

Although the reproductive response was numerically slightly higher in the humid region, male presence produced a clear and statistically significant response under both climatic conditions. Therefore, this method can be applied in regions with different climatic characteristics, provided that appropriate nutritional and management conditions are ensured.

From a practical perspective, the male effect represents a simple, low-cost and hormone-free method for reproductive management in Carpathian goat herds. Its application may contribute to a more efficient organization of the breeding season and facilitate the grouping of kidding events in extensive and semi-extensive production systems.

ABSTRACT

The accelerating expansion of the world population, changing dietary habits, and the continuous increase in protein consumption necessitate a re-evaluation of traditional animal and plant-based protein production systems in terms of environmental, economic, and sustainability. In particular, the high greenhouse gas emissions, intensive land and water use, and adverse effects on biodiversity associated with animal-based protein production have positioned the development of sustainable alternative protein sources as one of the leading research priorities on a global scale. In this regard, the utilization of plant-based by-products generated in the food industry for alternative protein production has emerged as a significant strategy in terms of both the circular bioeconomy and the zero-waste approach. By-products such as fruit and vegetable processing residues, brewer's spent grain, spent coffee grounds, oilseed meals, cereal bran, and legume hulls are among the potential raw materials that can be converted into high-value-added protein sources, owing to their rich content of protein, dietary fiber, polyphenols, and other bioactive compounds. However, lignocellulosic components such as cellulose, hemicellulose, pectin, and lignin present in the plant cell wall limit the recovery of protein; consequently, conventional extraction methods exhibit significant disadvantages, including low yield, prolonged processing time, and high chemical consumption. To overcome these limitations, green technologies such as ultrasound-, enzyme-, and microwave-assisted extraction, supercritical fluid extraction, deep eutectic solvents, pulsed electric field, high hydrostatic pressure, and membrane filtration have emerged as alternative approaches. In addition, the production of microbial proteins—particularly single-cell protein—from lignocellulosic biomass through fermentation bioprocesses, as well as algae- and insect-based bioconversion systems, stand out as innovative approaches that enable the conversion of low-value biomass into protein sources with high added value. These technologies not only enhance protein yield, purity, and functional properties but also significantly reduce energy consumption, organic solvent use, and environmental impact. Owing to their superior techno-functional properties such as emulsification, foaming, water- and oil-binding capacity, and gelation the recovered proteins are utilized in numerous food applications, including plant-based meat analogues, dairy alternatives, functional beverages, and enriched bakery products. Nevertheless, variability in raw material composition, the industrial scalability of extraction processes, food safety, regulatory frameworks, and consumer acceptance remain among the key challenges in this field. This review examines current extraction and bioconversion approaches for the utilization of plant-based by-products in alternative protein production, along with the functional food applications of these proteins and their potential contributions to sustainable food systems.

Keywords: Alternative proteins, Plant-based by-products, Green extraction, Sustainable food systems.

INTRODUCTION

The global agri-food system faces the dual challenge of meeting the nutritional needs of a rapidly growing population while reducing the environmental burden of food production. The global population is projected to reach 8.6 billion by 2030, 9.7–9.8 billion by 2050, and approximately 11.2 billion by 2100. Meeting these demands is expected to require a substantial increase in food production, while land, water, and energy resources are becoming increasingly scarce (Choręziak et al., 2025; Dhiman et al., 2026; Leite et al., 2026).

The anticipated increase in food demand is particularly critical for protein supply. Protein requirements are influenced by factors such as age, health status, and physical activity; an average adult is estimated to require approximately 1–1.6 g of protein per kilogram of body weight per day. Meat has traditionally been a major protein source because of its complete amino acid composition and cultural acceptance. However, the projected doubling of meat demand by 2050, driven by population growth, urbanization, and changing dietary preferences, would intensify pressure on land, water, and energy resources. Animal agriculture is estimated to generate approximately 7.1 gigatonnes of carbon dioxide (CO_2) annually and to account for about 14.5% of total greenhouse gas emissions (Singh & Krishania, 2026). Livestock production is also associated with deforestation, habitat conversion, biodiversity loss, soil degradation, water pollution, overgrazing, and desertification. In addition, the misuse and overuse of antibiotics in intensive animal production have been linked to the rise of antibiotic resistance (Malila et al., 2024). Consequently, the development of alternative protein sources has become a strategic priority. Balancing animal-derived proteins with plant proteins and other alternatives could contribute to more sustainable food systems, support biodiversity, and improve the distribution of high-quality proteins across populations (Choręziak et al., 2025).

Alternative proteins can be obtained from plants, fungi, insects, algae, and cultured meat. They generally contain lower levels of saturated fatty acids and may provide bioactive compounds, making them relevant to the prevention of lifestyle-related health conditions (Sarathy et al., 2025). Compared with animal-based production, plant-based foods require less land and water and generate lower CO_2 emissions. They may also help reduce fluctuations in the availability and price of protein-rich foods caused by extreme weather events, pandemics, conflicts, and inflation (Ahmad et al., 2025; Hadidi et al., 2024).

Beyond conventional plant sources, agri-food by-products represent an abundant and underutilized reservoir of proteins, amino acids, lipids, fatty acids, sugars, dietary fibers, pigments, minerals, vitamins, peptides, and other bioactive compounds. Relevant materials include husks, straw, stover, peels, pomace, seeds, spent grains, shells, bran, organs, whey, factory vegetable-oil residues, and other agricultural by-products. These streams are increasingly investigated for the recovery of food ingredients, food enzymes, food additives, and bioactive compounds, including compounds with antimicrobial activity (Leite et al., 2026; Ospina-Maldonado et al., 2024). Recovered components have been incorporated into functional beverages, nutrient-enriched snacks, and food supplements (Ververis et al., 2026). Particularly, protein-rich plant-based co-products offer significant potential as value-added ingredients in food applications due to their balanced amino acid compositions, low contaminant levels, and superior technological functionalities, such as emulsifying, gelling, and foaming properties. Their recovery, however, is complicated by the lignocellulosic or oleaginous matrices in which the proteins are embedded (Gaber et al., 2025). Protein extraction is therefore a critical step in

determining the yield, purity, nutritional quality, and techno-functional performance of plant protein ingredients and hydrolysates. Conventional approaches, including solvent-based extraction and alkaline extraction, remain widely used because they are operationally simple and relatively inexpensive. Nevertheless, these methods may require large quantities of water or chemicals, consume substantial energy, exhibit limited selectivity, and promote protein denaturation or degradation, thereby reducing nutritional and functional quality (Bekiroglu et al., 2025; Sabaghi & Seyedalmoosavi, 2025; Gaber et al., 2025). These limitations of traditional methods have increased the need for more environmentally friendly and resource-efficient approaches promoting the development of green extraction technologies. Green extraction technologies, including ultrasound-, enzyme-, and microwave-assisted extraction, supercritical fluid extraction, deep eutectic solvents, pulsed electric field, high hydrostatic pressure, and membrane filtration, offer promising strategies for improving protein recovery while reducing the environmental impact associated with conventional extraction processes (Khalid et al., 2025; Sabaghi & Seyedalmoosavi, 2025; Gaber et al., 2025). In addition, the production of microbial proteins, particularly single-cell protein, from lignocellulosic biomass through fermentation bioprocesses, as well as algae- and insect-based bioconversion systems, represents an innovative approach for converting low-value biomass into high-value protein sources (Leite et al., 2026; Rajput et al., 2026). These approaches can improve protein yield, purity, and functional properties while contributing to reduced energy consumption, chemical use, and environmental impact (Dhiman et al., 2026). The selection and optimization of these extraction and bioconversion approaches should balance process efficiency, cost, and protein purity according to the requirements of different industrial applications (Sabaghi & Seyedalmoosavi, 2025).

The value of extracted proteins in food manufacture is commonly assessed through techno-functional properties, including solubility or dispersibility, water- and oil-holding capacity, emulsifying and foaming behavior, and gelation. However, they are highly dependent on the extraction method, protein aggregation state, and composition of the surrounding food matrix, particularly in plant-derived proteins (Naibaho, 2027). Physical structure-modifying treatments, including high-pressure processing (HPP), ultrasound, pulsed electric fields (PEF), cold atmospheric plasma, and extrusion, can further improve the functionality of protein-rich by-products. These treatments may reduce antinutritional factors, promote protein unfolding, and enhance solubility by modifying protein structure and fiber composition. Such changes can facilitate the incorporation of valorized by-products into new food applications (Chen & Ozturk, 2026).

Technological advancements in the recovery and processing of proteins are also contributing to the development of the alternative protein sector. These advancements not only contribute to improving the sensory and nutritional attributes of alternative protein products, including taste, texture, and nutritional quality, but also accelerate research and development activities and market growth through investments made by major food and technology companies in the sector. Accordingly, the integration of alternative proteins into existing food systems is not limited solely to the replacement of animal-derived proteins; rather, it is increasingly regarded as part of a broader transition toward more sustainable, resilient, and ethical protein production models. In this context, agri-food residues, processing by-products, and industrial wastewater represent protein-rich yet underutilized resources with considerable potential for protein recovery (Dhiman et al., 2026). In particular, plant-based proteins play an important role in modern food systems owing to their potential to enhance protein accessibility, support environmental sustainability, and contribute to the prevention of chronic diseases. The applications of these proteins encompass a broad range of products, from meat analogues and dairy alternatives to protein supplements and functional beverages (Mia et al., 2026).

This review comprehensively examines the potential of agricultural and industrial by-products for alternative protein production, innovative green extraction methods for protein recovery, and the applications of the recovered proteins in various food products.

Plant-Based By-Products As Sustainable Protein Sources

Food loss and waste represent major sustainability challenges for global food systems. Approximately one-third of the food produced worldwide, corresponding to nearly 1.3 billion tonnes annually, is lost or wasted and contributes an estimated 8–10% of global greenhouse-gas emissions (Boudalia et al., 2026). In this context, the valorization of plant-based by-products generated during food processing is considered a viable strategy that can contribute to the more efficient utilization of existing agricultural resources and the diversification of alternative protein sources.

Over the past two decades, plant proteins have attracted sustained interest as nutritious and sustainable sources of essential amino acids. While serving as an alternative to animal-derived proteins, which are costly or inadequately available in developing nations, they are increasingly being incorporated into daily diets in developed countries, particularly in vegan food products (Akhtar et al., 2022). In addition to their availability, cost-effectiveness, and versatile functional properties within food systems, the utilization of plant-based proteins has increased in parallel with growing consumer interest in more affordable and environmentally sustainable diets and the widespread adoption of veganism and vegetarianism in Western societies (Munialo et al., 2022; Coronel-León et al., 2026). The growing interest in plant-based proteins has also highlighted the importance of valorizing plant-based by-products, generated at various stages of the food supply chain such as harvesting, processing, and refining, as protein sources. These by-products include oilseed meals derived from soybean, sunflower, and canola processing; fruit and vegetable residues originating from juice production, such as apple pomace, citrus peel, and grape pomace; cereal milling by-products like wheat and rice bran; and hulls obtained from legume processing (Shawky et al., 2025). In addition to proteins, these by-products contain dietary fiber, carbohydrates, minerals, vitamins, phenolics, flavonoids, carotenoids, and other bioactive compounds (Danciu et al., 2026; Khalid et al., 2025).

The protein content of plant-based by-products varies depending on the source and the nature of the by-product. On a dry-matter basis, fruit and vegetable pomaces generally contain 8–15% protein, whereas peels contain approximately 2–10% and pulps 1–5%. With approximately 10-25% protein and 15-65% lipid contents, seeds are considered among the more protein-dense fractions. These nutritional attributes render fruit seeds, pomaces, and kernels valuable resources for valorization (Danciu et al., 2026; Khalid et al., 2025).

The significance of valorizing plant-based by-products becomes increasingly apparent when considering their production volumes. Fruit- and vegetable-processing residues account for approximately 16% of total food by-products and contribute about 6% of global greenhouse-gas emissions. Brewer's spent grain (BSG) represents approximately 85% of the brewing industry's solid by-products, with global production exceeding 39 million tonnes annually. Similarly, several million tons of spent coffee grounds are generated annually, and this material constitutes a significant waste stream originating from coffee production (Danciu et al., 2026).

Cereal processing by-products constitute a significant group among plant-based protein sources. Global cereal production exceeds 2.8 billion tons annually (FAO, 2023), and milling and dehulling processes generate various fractions such as pericarp, aleurone layer, embryo, and bran. Despite their nutritional value, these fractions, which contain fibers, bioactive peptides, lipids, phenolic compounds, phytosterols, and other health-promoting components in

addition to proteins, are frequently utilized as animal feed or discarded (Aït-Kaddour et al., 2024).

Brewers' spent grain, a prominent example of cereal processing by-products, contains approximately 60% carbohydrates (including roughly 50% dietary fiber), 30% protein, and 10% lipids, in addition to minerals and bioactive polyphenols. Its protein fraction is dominated by water-insoluble hordeins and glutelins. Moreover, its content of ferulic acid, *p*-coumaric acid, caffeic acid, arabinoxylan, and β-glucan is reported to contribute to its antioxidant, anti-inflammatory, hepatoprotective, and prebiotic potential (Danciu et al., 2026). With global beer production approaching 180 million tonnes per year, BSG production is estimated to correspond to approximately 20% of this volume and to represent approximately 85% of the brewing industry's solid by-products (Aït-Kaddour et al., 2024; Saberian et al., 2024).

Spent coffee grounds (SCG) are also among the plant-based by-products that can be valorized for their protein and other valuable components. The disposal of SCG, generated in massive quantities, poses a significant challenge from an environmental management perspective. On a dry basis, SCG generally contain 6–16% protein, 10–18% lipids, and 60–70% total dietary fiber, mainly in the form of cellulose, hemicellulose, and lignin. They also contain chlorogenic acid, caffeine, melanoidins, diterpenes such as kahweol and cafestol, galactomannan, arabinogalactan, and other phenolic compounds (Choe, 2025; Danciu et al., 2026).

Oilseed meals and cakes constitute another notable group of plant-based by-products, distinguished by their protein content. Approximately 39% of oilseed meals and press cakes are generated during food production and processing, with substantial quantities arising from the processing of soybeans, sunflower, rapeseed, pumpkin seeds, hemp seeds, and other oil-bearing crops (Chen & Ozturk, 2026). Although traditionally utilized as low-value animal feed or discarded, the protein content of oilseed meals can reach up to 50% on a dry matter basis, thereby presenting significant potential for utilization in human nutrition (Kanimozhi et al., 2026). Furthermore, oilseed by-products also contain lipids and other valuable bioactive compounds (Aït-Kaddour et al., 2024).

Overall, plant-based agro-industrial by-products hold considerable potential for the diversification of alternative protein sources, owing to their high production volumes, protein content, and other nutritional and bioactive components (Nirmal et al., 2025). The valorization of these resources, traditionally utilized as animal feed or discarded, can contribute to the diversification of the protein supply without requiring additional agricultural inputs, thereby supporting circular and resource-efficient food systems (Naibaho, 2027).

Emerging Extraction, Processing And Bioconversion Technologies For Alternative Proteins

The primary objective of any extraction procedure is to maximize recovery of the target compound while minimizing adverse changes to its properties and limiting the co-extraction of undesired constituents (Chandran et al., 2024). Protein extraction is particularly challenging because plant proteins are often tightly entrapped within cell walls and intracellular cotyledon matrices, and interactions with the extraction solvent can modify their structural characteristics. Efficient extraction therefore requires technologies that can disrupt plant-cell integrity and facilitate protein release (Chandran et al., 2023).

In protein recovery, solvent extraction and alkaline extraction-isoelectric precipitation are among the widely used conventional methods due to their reliance on simple, reliable, and well-defined protocols. Solvent extraction commonly employs organic solvents such as hexane,

ethanol, acetone, and methanol to recover proteins and other constituents from finely ground plant materials. After the protein-rich liquid fraction is separated from the solid residue, the proteins are precipitated and the solvent is evaporated or recovered for reuse (Kaur et al., 2025).

Isoelectric precipitation following alkaline extraction is another widely utilized conventional method in the industrial production of plant-based protein isolates and concentrates. This method exploits the pH-dependent solubility properties of proteins. In the initial stage, the pH is typically elevated to a range of 8-10 through the addition of sodium hydroxide to induce protein solubilization, during which fiber-rich fractions are separated. Subsequently, the pH is lowered to approximately 4.0-4.5 via acid addition. Under these isoelectric conditions, where protein solubility reaches a minimum, the proteins are recovered through precipitation (Nartea et al., 2023).

Conventional methods have long been used to produce plant-protein concentrates and isolates because of their operational simplicity, established protocols, and relatively low initial set-up costs. Nevertheless, their reliance on intensive chemical and thermal treatments creates important technological and environmental constraints. These methods may involve high energy consumption, environmental contamination, hazardous solvent residues, and reduced extraction quality or protein recovery (Ahmad et al., 2025). Incomplete protein recovery and heat- or pH-induced denaturation may additionally impair protein solubility, emulsifying capacity, and textural properties. Therefore, these limitations restrict the use of recovered proteins in food formulations in which such functionalities are essential and underscore the need for extraction approaches that combine high recovery efficiency with reduced environmental impacts and improved protein quality (Shawky et al., 2025).

In this context, various advanced extraction technologies have been developed and optimized for protein recovery over the past decade. Methods employing ultrasound-assisted extraction (UAE), enzyme-assisted extraction, microwave-assisted extraction (MAE), supercritical fluid extraction, and deep eutectic solvents present considerable potential for enhancing protein yield, purity, and functional properties while mitigating resource requirements and environmental burdens (Issa et al., 2025).

Ultrasound-assisted extraction, also known as sonoprocessing, is a promising non-thermal technology for protein recovery and modification. Compared with conventional methods, sonication can reduce processing time, energy consumption, and chemical use, potentially lowering the carbon footprint of protein processing. UAE uses mechanical sound waves at frequencies above the range of human hearing, generally above 20 kHz. In food processing, high-power ultrasound commonly operates at frequencies between 20 and 100 kHz (Ahmad et al., 2025). The effectiveness of UAE is primarily attributed to acoustic cavitation. Alternating compression and rarefaction cycles generate microbubbles in the liquid extraction medium. These bubbles grow and collapse violently within microseconds, producing localized high pressures and temperatures, intense hydrodynamic shear forces, and high-velocity liquid microjets (Ahmad et al., 2025; Chen & Ozturk, 2026). The implosion of these bubbles generates localized extreme conditions of temperatures up to 5000 K and pressures of 50 MPa, alongside high-velocity liquid microjets (approximately 400 km/h) and intense shear forces (Sharma et al., 2026). This cell-disruption mechanism is particularly relevant to agro-industrial residues, in which cellulose, hemicellulose, pectin, and lignin form rigid lignocellulosic barriers that restrict protein release into the liquid phase. Unlike conventional extraction, which may produce limited structural disruption, ultrasound can damage cell-wall architecture and facilitate protein liberation from the matrix (Gumus & Yildiz, 2024). UAE generally requires shorter treatment times and lower temperatures than conventional methods, which may help preserve the

structure of sensitive proteins. It is also considered environmentally favorable because it can reduce the need for strong chemicals and excessive energy inputs (Kaur et al., 2025).

Enzyme-assisted extraction uses biocatalysts to accelerate biological reactions and has increasingly been applied to reduce the need for harsh chemicals, shorten extraction times, and improve extraction efficiency. In plant-protein extraction, enzymes degrade the complex cell-wall structure composed of hemicellulose, cellulose, and lignin, thereby facilitating the release of intracellular proteins. Commercial preparations used for this purpose include Pectinex Ultra SP-L, Pectinex UF, Viscozyme L, pectinase, and cellulase, which provide hemicellulase, cellulase, and pectinase activities. Proteases such as Alcalase and Protex can additionally facilitate the passage of smaller protein fragments through the disrupted cell wall by hydrolyzing proteins into smaller molecules (Akyüz et al., 2024). The efficiency of enzyme-assisted extraction depends on enzyme type and concentration, the enzyme-to-substrate ratio, temperature, and extraction time. Protein yield and purity are also associated with the extent of cell-wall disruption. Optimal pH conditions are therefore required to prevent enzyme inactivation and protein denaturation. Typical extraction conditions involve alkaline pH values of 8–10 and temperatures of 45–60 °C (Huang et al., 2024).

Microwave-assisted extraction is a rapid, energy-efficient, and environmentally favorable technology for recovering proteins and other value-added constituents from agro-industrial by-products (Aït-Kaddour et al., 2024; Ligarda-Samanez et al., 2025). It uses non-ionizing electromagnetic waves in the frequency range of 300 MHz to 300 GHz. Frequencies of 2.45 GHz are commonly used in domestic systems, whereas 915 MHz or 2.45 GHz are typically applied at industrial scale (Sharma et al., 2026). Unlike conduction- or convection-based heating, MAE produces rapid and volumetric heating throughout the material (Hadidi et al., 2024). During microwave treatment, polar molecules in the plant matrix interact directly with electromagnetic radiation through dipole rotation and ionic conduction, generating dielectric heating (Maqsood et al., 2025). Free water molecules within biological cells are particularly important microwave-absorbing regions. Their rapid heating and vaporization increase intracellular pressure and generate abrupt temperature and pressure gradients, causing intracellular water to expand and cell-wall and membrane structures to rupture (Bagasettihalli Kariyappa et al., 2025; Hadidi et al., 2024; Shawky et al., 2025). The resulting cellular disruption promotes deeper solvent penetration, increases the solubilization rate of target proteins and bioactive compounds, and accelerates their release into the extraction medium through improved mass transfer (Bagasettihalli Kariyappa et al., 2025; Shawky et al., 2025). In addition to its rapid heating profile, MAE can reduce solvent requirements and extraction time while improving extraction efficiency compared with conventional processes. Its ability to operate synergistically with other techniques, including UAE and enzyme-assisted extraction, also supports its integration into biorefinery frameworks designed to recover high-value constituents from plant-based agro-industrial residues (Maqsood et al., 2025).

Supercritical-fluid extraction is another green alternative to conventional extraction. It uses non-toxic solvent systems, operates at low temperatures and over short extraction times, enhances diffusion, and reduces energy consumption. Its performance depends on the optimization of pressure, temperature, extraction time, and CO_2 flow rate, as well as on matrix characteristics such as moisture content, particle size, porosity, and shape. These parameters influence extraction selectivity and yield. The resulting extracts may contain high-value compounds with relevant biological activities, purity, and stability, supporting their potential use as functional-food ingredients (Calleja-Gómez et al., 2024).

Eutectic-mixture frameworks offer non-toxic and highly selective alternatives for biomolecule separation. Their mild thermal operating conditions can support structural stability during dissolution, while their solvent systems can dissolve complex protein matrices while preserving native three-dimensional conformation. Customizable polarity ranges, localized pH zones, and fluid-dynamic properties facilitate intact mass transfer into the liquid phase (Mohammad, 2026). The efficacy of deep-eutectic-solvent extraction depends largely on the selection of the hydrogen-bond acceptor and donor. These components collectively determine key solvent properties, including polarity, viscosity, hydrogen-bonding capacity, and pH. The polarity of the deep eutectic solvent must also correspond to the target compound. Hydrophilic deep eutectic solvents are generally more suitable for extracting phenolic compounds and polar proteins. In addition, the extensive hydrogen-bond network in these solvents can disrupt hydrogen bonds within the plant cell-wall matrix and facilitate the separation of intracellular proteins (Khalid et al., 2025).

In addition to green extraction technologies, bioconversion of low-value agricultural and food-processing residues provides an alternative route for protein production within a circular bioeconomy framework. In particular, microbial proteins, especially single-cell protein, can be produced from lignocellulosic residues and food waste through submerged or solid-state fermentation using bacteria, yeasts, fungi, and microalgae. These microorganisms can convert low-cost waste streams into protein-rich biomass, with single-cell protein generally containing high levels of protein and requiring relatively low land and water inputs, thereby supporting waste valorization and resource efficiency (Rajput et al., 2026; Sekoai et al., 2024). Similarly, algae-based systems have attracted attention as alternative protein platforms, with microalgae such as *Spirulina* and *Chlorella* reported as protein-rich biomass sources for food and feed applications (Navarré et al., 2025; Sekoai et al., 2024). Insect-based bioconversion, particularly using black soldier fly larvae (*Hermetia illucens*), also enables the conversion of organic waste streams into protein- and lipid-rich biomass, further contributing to circular waste-to-protein systems (Dhiman et al., 2026). These bioconversion approaches therefore provide complementary strategies for converting underutilized biomass and organic waste streams into value-added protein sources (Bai et al., 2026; Dhiman et al., 2026).

Physical Modification And Structuring Of Proteins Derived From Plant-Based By-Products

The incorporation of proteins recovered from agro-industrial by-products into food systems as functional ingredients depends on the controlled manipulation of their molecular conformation (Ligarda-Samanez et al., 2025; Rasool et al., 2026). Physical processing techniques employed for this purpose can be categorized into two groups: non-thermal physical treatments and structuring techniques that impart specific structural and textural properties to the proteins. While high-pressure processing and pulsed electric fields are among the non-thermal physical treatments; extrusion, electrospinning, and three-dimensional (3D) printing are the primary techniques utilized for protein structuring. These physical and mechanical processes, which do not require chemical or enzymatic inputs, can facilitate the enhancement of techno-functional properties by inducing controlled modifications in the protein structure (Ahmad et al., 2025; Farsani et al., 2026).

The effects of physical treatments on protein structure are highly dependent on processing conditions. Non-thermal processes, in particular, can alter weak non-covalent interactions such as hydrogen bonds and hydrophobic interactions, thereby inducing protein unfolding and the exposure of hydrophobic amino acid residues and free sulfhydryl groups. Consequently, these structural modifications can yield enhancements in solubility, interfacial emulsion stability, and

foaming capacity (Ahmad et al., 2025; Ligarda-Samanez et al., 2025). However, these effects vary depending on the processing conditions; while insufficient treatment leads to limited structural modifications, over-processing can result in irreversible denaturation, aggregation, or the loss of bioactivity. Furthermore, although these technologies generally facilitate the preservation of nutritional composition under mild conditions, the energy requirements—particularly those of high-pressure processing—must be taken into consideration during process design (Bekiroglu et al., 2025).

Among these techniques, high-pressure processing, also known as high hydrostatic pressure processing, is a non-thermal technology based on the application of pressures up to 800 MPa to food systems for a duration of several minutes. The uniform transmission of pressure throughout the medium ensures that the treatment effect is largely independent of product composition, size, and shape, thereby preserving the macroscopic integrity of the product. The impact of HPP on proteins is driven by the disruption of hydrophobic, electrostatic, and hydrogen bond interactions; a phenomenon that can subsequently influence molecular rearrangement, gelation, and aggregation (Chen & Ozturk, 2026). At appropriate pressure levels, the destabilization of the secondary, tertiary, and quaternary structures of proteins can result in partial or complete unfolding, the dissociation of subunits, a decrease in α-helical content, and an increase in β-sheet and random coil conformations. The exposure of hydrophobic residues, sulfhydryl groups, and charged side chains consequently alters the surface properties and interaction potential of the proteins (Mia et al., 2026). The manifestation of these structural modifications in functional properties depends on pressure intensity, holding time, temperature, pH, ionic strength, protein structure, and the composition of the food matrix. While moderate pressure levels can enhance solubility, emulsification, or gelation, excessive pressure can diminish techno-functional performance due to aggregation, denaturation, and phase separation (Ahmad et al., 2025).

The pulsed electric field process is based on inducing a transmembrane potential difference and electroporation through the application of short, high-voltage pulses of 20–80 kV cm^{-1} for durations of 1–100 μs to plant, microbial, and fungal cells. The resulting transient or permanent nanopores increase membrane permeability, thereby facilitating the release of intracellular water, ions, metabolites, and proteins, while the microchannels that enhance solvent-solute mobility accelerate mass transfer and improve substrate accessibility for microbial metabolism (Sharma et al., 2026). PEF can also alter protein conformation by promoting protein unfolding, charge redistribution, and the exposure of hydrophobic regions via electric field-induced molecular polarization (Teng et al., 2025). These modifications can enhance solubility, water-holding capacity, emulsification, and foaming properties; meanwhile, the inactivation of lipoxygenase, trypsin inhibitor activity, and allergenic structures can contribute to the improvement of flavor and nutritional value. However, an increase in processing intensity can alter the volatile compound profile and promote the formation of oxidative volatile compounds (Anbarasan et al., 2023).

In addition to the physical modification of proteins, structuring techniques are employed to generate desired structural properties in food applications. Among these, extrusion is a continuous thermal process widely utilized in the processing of plant-based proteins due to its short processing time, high efficiency, cost-effectiveness, and technological maturity. Through the combined effects of temperature, pressure, and shear forces, the material is mixed, homogenized, extruded, expanded, and transformed into organized fibrous protein structures (Xiao et al., 2023). Although low-moisture extrusion is generally performed at a moisture content of approximately 30%, moisture levels ranging from 10% to 35% have also been reported; this method yields dry, porous textured vegetable proteins suitable for use in

rehydrated products such as nuggets and burgers. High-moisture extrusion (HME), on the other hand, is typically applied at 50-70% moisture, though moisture levels in the range of 40-80% can also be utilized. While this process facilitates the formation of fibrous structures resembling muscle tissue, it can enhance chewiness and mouthfeel; furthermore, it can promote protein gelation, recombination, and fat emulsification (Zhang et al., 2021; Bisht et al., 2025; Imran et al., 2026). The capability of HME to provide low energy input, zero waste discharge, high production efficiency, and a desirable product texture—owing to its prevention of product expansion and reduction of viscous energy dissipation—supports its utilization in the development of plant-based meat alternatives (Zhang et al., 2021).

In addition to extrusion, electrospinning and 3D printing are also utilized in the structuring of plant-based proteins. Electrospinning involves the dissolution and denaturation of plant proteins in alkaline reagents, followed by their coagulation through a spinneret to generate a fibrous material composed of organized proteins. In 3D printing, on the other hand, the molten protein is extruded through a nozzle and deposited in layers to form a fibrous structure (Xiao et al., 2023; Zahari et al., 2022).

Applications In Sustainable Food Systems

In the valorization of plant-based proteins recovered from agro-industrial by-products as food ingredients, it is crucial that they exhibit functional properties that are equivalent to, superior to, or distinct from existing protein alternatives (Ismail et al., 2020). The properties of proteins, such as solubility, emulsification, gelation, binding, and water and oil holding capacities, directly influence their potential applications across various food systems (Ciugureanu et al., 2025). In this context, plant proteins can be utilized in diverse product categories, including meat and dairy alternatives, protein-rich beverages, bakery products, pasta, and snacks (Du & Yang, 2024).

Plant-based meat alternatives constitute one of the prominent application areas for alternative proteins. In contrast to the complex architecture of animal meat, which consists of muscle, fat, and connective tissues, plant proteins predominantly exist in globular conformations. This structural discrepancy complicates the mimicking of the fibrous structure, texture, aroma, and mouthfeel of animal meat. Consequently, structuring techniques are employed to transform plant proteins into meat-like structures (Kaplan et al., 2025; Samad et al., 2024). The stability of the resulting structures, along with their physicochemical and sensory properties during cooking, is crucial for consumer acceptance. Modified proteins with enhanced thermal stability can mitigate undesired denaturation during thermal processing, while high solubility coupled with strong binding, water-holding, and oil-holding capacities can contribute to the structural integrity of the product (Keerthi et al., 2025). Coconut, butter, sunflower, canola, and sesame oils can enhance juiciness and tenderness; however, excessive fat content can exert a lubricating effect, thereby interfering with the protein denaturation that is crucial for the development of a meat-like texture (Samad et al., 2024). Consequently, protein functionality, lipid composition, and structuring technology must be evaluated in conjunction in the formulation of plant-based meat alternatives (Boukid, 2021). Current studies evaluating proteins derived from plant-processing by-products in meat-analogue formulations and the structural features of the resulting products are summarized in Table 1.

Table 1. Current studies evaluating proteins derived from plant-processing by-products in meat-analogue formulations

By-Product Protein Source	Application	Findings	References
Okara flour (29.35% protein), a soybean-processing by-product	Incorporation at 0–40% into high-moisture meat analogues (HMMA) formulated with soy protein isolate, wheat gluten, and corn starch	Increasing okara reduced protein density but increased dietary fiber from 0 to 7.59 g/100 g at 40% incorporation. Fibrous anisotropy was maintained up to 20% okara, whereas higher levels reduced firmness, cohesiveness, and elasticity and disrupted protein alignment and gel functionality.	Aussanasuwannakul et al., 2025
Biji (okara/soybean curd residue), a protein-containing soybean-processing by-product	Used at 5, 10, 15, and 20 g in plant-based patties	Biji addition improved water-holding capacity, crude protein content, and textural properties while reducing cooking loss and dimensional shrinkage. The 20 g formulation exhibited the highest WHC and protein content and the lowest cooking loss, with reduced levels of undesirable volatile compounds.	Nam et al., 2024
Brewer's spent grain, a protein- and fiber-rich brewery by-product	Incorporation into soy protein isolate-based high-moisture meat analogues	BSG improved texturization, reduced hardness, and increased in vitro protein digestibility (74.58–76.15%). Incorporation levels up to 23.4% were suitable for texturization, whereas higher levels impaired fibrous structure formation.	da Silva et al., 2024
Pineapple edible pomace (6.52 ± 0.34% protein) and peel pomace	Partial replacement of soy protein isolate during extrusion	Pineapple pomace enhanced expansion ratio, water absorption index (optimized at 150.39%), and degree of	Lu et al., 2025

(4.61 ± 0.15% protein)	for meat analogue production	texturization, promoting a meat-like fibrous structure.	
Jackfruit by-products	Jackfruit by-products at different levels (18%, 38%, 58%, and 78%)	A formulation containing 58% jackfruit by-products and 20% wheat gluten achieved the highest sensory acceptance and provided higher protein (20.67 ± 3.96 g) and dietary fiber contents than the commercial meat analogue (14.26 ± 1.38 g protein).	(Hamid et al., 2020)

Dairy alternatives and protein-rich beverages constitute another prominent application area for plant-based proteins. These products serve as viable alternatives, particularly for consumers with lactose intolerance or milk protein allergies (Alehosseini et al., 2025). While cow's milk contains approximately 3.3 g of protein per 100 mL, the protein content of plant-based beverages varies significantly depending on the source used. Soy beverages contain about 4.0–4.8 g of protein per 100 mL; conversely, this value ranges from 0.3 to 0.7 g in rice beverages and is generally below 1 g in almond, oat, and coconut beverages (Yadav et al., 2026).

In the development of plant-based beverages, sensory and physicochemical properties are as critical as protein content. The emergence of beany, bitter, or off-flavors in these products, alongside a high starch content that negatively affects textural quality, can limit consumer acceptance. Furthermore, volatile compounds such as hexanal, hexanol, and pentanal, which can be generated as a result of lipid oxidation, can also contribute to off-flavors (Pointke et al., 2022). Acidification, fermentation, ultrasonication, and membrane filtration can be employed to improve protein functionality and sensory quality, whereas the blending of different proteins can contribute to the enhancement of amino acid profiles and beverage characteristics. These products can be targeted towards vegetarians, individuals with lactose intolerance or milk allergies, athletes, infants, and health-conscious consumers (Sabaghi & Seyedalmoosavi, 2025).

Among dairy products, plant-based cheese alternatives represent a more challenging application area because the technological functionality of dairy cheese is largely associated with the casein matrix. In these products, milk fat and/or proteins are partially or completely replaced by plant-based fats, oils, and proteins. The functional properties of the products largely depend on their fat, protein, dry matter, and calcium content. The inability of plant proteins to fully replicate the technological functionality of casein, coupled with their higher molecular weight compared to milk proteins, leads to functional differences. Therefore, achieving the characteristic texture, elasticity, and melting behavior of dairy cheese in plant-based alternatives poses a significant technological challenge, while modified starch can be utilized to mimic some of these properties (Kowalczewski et al., 2025).

In addition to meat and dairy alternatives, plant-based proteins can also be utilized in the formulations of bakery products, pasta, and snacks. Bread, cakes, pastries, and other bakery products rank among the staple foods widely consumed across different societies. Cereal-based snacks, on the other hand, enjoy a widespread consumption pattern as convenient and ready-to-

eat products (Boukid et al., 2024). However, these products are associated with several challenges in the contemporary context. The first concerns the elevated sugar and fat content typically found in bakery products, which has been linked to weight gain and the onset of non-communicable diseases, including diabetes, cardiovascular disease, and obesity. The second challenge relates to product deterioration, which encompasses chemical, physical, and microbiological alterations occurring in baked goods over time. Given that plant proteins are rich in bioactive compounds—such as antioxidant dietary fibers and phenolic compounds—their incorporation into the formulation of bakery and pasta products may be expected to contribute to the mitigation of these issues (Ahanchi et al., 2024). Furthermore, plant-based proteins can contribute to the quality enhancement of these products owing to their relatively high protein content and functional properties such as emulsification and gelation. On the other hand, mitigating off-flavors, enhancing processing efficiency, and raising consumer awareness are crucial for the broader utilization of plant-based proteins in snack products (Sabaghi & Seyedalmoosavi, 2025). The findings of current studies on the use of proteins derived from plant-processing by-products in the formulation of milk substitutes, bakery products, and extruded snacks are summarized in Table 2.

Table 2. Current studies evaluating proteins derived from plant-processing by-products in milk substitutes, bakery products, and extruded snacks

By-Product Protein Source	**Application**	**Findings**	**References**
Protein isolated from potato juice	Potato protein isolate was incorporated into plant-based cheese analogues as a protein source and functional ingredient	The optimized formulation (5% potato protein, 12% fat, 25% modified potato starch) showed increased hardness and viscosity and desirable melting properties, supporting its use as a lower-fat dairy cheese alternative in hot foods	Kowalczewski et al., 2025
Brewer's spent grain protein (BSGP)	Combined with lentil protein isolate to develop plant-based milk alternatives	Lentil–BSGP blending increased the proxy in vitro Digestible Indispensable Amino Acid Score (PIVDIAAS) from 0.48 and 0.50 for lentil protein and BSGP alone to 0.83, while improving sedimentation and creaming stability and emulsion whiteness.	Boeck et al., 2024

By-Product Protein Source	**Application**	**Findings**	**References**
Pumpkin, sunflower, and walnut oilseed cakes	Development of vegan yoghurt-like fermented beverages through lactic fermentation	Oilseed cake-based beverages contained 3.7–4.6% protein and up to 1.9% fiber, with lower syneresis (14–18%) and enhanced polyphenol and antioxidant contents. Pumpkin- and walnut-based formulations showed the best sensory acceptance, and all products remained microbiologically safe for 14 days	Radu et al., 2025
Defatted hemp cake	Utilization of defatted hemp cake (DHC; 34.50% protein), an oil-processing by-product, at 5–10% in corn grits for extruded snack production	Increasing DHC addition reduced expansion ratio and fracturability while increasing bulk density and hardness. The optimized formulation contained 5% DHC, 15% moisture, and 150 °C extrusion temperature, demonstrating the potential of DHC as a protein-rich by-product for extruded snack production	Jozinović et al., 2017
Brewer's spent grain, sugar beet pulp, and apple pomace	Incorporation of brewer's spent grain (11.08% protein at 15% addition), sugar beet pulp (SBP; 8.08% protein at 15% addition), and apple pomace (AP; 7.07% protein at 15% addition) at 5–15% into corn grits for directly expanded extruded snacks	BSG and SBP increased protein content, with a more pronounced effect for BSG, while AP reduced protein content. All by-products increased soluble and insoluble dietary fiber, with SBP providing the greatest improvement in fiber content. The addition of 5–15% by-products enhanced the nutritional value of corn snacks, with 10–15% incorporation enabling a "high in fiber" claim	Jozinovi´c et al., 2021
Spent coffee grounds	Incorporated into shortbread biscuits at concentrations ranging from 0% to 10%.	Increasing SCG addition proportionally increased protein content (5.54–7.08%) and enhanced dietary fiber and antioxidant properties. The 10% SCG formulation showed the highest protein content, favorable aroma, reduced hardness, and good storage stability	Koay et al., 2023

By-Product Protein Source	Application	Findings	References
Sunflower seed cake	Protein enrichment of gluten-free bread using sunflower seed cake, an oil-processing by-product (up to 15%).	Sunflower cake increased protein content from 7.44 to 9.69% (d.b.) and enhanced fiber and polyphenol contents. The 15% formulation exhibited the most favorable sensory acceptance and desirable textural properties, supporting its use as a protein-rich by-product for gluten-free bread.	Blicharz-Kania et al., 2023
Brewer's spent grain flour	Utilization of brewer's spent grain flour (BSGF; 15.5 ± 0.14 g protein/100 g) at 40–60% as a protein-rich by-product in chocolate cakes	BSGF increased protein, dietary fiber, zinc, and antioxidant capacity, with 60% substitution providing the highest nutritional enrichment. The 40% formulation achieved the best consumer acceptance, supporting BSGF as a functional protein-rich ingredient for bakery products	Paiva et al., 2025
Brewer's spent grain	Protein enrichment of bread using brewer's spent grain (16.6 ± 1.6% protein) at 15–30% flour substitution	Protein content increased from 7.5% to 8.1% and 11.3%, while dietary fiber increased from 7.4% to 16.4% and 24.4% with 15% and 30% BSG, respectively. The 15% BSG formulation reduced shelf life from 14 to 12 days, whereas 30% BSG reduced it to 6 days at 20 °C	Papadimitriou et al., 2026

CONCLUSIONS AND FUTURE DIRECTIONS

Driven by population growth, climate change, and resource constraints, the growing interest in sustainable, healthy, and ethical food options underscores the significance of plant-based and alternative protein sources. In this context, the valorization of agro-industrial by-products—such as oilseed meals, cereal brans, and fruit and vegetable pomaces—into high-value protein sources offers substantial potential for mitigating the environmental impacts of conventional protein production and supporting the circular bioeconomy. Advanced green technologies, including ultrasound-, enzyme-, and microwave-assisted extraction, supercritical fluid extraction, and deep eutectic solvents, enable the recovery of functional proteins and bioactive compounds while reducing chemical waste and environmental footprints. Nevertheless, the utilization of the resulting proteins, particularly in meat and dairy alternatives, entails various challenges in terms of achieving the targeted structural, sensory, and nutritional properties. Therefore, alongside protein recovery, their functional and structural characteristics in food applications must also be considered. Future studies must focus on multi-objective optimization

strategies that comprehensively evaluate the relationships among extraction and processing conditions, structural transformations of proteins, sensory properties, and nutritional functionality. Furthermore, the holistic consideration of criteria such as sensory quality, nutritional value, environmental impact, safety, and economic accessibility is crucial for the effective utilization of proteins derived from agro-industrial by-products in food systems.

ABSTRACT

Mycotoxins, toxic secondary metabolites produced by fungi such as *Aspergillus*, *Fusarium*, and *Penicillium*, represent one of the most significant chemical hazards in food systems. They contaminate cereals, nuts, fruits, and processed products, posing risks not only through acute toxicity but also via chronic exposure that can disrupt the human gut microbiome. The microbiome, a complex ecosystem of bacteria, fungi, and archaea, plays a central role in digestion, immune regulation, and metabolic homeostasis. Evidence suggests that mycotoxins such as aflatoxins, ochratoxin A, fumonisins, and deoxynivalenol can alter microbial diversity, reduce beneficial taxa, and promote dysbiosis, thereby increasing susceptibility to gastrointestinal disorders, metabolic dysfunction, and immune imbalance. This review synthesizes current knowledge on the ecological interactions between foodborne mycotoxins and the human microbiome, emphasizing the need for integrated risk assessment. The Hazard Analysis and Critical Control Points (HACCP) framework provides a systematic approach to identifying and controlling hazards at critical points in food production and processing. Applying HACCP principles to mycotoxin contamination involves monitoring agricultural practices, storage conditions, and processing steps where fungal growth and toxin production are most likely. By incorporating **microbiome-focused biomarkers**, such as microbial diversity indices, short-chain fatty acid levels, NF-κB activation, and metabolomic signatures, into HACCP risk assessment, food safety management can evolve beyond traditional toxicological thresholds to include microbial resilience and host health outcomes. Case studies highlight how HACCP interventions, including improved grain storage, rapid detection methods, and biocontrol strategies, reduce mycotoxin exposure. Ultimately, aligning HACCP with microbiome research offers a proactive strategy to mitigate the long-term health consequences of mycotoxin contamination. This interdisciplinary approach underscores the importance of integrating food safety, microbiology, and public health perspectives to safeguard consumer wellbeing and ensure sustainable food systems.

Keywords: Foodborne mycotoxins, Human gut microbiome, Microbiome dysbiosis, HACCP framework, Critical control points, Risk assessment, Food safety management

INTRODUCTION

Mycotoxins are toxic secondary metabolites produced by fungi such as *Aspergillus*, *Fusarium*, and *Penicillium*. They contaminate staple foods including cereals, nuts, coffee, dried fruits, and

spices, and represent one of the most significant chemical hazards in food safety (Khan, 2024). Chronic exposure to mycotoxins has long been associated with hepatotoxicity, nephrotoxicity, immunosuppression, and carcinogenesis (Mafe & Büsselberg, 2026). More recently, attention has shifted to their impact on the **human gut microbiome**, a complex ecosystem essential for digestion, immune regulation, and metabolic homeostasis.

Evidence indicates that mycotoxins disrupt microbial diversity, reduce beneficial taxa, and promote dysbiosis. For example, deoxynivalenol (DON) impairs short-chain fatty acid production and increases intestinal inflammation (Mafe & Büsselberg, 2026), while aflatoxin B_1 alters microbial composition and epithelial barrier integrity (Khan, 2024). These bidirectional interactions are critical: gut microbes can metabolize and detoxify certain mycotoxins, but they can also bioactivate others, amplifying toxicity (Mafe & Büsselberg, 2026).

The **Hazard Analysis and Critical Control Points (HACCP)** framework provides a systematic approach to identifying and controlling hazards at critical points in food production. Applying HACCP principles to mycotoxin contamination involves monitoring agricultural practices, storage conditions, and processing steps where fungal growth and toxin production are most likely (Khan, 2024). Integrating microbiome endpoints into HACCP risk assessment could enhance food safety management by considering not only toxicological thresholds but also microbial resilience and host health outcome

TYPES OF FOODBORNE MYCOTOXINS

Aflatoxins

Produced mainly by *Aspergillus flavus* and *A. parasiticus*, aflatoxins are potent hepatotoxins and carcinogens. Aflatoxin B_1 is the most toxic, linked to liver cancer and immune suppression (Mafe & Büsselberg, 2024). Studies show that aflatoxins disrupt gut microbial balance, reducing beneficial *Lactobacillus* and *Bifidobacterium* populations, while increasing opportunistic pathogens (Mafe & Büsselberg, 2026).

Ochratoxin A (OTA)

Generated by *Aspergillus* and *Penicillium* species, OTA contaminates cereals, coffee, and dried fruits. It is nephrotoxic and immunotoxic, and recent findings suggest it alters gut microbial composition, impairing epithelial barrier function and promoting dysbiosis (Khan, 2024). OTA exposure has been linked to reduced microbial diversity and increased inflammatory signaling pathways such as NF-κB (Mafe & Büsselberg, 2026).

Fumonisins

Produced by *Fusarium verticillioides*, fumonisins contaminate maize and maize-based products. Fumonisin B_1 interferes with sphingolipid metabolism and has been associated with esophageal cancer (Mafe & Büsselberg, 2024). In the gut, fumonisins disrupt microbial communities and impair short-chain fatty acid production, contributing to intestinal inflammation (Mafe & Büsselberg, 2026).

Deoxynivalenol (DON)

Also known as vomitoxin, DON is produced by *Fusarium graminearum* and contaminates wheat, barley, and maize. DON induces gastrointestinal distress and immune dysregulation. It reduces microbial richness, impairs SCFA production, and increases pro-inflammatory cytokines, thereby exacerbating dysbiosis (Khan, 2024; Mafe & Büsselberg, 2026).

Zearalenone (ZEN)

Produced by *Fusarium* species, ZEN is an estrogenic mycotoxin found in maize and wheat. It disrupts hormonal balance and reproductive health. In the gut, ZEN alters microbial composition and may promote the growth of taxa capable of metabolizing estrogen-like compounds, further complicating host–microbe interactions (Mafe & Büsselberg, 2026)

MICROBIOME IMPACTS OF FOODBORNE MYCOTOXINS

The gut microbiome refers to the diverse community of microorganisms living in the digestive tract, primarily in the intestines. These microorganisms play essential roles in digestion, nutrient absorption, and the synthesis of certain vitamins and hormones. The balance and composition of the gut microbiome can significantly impact overall health, including metabolic function, mental health, and immune response.

Each individual has a unique gut microbiome influenced by various factors, including genetics, diet, lifestyle, and environmental exposures. Maintaining a balanced and diverse gut microbiome is crucial for supporting various bodily functions and promoting overall well-being.

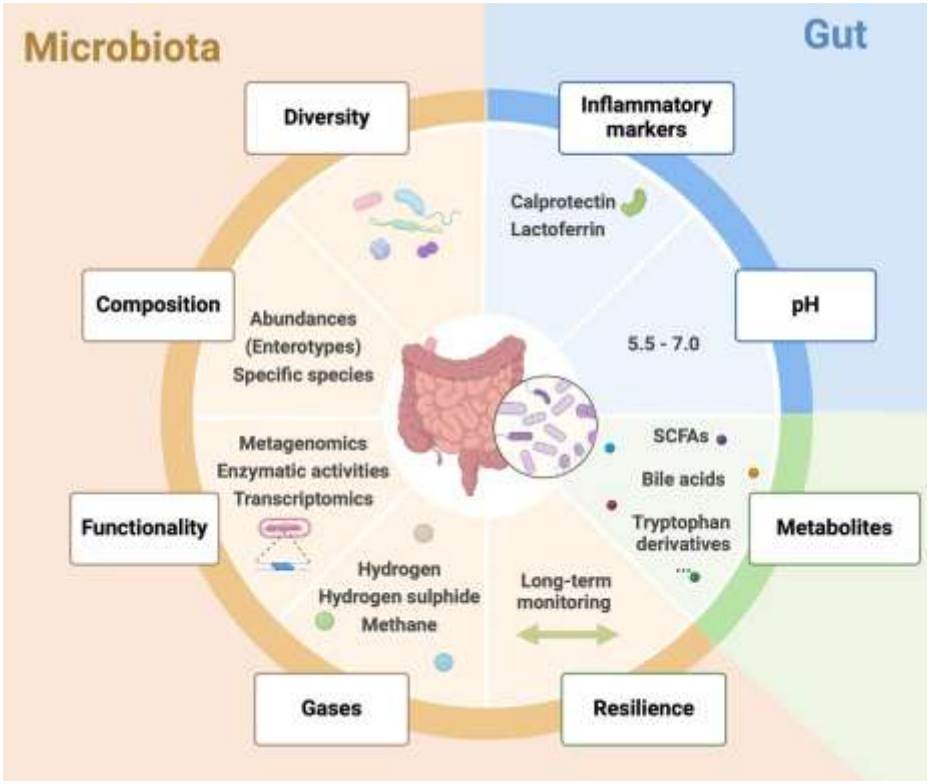

Figure 1. Potential markers of a healthy gut microbiota. A healthy gut microbiota is characterised by a diverse and balanced community of microorganisms that perform vital functions for the host. Several key markers have been proposed to assess these, including microbial diversity, composition (abundances, enterotypes, specific species), functionality (metagenomics, enzymatic activities, transcriptomics) and resilience (through long-term monitoring). Production of important metabolites like SCFAs, bile acids and tryptophan derivatives, as well as gases (hydrogen, hydrogen sulfide, methane), are potential indicators. Additionally, gut health indicators such as pH levels and the presence of inflammation markers (like calprotectin, lactoferrin) can be used for assessing overall gut health. SCFAs, short-chain fatty acids (from Van Hul et al., 2024).

Exposure to foodborne mycotoxins can disrupt this balance, leading to microbiome dysbiosis and downstream health consequences

Alterations in Microbial Diversity

Aflatoxins, particularly aflatoxin B_1, reduce beneficial taxa such as *Lactobacillus* and *Bifidobacterium* while promoting opportunistic pathogens (Chałaśkiewicz et al., 2025). This imbalance increases intestinal permeability and weakens epithelial barrier integrity (Mafe & Büsselberg, 2026).

Metabolic Effects

Deoxynivalenol (DON) is one of the most studied mycotoxins. It reduces the production of short-chain fatty acids (SCFAs), which are crucial for gut health and immune modulation. DON exposure also elevates pro-inflammatory cytokines, contributing to chronic intestinal inflammation (Li et al., 2019). Fumonisins, especially fumonisin B_1, disrupt sphingolipid metabolism and alter microbial composition, reducing *Clostridiaceae* and *Campylobacteraceae* while increasing *Ruminococcaceae* and *Faecalibacterium* (Yunus Zeebone et al., 2023; Zhang et al., 2021).

Immune Dysregulation

Ochratoxin A (OTA) is nephrotoxic and immunosuppressive, but also directly affects the microbiome. OTA activates NF-κB signaling, leading to chronic inflammation and reduced microbial diversity (Więckowska et al., 2025; Izco et al., 2021). Dysbiosis caused by OTA increases susceptibility to infections and metabolic disorders.

Bidirectional Interactions

The relationship between mycotoxins and the microbiome is **bidirectional**. Gut microbes can metabolize and detoxify certain mycotoxins, but they may also bioactivate others, amplifying toxicity (Mafe & Büsselberg, 2026). This dual role highlights the need for integrated risk assessment approaches that consider microbial resilience alongside toxicological thresholds.

HACCP CONTROL POINTS FOR MYCOTOXIN MANAGEMENT

The **Hazard Analysis and Critical Control Points (HACCP)** framework provides a systematic approach to identifying, evaluating, and controlling hazards in food production. When applied to mycotoxins, HACCP emphasizes prevention at critical stages rather than relying solely on end-product testing. Integrating microbiome considerations into HACCP adds a novel dimension, ensuring that food safety strategies also protect gut microbial health.

1. ***Primary Production (Agriculture)***

Critical Control Point (CCP): Crop cultivation and harvesting

Mycotoxins such as aflatoxins and fumonisins originate in the field, particularly under warm and humid conditions (Khan, 2024).

Preventive measures: crop rotation, resistant varieties, biocontrol agents (e.g., *Aspergillus flavus* biocompetitive strains).

Microbiome relevance: reducing contamination at source minimizes downstream exposure that disrupts gut microbial diversity

2. ***Post-Harvest Handling and Storage***

Critical Control Point (CCP): Grain drying and storage

Improper drying and high moisture favor fungal growth and OTA production (Izco et al., 2021).

Preventive measures: rapid drying to <13% moisture, controlled humidity, aeration systems.

Microbiome relevance: OTA exposure is linked to NF-κB activation and dysbiosis (Więckowska et al., 2025).

3. ***Processing and Manufacturing***

Critical Control Point (CCP): Milling, sorting, and detoxification steps

DON and ZEN often persist through processing; sorting and cleaning reduce contamination (Li et al., 2019).

Emerging technologies: enzymatic detoxification, microbial biotransformation.

Microbiome relevance: microbial detoxification strategies may preserve gut microbial resilience.

4. *Distribution and Retail*

Critical Control Point (CCP): Packaging and transport

Contamination can occur during storage and distribution if conditions favor fungal growth.

Preventive measures: HACCP monitoring of supply chains, traceability systems.

Microbiome relevance: minimizing chronic low-dose exposure reduces risk of long-term dysbiosis.

5. ***Consumption and Public Health Monitoring***

Critical Control Point (CCP): Consumer awareness and biomarker surveillance

Incorporating microbiome-sensitive biomarkers into HACCP risk assessment could provide early warning of subclinical effects (Mafe & Büsselberg, 2026).

Public health programs should integrate dietary monitoring with microbiome analysis to assess cumulative impacts.

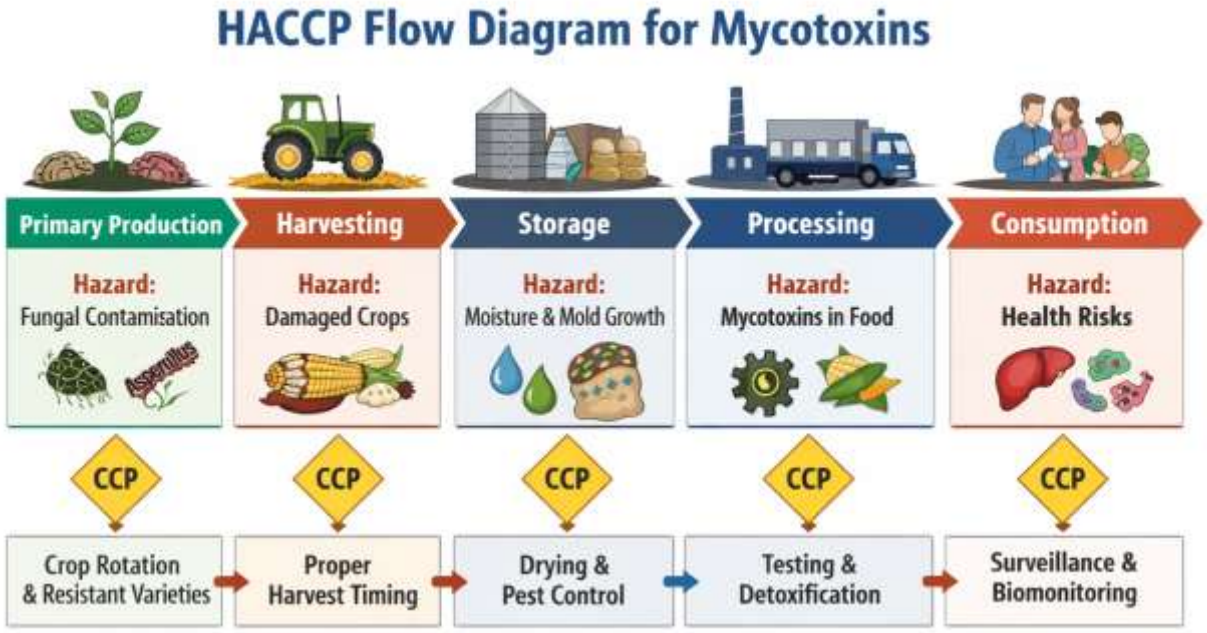

Figure 2. HACCP flow diagram for mycotoxin control in food systems

MICROBIOME BIOMARKERS IN FOOD SAFETY

In recent years, food safety science has begun to recognize that the **human gut microbiome** is not only a passive target of dietary contaminants but also an active participant in shaping health outcomes. This realization has led to the proposal of **microbiome biomarkers** as complementary tools within HACCP-based risk assessment frameworks. Unlike traditional monitoring, which focuses on detecting chemical residues such as aflatoxins or fumonisins in food products, microbiome biomarkers provide a **biological readout** of how these toxins affect host physiology even at low, chronic exposure levels.

One of the most widely studied indicators is **microbial diversity**. Healthy gut ecosystems are characterized by high richness and evenness, measured through indices such as Shannon and Simpson. Exposure to aflatoxin B_1 has been shown to reduce microbial diversity, weakening the resilience of the gut ecosystem and increasing susceptibility to opportunistic pathogens (Chałaśkiewicz et al., 2025). This decline in diversity can therefore serve as an early warning biomarker of toxin-induced dysbiosis.

Another critical set of biomarkers involves **short-chain fatty acids (SCFAs)**, including acetate, propionate, and butyrate. These metabolites are produced by gut microbes during fiber fermentation and play essential roles in maintaining intestinal barrier integrity and modulating immune responses. Studies demonstrate that deoxynivalenol (DON) and fumonisins significantly reduce SCFA production, leading to impaired gut function and chronic inflammation (Li et al., 2019; Yunus Zeebone et al., 2023). Monitoring SCFA levels in fecal or blood samples thus provides a functional biomarker of microbiome health under toxin stress.

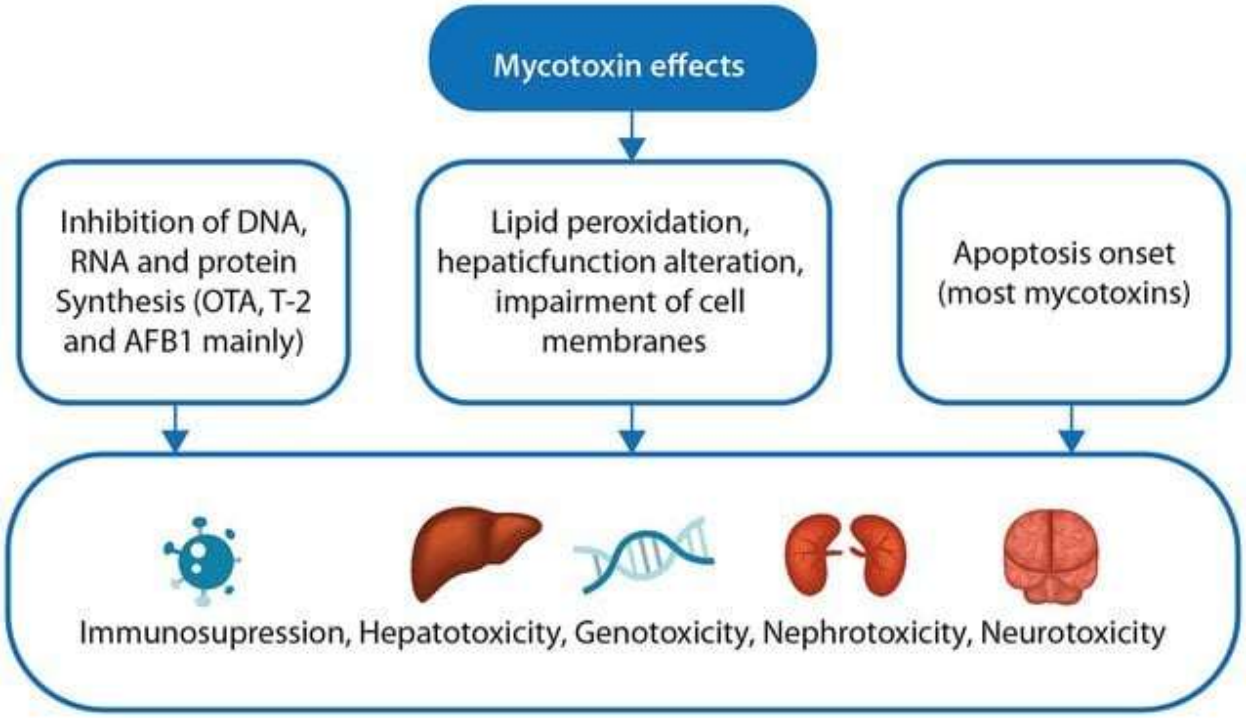

Figure 3. Major mechanisms of mycotoxin toxicity and their effects. Different mechanisms of mycotoxins can affect different organs and tissues in birds such as inhibition of protein synthesis, lipid peroxidation, hepatic function impairment, apoptosis modulation, among others. DNA, deoxyribonucleic acid; RNA, ribonucleic acid; OTA, ochratoxin; AFB1, aflatoxin B1 (from Gómez-Osorio et al., 2024).

The immune system offers another layer of biomarker evidence. Mycotoxins such as ochratoxin A (OTA) activate **NF-κB signaling**, resulting in elevated levels of pro-inflammatory cytokines like IL-6 and TNF-α. These cytokines are measurable in serum and reflect immune dysregulation linked to microbiome imbalance (Więckowska et al., 2025; Izco et al., 2021). Their inclusion in HACCP monitoring would allow food safety systems to capture not only chemical hazards but also their biological consequences.

Beyond immune markers, **metabolomic signatures** provide a systems-level perspective. Alterations in bile acids, sphingolipids, and estrogen-like metabolites have been associated with fumonisin and zearalenone exposure (Zhang et al., 2021). These shifts reveal how toxins disrupt host–microbe metabolic interactions, offering highly specific biomarkers for risk assessment.

Finally, **probiotic resilience markers** highlight the protective role of beneficial microbes. The survival and activity of taxa such as *Lactobacillus* and *Bifidobacterium* under toxin stress can serve as indicators of microbiome robustness. Probiotic supplementation has been shown to mitigate DON and OTA effects, suggesting that resilience markers could guide preventive interventions within HACCP frameworks (Mafe & Büsselberg, 2026).

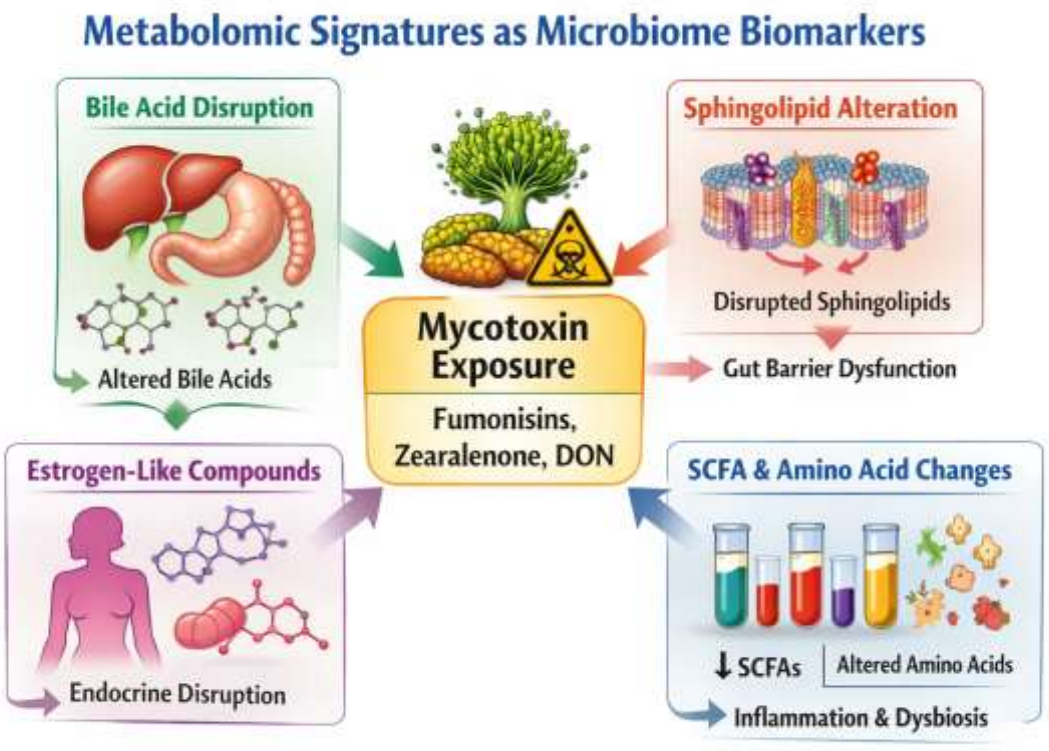

Figure 4. Metabolomic signatures as microbiome biomarkers in food safety. Mycotoxin exposure alters bile acid metabolism, sphingolipid integrity, estrogen-like compounds, and SCFA/amino acid profiles, providing measurable indicators of toxin impact on gut health.

CONCLUSION

The interplay between **foodborne mycotoxins** and the **gut microbiome** represents a critical frontier in modern food safety research. Mycotoxins such as aflatoxins, ochratoxin A, deoxynivalenol, fumonisins, and zearalenone exert not only direct toxicological effects but also profound influences on microbial composition, metabolism, and immune regulation. These interactions reshape the intestinal ecosystem, leading to dysbiosis, inflammation, and metabolic imbalance.

Integrating microbiome-based indicators into the HACCP framework transforms food safety from a purely chemical surveillance system into a **biological risk-assessment model**. By monitoring microbial diversity, SCFA production, cytokine activation, and metabolomic signatures, HACCP can detect early biological responses to contamination long before clinical symptoms appear. This approach aligns with the principles of preventive toxicology and precision nutrition, emphasizing resilience and health maintenance rather than reactive control.

ABSTRACT

Maintaining or achieving Good chemical status of surface waters is a fundamental objective of the European Union Water Framework Directive (WFD) (2000/60/EC). Urban rivers are particularly vulnerable to multiple anthropogenic pressures, including untreated wastewater discharges, stormwater runoff, and diffuse urban pollution, which collectively contribute to the deterioration of water quality. In Albania, comprehensive assessments of spatial variations in the chemical status of urban rivers remain limited, constraining the identification of pollution pressures and the prioritization of effective management measures required to support WFD implementation. This study investigates how urban influence is reflected in the chemical status of the Lana River, an urbanized tributary of the Ishëm River Basin. Monitoring was conducted from April 2024 to February 2026 at Lana 1, upstream, representing the key entry point of urban influence, and Lana 2, representing the site where urban pressures are accumulated. Lana 1 was monitored quarterly and Lana 2 monthly to capture pollution intensity and temporal variability. The investigated parameters included pH, electrical conductivity (EC), biochemical oxygen demand (BOD_5), chemical oxygen demand (COD), and the priority substances cadmium (Cd), nickel (Ni), and lead (Pb). Metals were determined by atomic absorption spectroscopy (AAS) and assessed against the corresponding Annual Average Environmental Quality Standards (AA-EQS). The results revealed a clear spatial deterioration in water quality along the urban reach of the river. Mean pH remained relatively stable, changing only from 7.73 at Lana 1 to 7.69 at Lana 2, whereas mean EC increased from 579 to 833 µS/cm. Median BOD_5 and COD values increased from 22.42 to 80.0 mg/L and from 61.80 to 160 mg/L, indicating increased dissolved loads and intensified organic pollution consistent with the cumulative influence of urban pressures. Mean concentrations also increased downstream, from 0.56 to 0.71 µg/L for Cd, 18.86 to 25.49 µg/L for Pb, and 12.38 to 14.26 µg/L for Ni. Cd, Pb, and Ni exhibited frequent exceedances of their corresponding AA-EQS, with the most pronounced downstream increases observed for Cd and Pb. Overall, the integration of physicochemical indicators with priority-substance compliance revealed downstream water-quality deterioration along the urban reach of the Lana River and shows that for the investigated priority substances, for a period of two years of consistent quality monitoring, the river water failed to achieve good chemical status. The upstream-downstream monitoring approach, as applied in this case study, provides an evidence basis for prioritizing wastewater pollution control and strengthening pollutant source-oriented monitoring in compliance with WFD requirements for river management.

Keywords: Chemical status assessments, Priority substances, Wastewater pressure

INTRODUCTION

Urban rivers are among the aquatic systems most strongly affected by anthropogenic pressures because they receive pollutant inputs from densely populated and highly modified catchments. Untreated or insufficiently treated wastewater, stormwater runoff, industrial discharges and

diffuse urban sources can alter physicochemical conditions and introduce organic matter, nutrients and potentially toxic substances into receiving waters. These pressures commonly generate longitudinal changes in water quality, often characterized by increasing pollutant concentrations downstream of urban areas (Glińska-Lewczuk et al., 2016; Szklarek et al., 2021; Wiesner-Sękala and Kończak, 2023). Electrical conductivity (EC), biochemical oxygen demand (BOD_5) and chemical oxygen demand (COD) provide complementary evidence of changes in dissolved and organic loads, although they do not independently determine chemical status under the Water Framework Directive.

Among urban contaminants, cadmium (Cd), lead (Pb) and nickel (Ni) are of particular environmental concern because of their persistence, toxicity and potential effects on aquatic ecosystems. Their occurrence in rivers may be associated with municipal and industrial effluents, urban runoff, atmospheric deposition, contaminated sediments and natural catchment characteristics. Recent investigations of a small urban river in Poland demonstrated spatial and seasonal variability in Cd, Pb, Ni, and other metals and highlighted the relevance of stormwater drainage and urban catchment characteristics for their distribution (Śniady et al., 2026). European-scale monitoring has also shown that temporal trends in Cd and Pb concentrations differ considerably among catchments in response to changes in pollutant emissions and catchment-specific characteristics (Eklöf et al., 2024). Investigations of surface waters affected by municipal and industrial discharges have also reported exceedances of Environmental Quality Standards for priority metals, confirming that these substances remain relevant constraints on the achievement of good chemical status (Wiesner-Sękala and Kończak, 2023).

Under the European Union Water Framework Directive (WFD), good chemical status requires compliance with Environmental Quality Standards (EQS) for priority substances (European Parliament and Council, 2000). Directive 2008/105/EC and its amendment, Directive 2013/39/EU, establish Annual Average Environmental Quality Standards (AA-EQS) for assessing long-term exposure to priority pollutants in surface waters (European Parliament and Council, 2008, 2013). Physicochemical parameters provide supporting information on general water-quality conditions, whereas WFD chemical-status classification is determined by compliance with the applicable EQS for priority substances.

However, evidence concerning upstream-downstream changes and the chemical status of urban rivers in Albania remains limited. Previous investigations have identified substantial anthropogenic pressures and water-quality deterioration within the Ishëm River Basin, but detailed assessments of individual urban tributaries remain scarce (Keci et al., 2021). This information gap restricts the identification of pollution gradients and the prioritization of wastewater-control and source-oriented monitoring measures. Upstream-downstream monitoring provides a practical means of directly comparing water-quality conditions along a defined river reach, particularly when observations from two stations are paired in time (Chen et al., 2021).

This study assessed how urban influence was reflected in water quality and chemical status along the Lana River, an urbanised tributary of the Ishëm River Basin. It aimed to identify downstream changes in pH, EC, BOD_5 and COD, quantify spatial and temporal variations in Cd, Pb and Ni, and assess whether their concentrations complied with the corresponding AA-EQS. The upstream-downstream monitoring design was applied to compare water-quality conditions at the upstream entry to the main urban reach with those observed after the accumulation of urban pressures.

MATERIALS AND METHODS

Study area and monitoring design

The Lana River is an urban tributary of the Ishëm River Basin that flows through Tirana, the largest and most densely populated city in Albania. The river receives cumulative pressures associated with urban development, including wastewater discharges, stormwater runoff, and diffuse inputs from the surrounding catchment. An upstream-downstream monitoring design was therefore applied to evaluate changes in water quality along its urban reach.

Two monitoring stations were selected (Figure 1). Lana 1 was located at the upstream entry to the main urban reach and represented conditions before the accumulation of the principal urban pressures. Lana 2 was located downstream of the urban area and was selected to represent the cumulative influence of wastewater and other urban pollutant inputs. The two stations were used to assess downstream changes in physicochemical conditions and priority-metal concentrations.

Monitoring was conducted from April 2024 to February 2026, covering 17 sampling campaigns. Lana 1 was sampled quarterly, providing eight observations during the study period, whereas Lana 2 was sampled monthly to capture greater temporal variability in downstream water quality. Eight sampling dates common to both stations were used for paired upstream-downstream statistical comparisons.

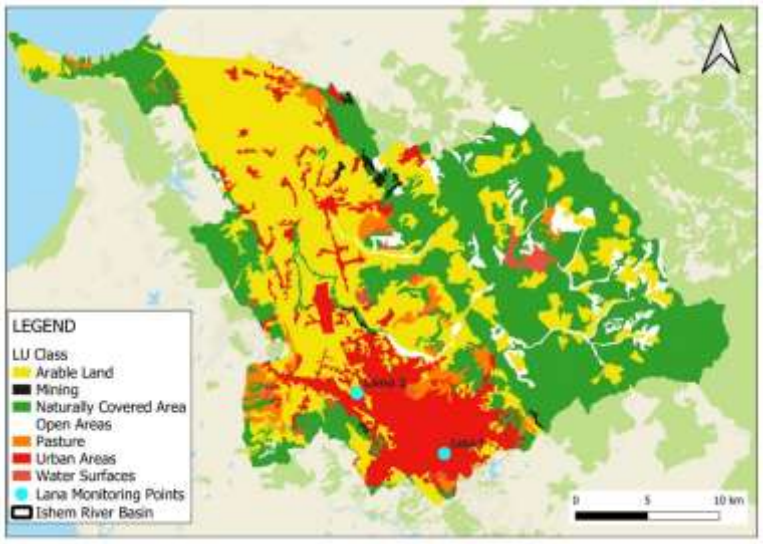

Figure 1. Location of the Lana River monitoring stations within the Ishëm River Basin.

Water sampling and analytical methods

Water samples were collected at both monitoring stations and transported to the laboratory of the Agricultural University of Tirana. Their preservation and subsequent analysis followed established laboratory procedures within the EN ISO/IEC 17025 accreditation framework. All investigated parameters were determined under laboratory conditions.

The physicochemical parameters included pH, electrical conductivity (EC), biochemical oxygen demand (BOD_5), and chemical oxygen demand (COD). Electrical conductivity was

expressed in µS/cm, while BOD_5 and COD were expressed in mg/L. These parameters were selected to characterize general water-quality conditions and changes in dissolved and organic loads along the investigated river reach.

The investigated priority metals were cadmium (Cd), nickel (Ni) and lead (Pb). Their total concentrations were determined by atomic absorption spectroscopy using a NOVAA 800D instrument and expressed in µg/L. Laboratory quality-control procedures were applied during sample preparation and instrumental analysis in accordance with the accredited analytical methods.

Environmental Quality Standard assessment

Measured Cd, Pb, and Ni concentrations were evaluated against the Annual Average Environmental Quality Standards established for inland surface waters under Directive 2008/105/EC, as amended by Directive 2013/39/EU. The applicable AA-EQS values were 1.2 µg/L for Pb and 4.0 µg/L for Ni. For Cd, the applicable AA-EQS ranges from 0.08 to 0.25 µg/L, depending on the water-hardness class.

Individual monitoring results were compared with the corresponding AA-EQS to identify the occurrence and frequency of concentrations above these reference values. Overall compliance was evaluated by comparing the mean concentration of each investigated metal with its corresponding AA-EQS. In accordance with the WFD "one-out, all-out" principle, non-compliance with the applicable AA-EQS for any of the investigated priority substances was interpreted as failure to achieve good chemical status with respect to the substances included in this study.

Statistical analysis

Descriptive statistics, including mean, median, minimum, maximum, and standard deviation, were calculated to characterize the distribution and temporal variability of each parameter at the two monitoring stations. Because the stations were sampled at different frequencies, all available observations were used for the station-specific descriptive analysis.

Upstream-downstream statistical comparisons were restricted to the eight dates on which both stations were sampled. The Wilcoxon signed-rank test was applied to the paired observations because of the small sample size and without assuming a normal distribution of the data. This non-parametric approach is suitable for evaluating paired water-quality observations collected using an upstream-downstream monitoring design and has been applied in comparable river assessments (Chen et al., 2021). Statistical significance was established at $p < 0.05$.

RESULTS AND DISCUSSION

Descriptive statistical analysis was used to characterize the distribution and temporal variability of the investigated physicochemical parameters and priority-metal concentrations. The results showed clear differences between the upstream and downstream monitoring stations.

Physicochemical water-quality characteristics

The physicochemical results showed clear differences between the upstream and downstream monitoring stations (Table 1). Mean pH remained relatively stable, changing only from 7.73 at

Lana 1 to 7.69 at Lana 2. In contrast, EC increased substantially along the investigated urban reach. Mean EC increased from 579.64 µS/cm at Lana 1 to 833.19 µS/cm at Lana 2, indicating a greater dissolved ionic load downstream.

More pronounced changes were observed for the organic-pollution indicators. Median BOD_5 increased from 22.42 mg/L at Lana 1 to 80.00 mg/L at Lana 2, while median COD increased from 61.80 to 160.00 mg/L. Mean BOD_5 and COD were also substantially higher at Lana 2. The increases observed in BOD_5, COD, and EC provide complementary evidence of higher dissolved loads and intensified organic pollution after the river passes through the main urban area.

The wide concentration ranges and high standard deviations of BOD_5 and COD indicate substantial temporal variability and the influence of individual high-concentration events. Although elevated values were already recorded at Lana 1, their higher downstream values indicate further deterioration associated with the accumulation of urban pressures. Similar patterns have been reported in urban rivers affected by municipal wastewater, stormwater runoff, and diffuse urban inputs (Glińska-Lewczuk et al., 2016; Szklarek et al., 2021).

Table 1. Descriptive statistics of physicochemical parameters at the Lana River monitoring stations

Parameter	Station	Range	Mean	Median	SD
pH	Lana 1	7.20–8.20	7.73	7.78	0.33
	Lana 2	7.34–7.92	7.69	7.74	0.15
EC (µS/cm)	Lana 1	535–686	579.64	572.5	48.53
	Lana 2	628–1307	833.19	812.4	141.29
BOD_5 (mg/L)	Lana 1	0.61–206	49.69	22.42	67.54
	Lana 2	2.74–310	106.7	80	82.81
COD (mg/L)	Lana 1	0.50–469	115.88	61.8	152.7
	Lana 2	5.34–706	230.38	160	191.31

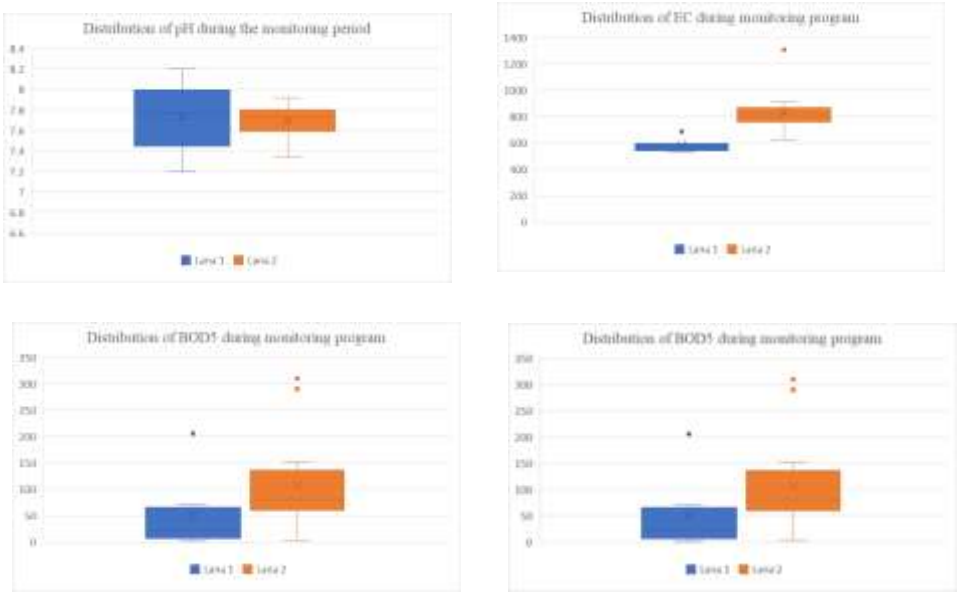

Figure 2. Distribution of pH, EC, BOD_5 and COD values during the monitoring period

Priority-metal concentrations and AA-EQS compliance

Cd, Pb, and Ni were detected at both stations and showed higher mean concentrations at Lana 2 (Table 2). Mean Cd increased from 0.56 to 0.71 µg/L, while the wider range and higher standard deviation at Lana 2 indicate greater temporal variability downstream. This pattern may reflect intermittent pollutant inputs or changes in hydrological conditions during individual monitoring campaigns.

Pb showed the largest absolute downstream increase, with its mean concentration rising from 18.86 µg/L at Lana 1 to 25.49 µg/L at Lana 2. The relatively high mean and median concentrations at both stations indicate persistent Pb contamination rather than an effect caused exclusively by isolated concentration peaks. Mean Ni increased from 12.38 to 14.26 µg/L and exhibited substantial temporal variability at both stations.

The downstream increases in Cd, Pb and Ni are consistent with cumulative pollutant inputs along the urban reach. Potential sources include municipal and industrial effluents, road and stormwater runoff, atmospheric deposition, and the mobilization of contaminated suspended material or sediments. Ni may also be influenced by natural catchment characteristics and therefore cannot be attributed exclusively to urban pollution. Comparable variability in Cd, Ni, Pb and other metals has been reported in the Bogdanka River, a small urban river affected by stormwater drainage and urban catchment pressures (Śniady et al., 2026).

Table 2. Descriptive statistics of Cd, Pb, and Ni concentrations at the Lana River monitoring stations (µg/L)

Parameter	Station	Range	Mean	Median	SD
Cd (µg/L)	Lana 1	0.354–0.837	0.56	0.55	0.16
	Lana 2	0.130–2.171	0.71	0.72	0.43
Pb (µg/L)	Lana 1	11.95–28.48	18.86	19.86	5.62
	Lana 2	10.66–37.90	25.5	24.9	7.36
Ni (µg/L)	Lana 1	0.05–23.60	12.38	14.36	8.91
	Lana 2	0.06–29.94	14.27	14.39	8.35

Comparison with the applicable AA-EQS revealed frequent concentrations above the corresponding reference values at the downstream station. At Lana 2, Pb exceeded the AA-EQS of 1.2 µg/L in all observations. Cd exceeded the upper hardness-dependent AA-EQS of 0.25 µg/L in 16 of 17 observations (94.1%), while Ni exceeded its AA-EQS of 4.0 µg/L in 15 of 17 observations (88.2%). Mean concentrations of all three metals were also above their corresponding AA-EQS values, indicating non-compliance during the monitoring period. Overall, Pb represented the most persistent concern, while Cd and Ni showed frequent concentrations above their corresponding reference values.

Although metal contamination was already evident at Lana 1, the higher mean concentrations at Lana 2 indicate additional deterioration along the urban reach. Studies on surface waters affected by municipal and industrial discharges have similarly reported elevated metal concentrations and failure to comply with the applicable Environmental Quality Standards (Wiesner-Sękala and Kończak, 2023).

Under the WFD "one-out, all-out" principle, the observed non-compliance indicates that the investigated river reach failed to achieve good chemical status with respect to Cd, Pb, and Ni. These findings identify priority-metal contamination as a persistent pressure and underline the importance of strengthening urban pollution-control measures along the Lana River.

Upstream-downstream statistical comparison

The upstream-downstream differences were evaluated using eight monitoring dates common to both stations. EC, BOD_5, COD, Cd, Pb, and Ni were consistently higher at Lana 2 during the paired monitoring campaigns. The Wilcoxon signed-rank test confirmed statistically significant downstream increases for all six parameters ($p=0.0078$; Table 3). In contrast, pH did not differ significantly between the stations ($p=0.25$).

These findings confirm that downstream deterioration was reflected in dissolved loads, organic-pollution indicators, and priority-metal concentrations, whereas pH remained comparatively stable. The findings are consistent with the value of paired upstream-downstream monitoring for identifying changes along a defined river reach while reducing the influence of temporal variation between observations (Chen et al., 2021).

The results should nevertheless be interpreted within the limitations of the monitoring design. The stations were sampled at different frequencies, and individual wastewater and stormwater outlets were not monitored. Consequently, the study identifies a clear upstream-downstream pollution gradient but does not quantify the contribution of specific emission sources.

Additional source-oriented and rainfall-event monitoring supported by river-discharge data would improve the identification of the processes controlling pollutant variability.

Table 3. Wilcoxon signed-rank test results for paired observations at Lana 1 and Lana 2.

Parameter	Number of pairs	Test statistic (W)	p -value	Statistical result
pH	8	8.5	0.25	Not significant
EC	8	0	0.0078	Significant increase
BOD_5	8	0	0.0078	Significant increase
COD	8	0	0.0078	Significant increase
Cd	8	0	0.0078	Significant increase
Pb	8	0	0.0078	Significant increase
Ni	8	0	0.0078	Significant increase

CONCLUSIONS

The integrated assessment of physicochemical parameters and priority-metal concentrations revealed clear downstream deterioration along the urban reach of the Lana River. While pH remained relatively stable, EC, BOD_5, and COD increased significantly at Lana 2, indicating higher dissolved loads and intensified organic pollution. Cd, Pb, and Ni concentrations also increased downstream, with the most pronounced changes observed for Pb and Cd.

Frequent AA-EQS exceedances, particularly at the downstream station, demonstrate persistent priority-metal contamination. Under the WFD “one-out, all-out” principle, the observed non-compliance indicates that the investigated river reach failed to achieve good chemical status with respect to the three priority substances included in this study.

The two-year upstream-downstream dataset provides new evidence of the cumulative influence of urban pressures on an under-investigated Albanian river. Although individual pollution sources were not investigated separately, the monitoring results clearly demonstrated downstream deterioration in water quality. These findings support the prioritization of wastewater-pollution control and more source-oriented monitoring, particularly at specific discharge points and during rainfall-related events, to strengthen WFD-based management of the Lana River.

Acknowledgments

This study was supported by the APPEAR project No. 320 AMoRE-Al, "Assessment of Pollutant Emissions to Support River Basin Management in Albania under the EU Water Framework Directive", funded by the Austrian Development Agency (ADA).

COMBINED TOXICITY OF MICROPLASTICS AND CHEMICAL POLLUTANTS IN AQUATIC ORGANISMS

Duygu Özhan TURHAN

Department of Biology, Faculty of Arts and Science, Inonu University, Malatya 44280, Turkey

duygu.turhan@inonu.edu.tr

ABSTRACT

Microplastics are widespread contaminants in aquatic ecosystems and have received increasing attention in recent years due to their potential environmental impacts. In aquatic environments, microplastics do not occur in isolation but coexist with heavy metals, pesticides, pharmaceuticals, and various organic contaminants. Their large surface area and physicochemical properties facilitate the adsorption of different chemicals onto their surfaces, raising concerns about their potential role in modifying the transport, bioavailability, and toxicity of coexisting pollutants. This review aims to evaluate the toxicological effects of combined exposure to microplastics and chemical pollutants in aquatic organisms. Available evidence indicates that interactions between microplastics and heavy metals, pesticides, pharmaceuticals, and other organic contaminants may vary depending on polymer type, particle size, surface characteristics, aging processes, and the physicochemical conditions of the surrounding environment. Combined exposures have been associated with oxidative stress, alterations in antioxidant defense systems, neurotoxic and genotoxic responses, as well as adverse effects on growth, development, reproduction, and behavior. However, the influence of microplastics on the toxicity of coexisting chemicals is not uniform. Depending on the properties of the contaminant, microplastic characteristics, exposure duration, and concentration, combined exposure may result in synergistic, antagonistic, or additive effects. Overall, interactions between microplastics and chemical pollutants represent an important factor that may modify the biological effects of contaminants in aquatic ecosystems. Considering combined effects alongside the toxicity of individual pollutants in environmental risk assessment may provide a more realistic understanding of exposure scenarios occurring in natural aquatic environments.

INTRODUCTION

1. Definition and Environmental Formation of Microplastics

Plastic products are widely used in applications ranging from daily life to industry due to advantageous properties such as light weight, durability, versatility, and low production cost. However, the rapid increase in plastic use and the long-term persistence of the resulting plastic waste in the environment have made plastic pollution an important global environmental problem. Plastic materials entering the environment can fragment over time into smaller plastic

particles under the influence of physical, chemical, and biological processes. Microplastics (MPs) are generally defined as synthetic polymer particles with an upper size limit of 5 mm, although there is no definitive consensus regarding the lower size limit. Furthermore, the continued fragmentation of microplastics under environmental conditions may lead to the formation of nanoscale plastic particles (Li et al., 2018).

2. Environmental Transport and Distribution of Microplastics

Certain characteristics of microplastics, such as their light weight, diverse morphologies, and extremely long lifespans, contribute substantially to their transport between environmental compartments. These properties also make microplastics one of the most widespread pollutants worldwide. Nearly all plastics and plastic-derived materials are produced on land and enter different environments through various pathways. In most scenarios, land acts as the initial receiving compartment for microplastics, which subsequently enter the environment through direct littering, improper waste management, accidental losses during disposal, and industrial spills (Horton & Dixon, 2018).

3. Physicochemical Properties of Microplastics and Their Role as Chemical Carriers

An important chemical characteristic common to microplastics is their capacity to adsorb and accumulate environmental pollutants, including heavy metals and organic contaminants. Moreover, microplastics contain various chemical additives, such as plasticizers and flame retardants, suggesting that they may act as both a “carrier” and a “source” of other chemicals. Microplastics are generally resistant to chemical reactions; however, exposure to UV radiation can induce photochemical degradation and lead to higher fragmentation rates. In addition, the hydrophobic properties of microplastics can determine their interactions within aquatic habitats and organisms. Consequently, microplastics exhibit distinctive environmental pollutant characteristics that influence their distribution, uptake, and toxicity in aquatic species (Hasan et al., 2024).

4. Biological Effects of Microplastics on Aquatic Organisms

The adverse effects of microplastics on fish reproduction have also become a growing concern. For example, microplastics may have serious consequences for the endocrine systems of fish. Plasticizers and various bisphenol analogues and phthalates, which are important endocrine disruptors, may leach from microplastics into the environment. These chemicals may mimic or induce hormonal imbalances, potentially leading to reduced fertility rates, alterations in offspring growth, or even changes in sex ratios (Hasan et al., 2024).

Huang et al. (2024) exposed juvenile *Carassius auratus* to different concentrations of polystyrene microplastics (PS-MPs; 200, 800, and 3200 µg/L) for 32 days and evaluated their effects on growth, tissue damage, and gene expression. PS-MPs were reported to accumulate particularly in the gastrointestinal tract and gills, and exposure resulted in varying degrees of histopathological damage in the intestine, gills, brain, and liver. In addition, the severity of tissue damage increased with increasing PS-MP concentration, and changes were detected in the expression of the genes examined in the liver, intestine, and gills (Huang et al., 2024).

5. Interactions of Microplastics with Organic Pollutants and Heavy Metals

According to previous studies, microplastics can act as carriers capable of adsorbing and enriching heavy metals as well as organic pollutants such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), pharmaceuticals, and personal care products (PPCPs) from water or soil. Microplastics are highly mobile. After adsorbing organic pollutants, they may transport these contaminants to new environments and cause adverse effects (Zhang et al., 2023).

Microplastics can adsorb and accumulate various organic pollutants, including persistent organic pollutants such as polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), as well as different heavy metals. The adsorption of heavy metals onto microplastic surfaces is influenced by several factors, including the physicochemical properties of the particles, surface modifications, aging, and environmental conditions (Ateia et al., 2022).

6. Interactions of Microplastics with Antimicrobials and Microorganisms

Various studies have investigated the adsorption and desorption behavior of antibiotics, particularly macrolides and quinolones, on different types of MPs, mainly polystyrene, polyethylene, and polylactic acid. To date, most studies have focused on the adsorption properties of pristine MPs, whereas desorption behavior has been investigated to a more limited extent. However, a large proportion of MPs present in the environment are aged. Once antibiotics are adsorbed by MPs, they can be transported along with the movement of MPs. Therefore, determining whether adsorbed antibiotics can desorb from microplastic surfaces is important for assessing the risks that these pollutants may pose in new environments (Zhang et al., 2023).

The co-occurrence of MPs and antimicrobials in the environment raises concerns regarding their combined ecological effects. Antimicrobials, which have substantially improved human and animal health and agricultural productivity, now frequently contaminate the environment through sources such as agricultural runoff and industrial discharges. For example, hydrophobic polymers such as polyethylene or polystyrene readily adsorb nonpolar antimicrobials, whereas charged or functionalized surfaces can bind ionizable antibiotics such as sulfonamides or tetracyclines. Their environmental presence not only poses ecological risks but also contributes to the proliferation of resistance genes (Tang, 2025).

7. Combined Toxicity of Pollutant Mixtures

Interactions between microplastics and coexisting pollutants may result in synergistic, antagonistic, or additive effects. When MPs carry other pollutants such as DBP, their large surface area may enable them to accumulate greater amounts of contaminants through an adsorptive carrier effect, thereby increasing toxicity. Conversely, MPs may reduce the bioavailability of pollutants through adsorption and enrichment, thereby decreasing their bioaccumulation. In addition, whether the interaction is synergistic or antagonistic may depend on MP concentration. Aggregation, disaggregation, and the corresponding exposure levels vary among different MP concentrations, which can result in inconsistent toxicity responses (Liang et al., 2025).

Turhan et al. (2026) evaluated the individual and combined effects of polyethylene microplastics (PE-MPs) and deltamethrin (DEL) during the early life stages of *Xenopus laevis*. PE-MPs alone did not cause marked mortality or malformations in embryos but induced changes in biochemical responses. Under combined exposure to DEL and PE-MPs, additive,

antagonistic, and synergistic interactions were reported depending on the biomarker and developmental stage. In embryos, additive effects were observed for GST and CaE, antagonistic effects for AChE, while the CAT response showed antagonistic or synergistic characteristics depending on the DEL concentration (Turhan et al., 2026).

The toxic effects of mixtures of MPs and hazardous chemicals may differ from the inherent toxicity of the individual substances depending on factors such as mixture concentration and ratio and interactions among the components. During the embryonic development of the amphibian *Rhinella arenarum*, non-toxic concentrations of copper and nonylphenol produced toxic effects depending on the mixture ratio (Aronzon et al., 2020). In *Daphnia magna* exposed to a mixture of silver ions and two different metal oxide nanoparticles, a synergistic effect greater than the toxic effects of the individual substances was confirmed (Park et al., 2019).

Liang et al. (2025) evaluated the combined toxicity of polypropylene microplastic fibers (MPFs) and dibutyl phthalate (DBP) in *Chlorella vulgaris*. Combined exposure was reported to cause more pronounced effects on photosynthesis, oxidative stress, and metabolism than individual exposures. In addition, the direction of combined toxicity changed depending on MPF concentration, with synergistic interactions at high MPF concentrations and antagonistic interactions at low MPF concentrations.

Wang et al. (2022) investigated the individual and combined toxic effects of polyvinyl chloride microplastics (PVC-MPs) and di(2-ethylhexyl) phthalate (DEHP) on *Danio rerio* embryos and larvae. The study used 0.1 ppm PVC-MPs and 71 µg/L DEHP, representing an environmentally relevant concentration. Individual exposure to PVC-MPs and DEHP inhibited embryo hatching, whereas this effect was reduced under combined exposure. Individual exposures also caused toxic effects on oxidative stress and cardiac development, while these effects were alleviated during combined exposure. The researchers reported an antagonistic interaction between PVC-MPs and DEHP and suggested that adsorption of DEHP by PVC-MPs, thereby reducing its bioavailability and bioaccumulation, may contribute to this antagonistic effect.

Zhang et al. (2022) showed that aged microplastics increased the accumulation of roxithromycin in *Carassius auratus* tissues in a microplastic size-dependent manner. Both aged microplastics and roxithromycin significantly increased superoxide dismutase (SOD) and catalase (CAT) activities in the liver and intestine while suppressing acetylcholinesterase (AChE) activity in the brain. In addition, smaller aged microplastics intensified roxithromycin-induced damage in the liver, gills, and brain, whereas larger microplastics caused more severe intestinal damage.

Similarly, in a 28-day study evaluating the combined effects of oxytetracycline and polystyrene microplastics on juvenile yellow catfish (*Pelteobagrus fulvidraco*), neither oxytetracycline nor 100 µg/L microplastics alone significantly affected growth, antioxidant and digestive enzyme activities, or intestinal microbial diversity. In contrast, combined exposure to oxytetracycline and 100 µg/L polystyrene microplastics increased SOD and CAT activities, caused mild intestinal damage, and increased the abundance of Proteobacteria (Tang, 2025).

CONCLUSION

The available evidence indicates that interactions between microplastics and chemical pollutants may significantly modify their toxic effects in aquatic organisms. Depending on microplastic characteristics, pollutant properties, concentration, and exposure conditions,

combined exposure may result in synergistic, additive, or antagonistic effects. These interactions can influence oxidative stress, neurotoxicity, growth, development, and other biological responses. Therefore, evaluating microplastics and chemical pollutants separately may not adequately reflect exposure scenarios in natural aquatic environments. Further studies using environmentally relevant concentrations and different microplastic–pollutant combinations are needed to better understand these complex interactions and to improve ecological risk assessment.

ABSTRACT

Human skin is a complex ecosystem that is home to millions of microorganisms known as the skin microbiome. These microorganisms play a vital role in regulating the immune system and protecting against pathogens. However, the media represents a significant discrepancy between scientific reality and how the skin is portrayed. Digital and traditional platforms consistently promote biologically unrealistic, sterile beauty standards that misrepresent normal microbial variation and trigger severe social stigmatization. Using a qualitative, multi-case study methodology, this paper examines the discrepancy between biological facts and media-driven aesthetic myths. We examined three distinct narratives: a ten-year autoethnographic experience of *Acne vulgaris*; the systemic aesthetic bullying of participant Stelina Kurila on Big Brother VIP Albania 5; and the digital activism of skin-positivity advocate Maia. Our findings reveal that media channels systematically moralize and misidentify biological dysbiosis as a failure of personal hygiene. They utilize a divisive normalization mechanism that marginalizes affected individuals. In contrast, skin-positivity movements successfully challenge these unscientific standards of perfection. This study concludes that aligning cultural narratives with genomic reality by shifting public communication from media-induced fear to evidence-based scientific awareness is a critical psychosocial and public health intervention, necessary for the mental well-being and social integration of individuals living with visible dermatological conditions.

Keywords: Skin microbiome, *Acne vulgaris,* Mass media, Aesthetic bullying, Stigmatization

INTRODUCTION

The human skin, the body's largest and most exposed organ, covers an average surface area of approximately 1.8 m² and accounts for about 15% of an adult's body weight (Belkaid and Segre, 2014; McKenna et al., 2024; McGrath, 2025). Contemporary microbiology no longer classifies the skin as merely a physical barrier. Instead, the skin is conceptualized as a dynamic, complex ecosystem and meta-organism comprising the macroscopic host and vast communities of symbiotic bacteria, fungi, and viruses (Belkaid and Segre, 2014; Byrd et al., 2018). Advances in molecular biology have shifted the scientific view of the skin from a passive covering to an active "immunological organ" (Grice and Segre, 2011; McGrath, 2025). The cutaneous microbiome is a "guardian of health" that regulates innate and adaptive immune responses, defends against invading pathogens, and supports critical physiological processes such as wound healing (Sanford and Gallo, 2013; Belkaid and Segre, 2014; Byrd et al., 2018). The

healthy skin microbiome is taxonomically dominated by four primary bacterial phyla: Actinobacteria, Firmicutes, Proteobacteria, and Bacteroidetes (Grice et al., 2009). Beneficial species, such as *Staphylococcus epidermidis*, act as primary defenders by producing antimicrobial peptides and other molecules that inhibit pathogen colonization and modulate host immunity (Sanford and Gallo, 2013; Belkaid and Segre, 2014; Nakatsuji et al., 2018). Conversely, *Cutibacterium acnes* is a lipophilic commensal, naturally dominates sebaceous units but is often unfairly associated with pathology. In reality, *C. acnes* usually contributes to inflammation only when the microbial balance is disrupted, a state of dysbiosis (Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013; Byrd et al., 2018).

However, the intersection of skin health and social perception is heavily influenced by the media, where physical appearance plays a significant role in shaping self-esteem and social integration, particularly among adolescents and young adults (Dalgard et al., 2015; Cohen et al., 2017; Yousaf et al., 2020). Dermatological conditions are more than just a cosmetic nuisance. They often cause significant psychological distress, including anxiety, depression, low self-esteem, and social isolation, similar to the distress experienced with chronic, disabling illnesses, such as arthritis or diabetes (Barankin and DeKoven, 2002; Dalgard et al., 2015; Germain et al., 2021; Christensen and Jafferany, 2023). Visible skin disorders often expose patients to stigmatization, teasing, and aesthetic cyberbullying (Luck-Sikorski et al., 2022; Chernyshov et al., 2024; Alfahaad et al., 2025). However, the media often oversimplifies this biological complexity. Digital platforms such as Instagram and TikTok promote heavily edited, filtered, and idealized images of perfect skin, establishing an unrealistic and sterile beauty standard by systematically removing natural pores and texture (Magin et al., 2011; Fardouly et al., 2015). This media construct consequently fosters a culture of fear regarding the skin's ecosystem, leading to an unnecessary obsession with aggressive disinfection and the overuse of cosmetic products (Basch et al., 2015). Recent studies on the skin-brain axis have revealed a possible link between certain bacterial species, including *Cutibacterium*, and positive psychological well-being, suggesting that a balanced microbiome is associated with reduced stress and improved mood (Luck-Sikorski et al., 2022; Tyson-Carr et al., 2025).

This article examines the significant contrast between the biological reality of the skin microbiome and media-driven aesthetic myths, analyzing how personal and digital media affect public perception. Through content analysis, we identify trends in dermatological representations, distinguishing media channels that foster pathophobia and misinformation (Vrenozi and Lugaj, 2025) from those that promote evidence-based health communication (Kite et al., 2023). This communication gap reflects broader public health dynamics in Albania, where inadequate scientific literacy fosters societal anxiety toward other medically significant taxa, allowing sensationalized fear to overshadow clinical reality (Vrenozi, 2025). Transitioning public discourse toward genomic realism, biological naturalism, and body diversity requires replacing media-induced panic with scientific awareness.

MATERIAL AND METHOD

This research uses a qualitative and analytical approach that combines media content analysis with case studies to examine the relationship between dermatological health and media narratives. The primary methodology involves systematically monitoring prominent Albanian media outlets, including Top Channel, TikTok, Instagram, JOQ Albania, Anabel Magazine, and Iliria News. These outlets were selected based on their significant public reach and influence on social discourse. Three case studies are analyzed to illustrate the tangible, real-world impact of these media narratives on psychological well-being and social integration.

1. A personal autoethnographic story: It involves the decade-long experience of one patient with *Acne vulgaris* from 2014 to 2024 (D. Myrtaj, personal communication). The story explores the tension between individual clinical reality and the "sterile" beauty standards promoted by the media.

2. Media representation of a reality show participant: This case study examined the public discourse surrounding Stelina Kurila during her time on the reality TV show Big Brother VIP Albania 5 in 2026. The case study examined public and digital responses, demonstrating how traditional and social media platforms can trigger intense public scrutiny and aesthetic judgment based on skin appearance. This case was chosen because of its high visibility, which sparked a national debate on skin appearance and health. Several media outlets documented the scandal, their editorial positions on natural beauty, and celebrities' reactions. A few examples are included here, such as Anabel Magazine (January 6, 2026) and Iliria News (January 5, 2026), as well as digital platforms such as Top Channel, JOQ Albania, TikTok, and Instagram.

3. Digital activism of a skin-positivity creator: This case study, taken from Maia's story in Changing Faces (March 7, 2023), examines the effect of digital activism in promoting skin positivity and challenging societal norms regarding beauty standards. It highlights narratives that challenge unrealistic beauty ideals and celebrate natural beauty.

By combining these three case studies, the manuscript aims to bridge the gap between contemporary biological science and the media's perception of the skin microbiome.

RESULTS AND DISCUSSIONS

Case Study 1. Autoethnographic Narrative of Acne vulgaris: Transitioning from media-induced fear to scientific awareness in acne management

The autoethnographic narrative highlights a profound discrepancy between the skin's biological reality and its hyper-sanitized media depiction (Magin et al., 2011), presenting a ten-year story of living with *Acne vulgaris* (D. Myrtaj, personal communication) (Figure 1). Although often dismissed as a minor cosmetic nuisance, the resulting psychological morbidity, including severe anxiety and depression, is clinically comparable in quality-of-life impairment to chronic, disabling conditions such as type 2 diabetes, heart disease, and severe arthritis (Barankin and DeKoven, 2002; Dalgard et al., 2015; Christensen and Jafferany, 2023). Throughout this decade, the patient was constantly exposed to unrealistic, sterile aesthetic standards on digital platforms like Instagram and TikTok, which filter out natural pores and texture to establish an unscientific baseline of perfection (Magin et al., 2011; Fardouly et al., 2015; tirananews, January 6, 2026).

Figure 1. The face images of the autoethnographic clinical progress: **A**- Started treatment 01.02.2024; **B**- After treatment 07.07.2026 ©danielamyrtaj

Because the human face represents the primary locus of the "social and relational self," the inability to meet this standard precipitated profound self-stigma and social anxiety (Barankin and DeKoven, 2002; Magin et al., 2011; Germain et al., 2021), compounded by "aesthetic bullying" from a public that moralizes cutaneous pathology as a failure of hygiene (Luck-Sikorski et al., 2022; Chernyshov et al., 2024; Alfahaad et al., 2025). To achieve this ideal, the patient initially adopted aggressive, media-promoted "bacterial destruction" protocols (Basch et al., 2015). However, rather than providing relief, these sterilization methods damaged the outermost layer of the epidermis, stripping the vital extracellular lipid matrix and elevating the skin's naturally acidic pH, which ultimately exacerbated her acne severity (Grice and Segre, 2011; Sanford and Gallo, 2013; McGrath, 2025).

The decisive turning point in both the patient's clinical management and psychological well-being was reached through scientific literacy, reframing the skin not as an unhygienic surface to sterilize, but as a living meta-organism (Belkaid and Segre, 2014; Byrd et al., 2018). According to the hologenome theory, the human host and resident cutaneous microbiota coexist in a symbiotic relationship in which commensals actively calibrate local immunological networks (Belkaid and Segre, 2014; Byrd et al., 2018; Nakatsuji and Gallo, 2019). The patient successfully destigmatized her condition and transformed a decade of fear into a managed reality by transitioning her internal narrative from a moralizing language of "uncleanliness" and "failure" to biological homeostasis (Magin et al., 2011; Alfahaad et al., 2025). This shift repositioned *Cutibacterium acnes* as a vital lipophilic commensal that contributes to inflammation only in a state of dysbiosis (Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013; Byrd et al., 2018), and highlighted *Staphylococcus epidermidis* as an essential "guardian of health" that secretes antimicrobial peptides to defend the host and regulate immune responses (Sanford and Gallo, 2013; Belkaid and Segre, 2014; Nakatsuji and Gallo, 2019). This alignment of cultural perception with genomic reality significantly reduced her psychological burden, enabling her to abandon makeup as a "mask" and accept natural skin variation (Tyson-Carr et al., 2025).

The culture of mass media's perfection filters out the reality of the human meta-organism (Magin et al., 2011; Fardouly et al., 2015), leaving the public shocked by natural appearance and detached from its genomic reality (Belkaid and Segre, 2014; Byrd et al., 2018). The true scandal is not the presence of *C. acnes*, but our collective failure to recognize its evolutionary role as a protective symbiont (Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013). Replacing media myths with scientific education is critical for cutaneous immune homeostasis and psychological well-being (Tyson-Carr et al., 2025). In the Albanian context, addressing these public misconceptions requires a systematic shift in communication strategies. Regional surveys reveal significant public knowledge gaps and low preparedness regarding local biological exposures (Vrenozi, 2025). This educational shift is essential to destigmatize visible skin conditions and promote a broader biological naturalism (Changing Faces, March 7, 2023; Alfahaad et al., 2025).

Case Study 2. Public Perception of Cutaneous Health on Reality Television: "Aesthetic Bullying" and Hygiene Stigmatization

The 2026 season of Big Brother VIP Albania 5 provided a contemporary example of "aesthetic bullying" under constant 24/7 public surveillance (Anabel Magazine, January 6, 2026; Top Channel, 2026). One notable incident occurred when participant Stelina Kurila appeared on camera without makeup (Joker Albania, 2026; Iliria News, January 5, 2026) (Figure 2/A).

Screenshots of her bare face quickly circulated across TikTok, Instagram, and Albanian portals like JOQ, Anabel, and Iliria News, triggering highly judgmental, offensive, and mocking commentary (Figure 2/A, B) (Anabel Magazine, January 6, 2026; Iliria News, January 5, 2026; Joker Albania, 2026; JOQ Albania, 2026; tirananews, January 6, 2026). This negative reaction to her visible *Acne vulgaris* highlights how the high visibility of facial lesions, particularly in central regions like the forehead and nose, attracts disproportionate public scrutiny, leading to severe external stigmatization, anxiety, and negative social impressions (Barankin and DeKoven, 2002; Germain et al., 2021; McKenna et al., 2024; Alfahaad et al., 2025).

Figure 2. The face images: S. Kurrila: **A**- BBV appearance 05.01.2026 ©ilirianews.al; **B**- treatment 02.03.2026 ©ledaaesthetic; Maia's: **C** and **D**- Social media vs Reality 07.03.2023 ©changingfaces.org.uk

Anabel Magazine (January 6, 2026) pointed out the profound irony that, although the show is categorized as reality, viewers were shocked by it. This backlash demonstrates the public's shifting perception of healthy skin, replacing it with the computer-enhanced standard of perfection seen on Instagram. This shift has driven a divisive normalization mechanism that categorizes natural biological variations as other or abnormal (Magin et al., 2011; Alfahaad et al., 2025; Anabel Magazine, January 6, 2026). Social media commentators have relied on erroneous stereotypes that moralize skin conditions, characterizing Kurila's acne as a scandal, filth, or a personal failure of hygiene and self-care (Alfahaad et al., 2025; Anabel Magazine, January 6, 2026; Iliria News, January 5, 2026; JOQ Albania, 2026). These judgments ignore that acne is a complex biological process involving microbial dysbiosis, hormonal shifts, and inflammatory dynamics, rather than a lack of cleanliness. Individuals with acne often invest significant resources in high-quality skincare products and dermatological treatments (Magin et al., 2011; Alfahaad et al., 2025; Anabel Magazine, January 6, 2026; Ruci, March 2, 2026). The media's focus on Stelina's aesthetic deviation aligns with mass media's consistent promotion of the ideal of perfect skin, such as hyper-idealized celebrity accounts on Instagram (Cohen et al., 2017) (Table 1).

Table 1. Comparative analysis of media representation, public perception, and biological reality of skin microorganisms

Feature	Presentation in Media	Public Perception	Scientific Evidence	Gaps in Albanian Media	References
Cutaneous Microbiota	Portrayed as pathogens requiring complete eradication for hygiene	Pathophobia; associating natural bacterial presence with filth and infection	Symbiotic ecosystem essential for physical barrier homeostasis and immunity	Binary framing; omission of ecological complexity and host-microbe mutualism	(Grice and Segre, 2011; Belkaid and Segre, 2014; Byrd et al., 2018; JOQ Albania, 2026; Top Channel, 2026)
Acne vulgaris	Portrayed as a superficial blemish or failure of personal hygiene	Triggers profound self-stigma, shame, and social isolation	Driven by genetic barriers, hormonal shifts, and follicular dysbiosis	Prioritizes commercial product marketing over microbiological explanations	Barankin and DeKoven, 2002; Fitz-Gibbon et al., 2013; Sanford and Gallo, 2013; Alfahaad et al., 2025; Anabel Magazine, January 6, 2026; JOQ Albania, 2026; Top Channel, 2026
Aesthetic Standards (Perfect skin)	Digitally filtered, edited, and hyper-idealized images across media platforms	Induces unrealistic beauty expectations, self-stigma, and appearance dissatisfaction	The healthy epidermis has natural texture, variations, and vital symbiotic microbes	Prioritizes artificial cosmetic perfection over biological and genomic realism	Barankin and DeKoven, 2002; Magin et al., 2011; Fardouly et al., 2015; Byrd et al., 2018; Alfahaad et al., 2025; Joker Albania, January 5, 2026; tirananews, January 6, 2026
Cutaneous Interventions	Cosmetic products marketed as universal, over-the-counter therapeutic cures	Uncritical product trust, delaying medical care in favor of self-medication	Requires professional clinical diagnosis and personalized, evidence-based therapy	Prioritizes commercial product marketing over clinical and scientific facts	Basch et al., 2015; Yousaf et al., 2020; Alfahaad et al., 2025; Ruci, March 2, 2026; Top Channel, 2026
Social Media "Skin Care"	Unregulated, simplified cosmetic advice promoted by non-medical influencers	High susceptibility to health misinformation and hazardous, unverified skin practices	Most digital advice lacks clinical grounding, empirical evidence, or safety verification	Omission of scientific screening, peer verification, or medical oversight	Basch et al., 2015; Yousaf et al., 2020; Iliria News, January 5, 2026; Joker Albania, January 5, 2026; tirananews, January 6, 2026

Feature	Presentation in Media	Public Perception	Scientific Evidence	Gaps in Albanian Media	References
Educational Media Role	Infrequent, isolated health campaigns or authentic patient narratives	Fosters public empathy, health literacy, and destigmatization	Strategic health communication reduces public stigma and builds support	Omission of systematic health campaigns; untapped educational capacity	Luck-Sikorski et al., 2022; Kite et al., 2023; Alfahaad et al., 2025; Vrenozi and Lugaj, 2025; Top Channel, 2026

In response, Albanian public figures, including O. Marashi, A. Musta, F. Haxhialiu, and L. Brati, criticized this hypocrisy. They noted that a public that demands naturalness is repulsed by its biological reality (Anabel Magazine, January 6, 2026). The resulting cyberbullying created a toxic social environment, inflicting severe psychological distress, including anxiety, social withdrawal, and diminished self-esteem, that can be as disabling as the clinical condition itself (Dalgard et al., 2015; Germain et al., 2021; Luck-Sikorski et al., 2022; Chernyshov et al., 2024; Alfahaad et al., 2025). To remediate this social "inflammation", mass media platforms must transition from spaces of aesthetic judgment and public panic to public health advocates that promote scientific awareness, eliminate misinformation, and destigmatize natural cutaneous variations (Basch et al., 2015; Kite et al., 2023; Vrenozi and Lugaj, 2025).

Case Study 3. Digital Activism and the Skin-Positivity Movement: The psychosocial transition from stigmatization to communication through acne positivity

Maia's longitudinal experience as a digital activist and content creator illustrates that having a visible facial dermatological condition during adolescence increases the risk of severe social discrimination and bullying (Barankin and DeKoven, 2002; Luck-Sikorski et al., 2022; Changing Faces, March 7, 2023). Her personal history of schoolyard harassment and derogatory online comments led to severe social anxiety and low self-worth. This aligns with clinical evidence showing that the psychological distress caused by visible facial lesions is comparable in severity to that caused by disabling systemic diseases (Barankin and DeKoven, 2002; Changing Faces, March 7, 2023; Alfahaad et al., 2025). Initially, she used heavy makeup as a defensive mask to conceal her skin and manage daily social interactions, a widely documented coping mechanism used to mitigate stigma (Barankin and DeKoven, 2002; Changing Faces, March 7, 2023).

Eventually, Maia repurposed her digital platforms to join the acne positivity movement, posting unedited, natural images of her face (Figure 2/C, D) to challenge the beauty industry's standard practice of using digital enhancement to project a flawless, "sterile" aesthetic (Magin et al., 2011; Cohen et al., 2017; Changing Faces, March 7, 2023). This shift highlights how a new model of health communication can treat digital networks as therapeutic environments and sources of social support (Basch et al., 2015; Yousaf et al., 2020; Kite et al., 2023). By reframing natural skin variation as a component of a living meta-organism rather than an aesthetic failure, such movements provide the empathy and inclusivity needed to remediate social dysbiosis and improve patients' quality of life (Belkaid and Segre, 2014; Byrd et al., 2018; Changing Faces, March 7, 2023; Alfahaad et al., 2025). If our social perception, or "social skin", is integral to health, then mass media must complement public health by eliminating misinformation and promoting a new aesthetic of genomic realism that aligns cultural narratives with biological reality (Barankin and DeKoven, 2002; Magin et al., 2011; Fitz-Gibbon et al., 2013; Basch et al., 2015; Kite et al., 2023; Tyson-Carr et al., 2025; Vrenozi and Lugaj, 2025).

Aligning cultural narratives with genomic realities is essential to alleviating the psychological burden imposed by unscientific standards of cutaneous perfection (Magin et al., 2011; Fardouly et al., 2015; Tyson-Carr et al., 2025).

CONCLUSIONS

This study's analysis reveals a profound, systemic discrepancy between contemporary scientific understanding of the skin and its depiction in the media. While biological research conceptualises the skin as a dynamic 'meta-organism' and an active immunological organ, media platforms consistently project a reductive, 'sterile' version of the human body. This computer-enhanced ideal, which systematically removes pores, texture, and natural variations, forces individuals to view healthy biological processes as 'aesthetic failures' or evidence of personal neglect. The case studies of Stelina Kurila and Maia, along with the personal autoethnographic story, highlight the severe psychosocial consequences of this media construct. Visible dermatological conditions are not merely cosmetic concerns; they can lead to psychological distress, including anxiety, depression, and social withdrawal, at levels comparable to those experienced with chronic disabling illnesses.

Transitioning public discourse from 'aesthetic bullying' towards inclusivity requires a fundamental shift in literacy. Ultimately, replacing media-driven myths with scientific facts about the skin microbiome is essential for destigmatisation. Understanding the role of biological homeostasis and the protective function of commensal microorganisms can help society move away from a 'culture of fear' and towards a more inclusive understanding of body diversity. Promoting scientific awareness is not just a clinical necessity but also a vital step in safeguarding the mental health and social integration of individuals living with visible skin conditions.

FARM-LEVEL ECONOMIC AND ENVIRONMENTAL BENEFITS OF FURCELLARIA LUMBRICALIS DIGESTATE BIOSTIMULANT: A 1,000 HA SCENARIO IN THE BALTIC SEA REGION

INESE SKAPSTE

Latvia University of Life Sciences and Technologies (LBTU), Faculty of Economics and Social Development, Institute of Economics and Finance, Jelgava, Latvia

ABSTRACT

Marine macroalgae of the Baltic Sea, particularly *Furcellaria lumbricalis*, represents a strategically underutilized biological resource with demonstrated potential for bioeconomy product development. This study quantitatively assesses the farm-level agronomic, economic, and environmental benefits of a *Furcellaria lumbricalis* digestate-based biostimulant within a 1,000 ha crop production scenario in the extended Baltic Sea region. The research methodology integrates three evidence layers: (1) laboratory vegetation experiments with *Furcellaria lumbricalis* digestate as biostimulant (basil and radish cultures); (2) international meta-analyses on biostimulant efficacy (Rouphael et al., 2022; Calvo et al., 2014); and (3) a synthetic 1,000 ha farm-level scenario model parameterized on meta-analytic mean values and author's calculations. Results demonstrate a triple-win effect: a 17.9% yield increase (895 t additional production per 1,000 ha), a 15% reduction in mineral fertilizer costs (savings of EUR 45,000 per 1,000 ha), and a 25% reduction in nitrogen losses (from 30 to 22.5 kg N/ha), generating a combined annual economic benefit of EUR 224,000 per 1,000 ha farm. Laboratory experiments confirm that a 3% digestate concentration significantly enhanced plant biomass by 52.7–85.4% compared to control, while 75% of the standard nitrogen dose with biostimulant addition maintained yield at the level of full mineral fertilization. Scenario extrapolation to the Baltic Sea region Cluster III countries (Latvia, Lithuania, Estonia, Poland) indicates indicative cumulative benefits of EUR 440–880 million per year at 5–10% arable land coverage. These results position *Furcellaria lumbricalis* biostimulant as a viable tool for sustainable intensification aligned with EU Farm to Fork and Baltic Sea eutrophication reduction objectives.

Key words: *Furcellaria lumbricalis*; marine biostimulant; Baltic Sea bioeconomy; nitrogen losses; sustainable intensification;

INTRODUCTION

The transition toward a climate-neutral, resource-efficient and biodiversity-friendly development model has fundamentally transformed the way in which biological resources are conceptualized and governed within the European Union and the Baltic Sea region. The EU Bioeconomy Strategy and the European Green Deal emphasize the need to replace fossil-based products with sustainable bio-based solutions, while simultaneously delivering positive climate, eutrophication-reduction and regional development outcomes (European Commission, 2019, 2020, 2022). In this context, marine bioeconomy and particularly the use of marine macroalgae has emerged as a strategic direction combining climate policy, food security, bioresource sustainability and coastal development goals.

The Baltic Sea represents an ecologically sensitive and economically intensively used maritime space, where shipping, fisheries, aquaculture, offshore wind energy and coastal tourism converge, generating strong anthropogenic pressure and a need for integrated resource

management (HELCOM, 2021; Baltic Sea Action Plan, 2021). Baltic Sea macroalgae, including *Furcellaria lumbricalis*, are increasingly regarded not only as a traditional hydrocolloid source, but as a feedstock for high-value-added bioproducts: biostimulants, biogas, compost and other cascade biorefinery outputs. At the same time, the marine algae biostimulant market remains in an early development stage, with commercialization constrained by agronomic uncertainties, techno-economic cost structures and regulatory ambiguity (Calvo et al., 2014; Lähteenmäki-Uutela et al., 2021).

Furcellaria lumbricalis is a red macroalgae endemic to the Baltic Sea with an estimated standing biomass of 236,000–276,000 t/year and significant carbon sequestration and nutrient extraction potential (Weinberger et al., 2020; Friedlingstein et al., 2023; Kotta et al., 2020). Despite its biological relevance, this resource remains largely unexploited in the bioeconomy. Previous research by the author has demonstrated the effectiveness of *Furcellaria lumbricalis* digestate as a biostimulant in controlled laboratory conditions (Skapste et al., 2025a; Skapste et al., 2025b; Vircava et al., 2026), and its favorable environmental profile in Life Cycle Assessment studies (Skapste et al., 2025e). However, experimental results at plot level have not yet been systematically translated into scalable farm-level economic and environmental scenarios at a regional level — a gap that constitutes the central problem of this study.

The study's research hypothesis holds that a *Furcellaria lumbricalis* based biostimulant in the Baltic Sea region can deliver a measurable combination of economic and climate benefits — increasing gross agricultural profit, reducing mineral fertilizer costs and nitrogen losses provided that sufficient biomass availability, an effective biorefinery process and an appropriate regulatory and market framework are in place. The objective of the paper is to quantitatively assess the farm-level impact of a *Furcellaria lumbricalis* digestate biostimulant on yield, fertilizer costs and nitrogen losses within a 1,000 ha scenario, and to contextualize these results within the extended Baltic Sea region's bioeconomy development patterns. The study contributes to sustainable agriculture and marine bioeconomy literature by bridging the gap between laboratory-scale experiments and regional-level policy and investment relevance.

MATERIALS AND METHODS

The methodology is structured as a three-layer evidence integration approach, combining *Furcellaria lumbricalis* specific laboratory experiments, international meta-analyses on biostimulant efficacy, and a synthetic 1,000 ha farm-level scenario model. This design structure corresponds to the innovation systems approach, where local knowledge is combined with global scientific findings (meta-analyses) to model technology impact at farm and regional level (Lundvall, 2010; Birner, 2018). From an endogenous growth theory perspective, biostimulant technology development is viewed as an investment in total factor productivity enhancement, where innovation allows higher output to be obtained from an unchanged resource pool (Romer, 1990; Aghion & Howitt, 1998).

Furcellaria lumbricalis biomass was collected from the Baltic Sea and subjected to anaerobic fermentation to produce a digestate biostimulant extract. Vegetation experiments were conducted under controlled laboratory conditions with basil (*Ocimum basilicum*) and radish (*Raphanus sativus*) crops. In basil experiments, digestate concentrations of 3% and 6% were applied under varying mineral nitrogen doses (100%, 75%, and 50% of standard rate). For radish experiments, the effect of biostimulant application was tested across mineral and organic substrates with reduced mineral nitrogen dosing (75% of standard rate). Plant growth parameters above-ground biomass, root length, and chlorophyll content were measured at standard phenological stages. Results were analyzed using ANOVA and paired t-tests at a significance level of $p < 0.05$ (Skapste et al., 2025a; Vircava et al., 2026).

To derive statistically robust and generalizable effect sizes for the 1,000 ha scenario model, the study draws on three key international meta-analyses. Rouphael et al. (2022), synthesizing over 1,000 field trials from 180 studies, reports that biostimulant application increases yield by an average of 17.9% (95% CI: 16.7–19.0%) across diverse crops and regions. Calvo et al. (2014), published in Plant and Soil, demonstrates that biostimulant integration allows a reduction in fertilization costs of approximately 15% and mineral nitrogen dose reduction of 20–30% without significant yield loss, consistent with the sustainable intensification paradigm (Godfray et al., 2010; Pretty & Bharucha, 2014). Colla & Rouphael (2015) additionally document nitrogen loss reduction potential in comparable ranges when biostimulants are integrated into fertilization schemes.

Based on these sources, the 1,000 ha scenario is defined as a synthetic, empirically grounded reference scenario, where biostimulant yield, cost, and nitrogen loss effects correspond to internationally recognized mean values — not maximum values. This conservative approach ensures scientific robustness and regional transferability. Detailed calculation steps, equations and assumptions are documented in Table 1 (this study). The key input parameters for the model are summarized in Table 1.

Table 1. Key input parameters of the 1,000 ha farm scenario model.

Parameter	Baseline	With Biostimulant	Source
Base yield Y_0 (t/ha)	5.00 t/ha	5.895 t/ha (+17.9%)	Rouphael et al. (2022)
Yield increase Δy (%)	—	17.9% (95% CI: 16.7–19.0%)	Rouphael et al. (2022)
Fertilisation costs C (EUR/ha)	300 EUR/ha	255 EUR/ha (–15%)	Calvo et al. (2014)
Nitrogen losses N (kg N/ha)	30 kg N/ha	22.5 kg N/ha (–25%)	Colla & Rouphael (2015)
Crop price P (EUR/t)	200 EUR/t	200 EUR/t	Author's assumption
Scenario area	—	1,000 ha	Author's assumption

RESULTS

Laboratory Experiment Results

Laboratory vegetation experiments confirmed the effectiveness of *Furcellaria lumbricalis* digestate as a biostimulant in Baltic Sea region agro-ecological conditions. In basil experiments, a 3% digestate concentration significantly enhanced above-ground biomass by 52.7–85.4% compared to the control ($p < 0.05$), while simultaneously allowing a reduction in mineral fertilizer dose, maintaining or improving yield parameters (Skapste et al., 2025a). The highest growth enhancement (85.4%) was observed in the treatment combining 6% biostimulant concentration with 75% of the standard mineral nitrogen dose, demonstrating the fertilizer-saving potential of the product.

In radish experiments across both mineral and organic substrates, the application of *Furcellaria lumbricalis* digestate biostimulant at 75% of the standard nitrogen dose maintained yield at a level comparable to or exceeding full mineral fertilization controls. This directly confirms the biostimulant's capacity to partially substitute mineral fertilizers without yield penalty, consistent with the fertilizer-saving approach described by Colla & Rouphael (2015) and Bulgari et al. (2019) (Vircava et al., 2026). These experimental results provide the empirical foundation for the *Furcellaria lumbricalis* digestate achieving meta-analytically identified mean biostimulant efficacy values in the 1,000 ha scenario.

1,000 ha Farm Scenario: Yield, Costs and Nitrogen Losses

The 1,000 ha farm scenario, parameterized on meta-analytic mean values (Rouphael et al., 2022; Calvo et al., 2014), demonstrates a triple-win effect of *Furcellaria lumbricalis* biostimulant integration across three dimensions simultaneously: economic (yield and income increase), resource efficiency (mineral fertilizer reduction), and environmental (nitrogen loss reduction). The scenario results are summarized in Table 2

Table 2. Summary of *Furcellaria lumbricalis* biostimulant impact in the 1,000 ha farm scenario.

Indicator	**Baseline Scenario**	**Biostimulant Scenario**
Yield Y (t/ha)	5.000 t/ha	5.895 t/ha (+17.9%; ΔY = +0.895 t/ha)
Total production Q (t/1,000 ha)	5,000 t	5,895 t (+895 t)
Additional income I (EUR/1,000 ha)	—	EUR 179,000 (895 t × EUR 200/t)
Fertilisation costs C (EUR/1,000 ha)	EUR 300,000	EUR 255,000 (–EUR 45,000; –15%)
Total annual economic benefit (EUR)	—	EUR 224,000
N losses (kg N/ha)	30 kg N/ha	22.5 kg N/ha (–25%; –7.5 kg N/ha)
N loss reduction (kg N/1,000 ha)	30,000 kg N	22,500 kg N (–7,500 kg N; effective ≈ –1,500 kg N to water)

Source: Author's calculations based on Rouphael et al. (2022), Calvo et al. (2014), Colla & Rouphael (2015).

The yield block of the scenario assumes a base yield without biostimulant of Y_0 = 5 t/ha. Applying the meta-analytic mean yield increase of 17.9% (Rouphael et al., 2022) gives a biostimulant scenario yield of $Y_1 = 5 \times 1.179 = 5.895$ t/ha. Additional production $\Delta Q = (Y_1 – Y_0) \times 1{,}000$ ha = $0.895 \times 1{,}000 = 895$ t, and at a crop price of EUR 200/t, additional income I = 895×200 = EUR 179,000 (author's calculations, Table 1).

In the fertilization cost block, based on Calvo et al. (2014), biostimulant application is assumed to allow a 15% reduction in fertilization costs. Standard fertilization costs in the baseline scenario are C_0 = EUR 300/ha, and in the biostimulant scenario $C_1 = 300 \times 0.85$ = EUR 255/ha, yielding total cost savings of $\Delta C = (C_0 – C_1) \times 1{,}000$ = EUR 45,000 across the 1,000 ha area. This saving reflects mineral fertilizer dose reduction, partially replacing inorganic nitrogen with

Furcellaria lumbricalis digestate biostimulant, consistent with the literature on nitrogen dose reductions of 20–30% while maintaining yield (Calvo et al., 2014; Colla & Rouphael, 2015).
In the nitrogen loss block, based on Colla & Rouphael (2015) and sources on nutrient leaching, baseline nitrogen loss N_0 = 30 kg N/ha is reduced to N_1 = 22.5 kg N/ha in the biostimulant scenario (–25%). Applying a runoff coefficient k_N = 0.2, representing the fraction of nitrogen entering aquatic ecosystems, the effective nitrogen loss reduction in the 1,000 ha area is $\Delta N = (N_0 – N_1) \times k\_N \times 1{,}000 = 7.5 \times 0.2 \times 1{,}000 = 1{,}500$ kg N per year. This result is particularly significant in the Baltic Sea context, where agricultural nitrogen loss accounts for approximately 30–40% of total marine nitrogen loading and is one of the main causes of eutrophication (HELCOM, 2021; Baltic Sea Action Plan, 2021).

Regional Extrapolation: Baltic Sea Region Cluster III Countries

Ward's hierarchical cluster analysis of the extended Baltic Sea region (10 countries: Denmark, Estonia, Finland, Germany, Iceland, Latvia, Lithuania, Norway, Poland, Sweden) based on GDP per capita, R&D expenditure, aquaculture production volume and export share of GDP (Eurostat, 2023; OECD, 2023; World Bank, 2023) identified four distinct bioeconomy development clusters. Cluster III — Latvia (1.57 million ha arable land), Lithuania (2.75 million ha), Estonia (1.1 million ha) and Poland (14.4 million ha) — is characterized by lower GDP and R&D intensity (0.72–1.44% of GDP) but high export openness (62–78% of GDP), indicating strong motivation for competitive and cost-efficient agricultural production (author's calculations; Eurostat, 2023; Skapste et al., 2025c).
Extrapolating the 1,000 ha scenario economic benefit of EUR 224,000 per year to Cluster III countries at 5–10% arable land coverage yields indicative cumulative benefits of EUR 440–880 million per year across the cluster (author's indicative estimate based on Eurostat, 2023). This finding is significant from a regional bioeconomy policy perspective and is consistent with Skapste et al. (2025c, 2025d) conclusions on the commercialization potential of Baltic Sea algae biostimulants. In these countries, with lower income and R&D intensity but high export competitive pressure, the biostimulant technology can be positioned as an instrument that simultaneously improves competitiveness and reduces environmental burden, aligned with the Circular Bioeconomy Strategy and the European Green Deal (European Commission, 2019; EUSBSR, 2025).

DISCUSSION

The triple-win effect demonstrated in the 1,000 ha scenario simultaneous yield increase, fertilization cost reduction and nitrogen loss mitigation — aligns precisely with the sustainable intensification paradigm defined by Godfray et al. (2010) and Pretty & Bharucha (2014) as increasing agricultural production without a proportional increase in resource inputs, while reducing environmental burden. This combination distinguishes biostimulants from traditional agronomic intervention tools, which typically improve one indicator at the expense of others. The results are particularly relevant in the context of the EU Farm to Fork Strategy target to reduce synthetic fertilizer use by at least 20% by 2030 and cut nutrient losses by 50% (European Commission, 2020).
From an endogenous growth theory perspective (Romer, 1990; Aghion & Howitt, 1998), the biostimulant effect represents a technological innovation as a total factor productivity (A) enhancer in the production function Y = Af (K, L). Biostimulant integration increases the A value, enabling higher yield Y at unchanged production factors K (land, equipment) and L (labour) a classic manifestation of innovation-driven growth. In quantitative terms, the biostimulant delivers EUR 224,000 total annual economic benefit to a 1,000 ha farm: EUR

179,000 from yield increase and EUR 45,000 from cost savings, alongside a 1,500 kg N reduction in nitrogen loss to water bodies (author's calculations, Table 2).

The fertilizer-saving approach modelled here does not represent full substitution of mineral fertilizers rather, a gradual reduction of mineral nitrogen dose from 100% to 80–85% of standard rate, supplemented with Furcellaria lumbricalis digestate biostimulant. This approach is consistent with the literature on biostimulants as 'fertilizer-saving' instruments (Calvo et al., 2014; Bulgari et al., 2019; Colla & Rouphael, 2015) and is methodologically important for two reasons: first, it reflects realistic agronomic practice that is acceptable to farmers and regulators; second, from an innovation diffusion perspective, incremental changes to fertilization schemes align with the innovation systems literature's requirement for compatibility with existing practices (Lundvall, 2010; Mazzucato, 2018).

The broader regional significance of the 1,000 ha scenario is captured through the cluster-level analysis. Cluster III countries (Latvia, Lithuania, Estonia, Poland) present a particularly compelling case for *Furcellaria lumbricalis* biostimulant adoption: their combination of lower R&D investment capacity and high export openness creates a structural need for cost-competitive, export-oriented innovations. For Latvia specifically, with its low R&D intensity (0.72% of GDP) and limited aquaculture sector (1,200 t/year), the demonstrated income gain and cost savings from biostimulant use represent a significant incentive, particularly given the country's strategic interest in developing a knowledge-based marine bioeconomy niche (Skapste et al., 2025c; Skapste & Grīnberga-Zālīte, 2025).

Several limitations of the present study should be acknowledged. First, the 1,000 ha scenario is a synthetic modelling exercise parameterized on meta-analytic averages from diverse crop species and geographic regions field trials under Baltic Sea agro-ecological conditions with a wider range of crops are needed to validate the results in situ. Second, the scenario uses a generalized crop price (EUR 200/t) and does not account for crop-specific variation, which could substantially affect the economic results for high-value crops (e.g., vegetables) or commodity cereals. Third, biostimulant production cost at pilot scale currently results in a negative NPV at an 8% discount rate (ROI of 6.2%/year, payback 16 years), indicating that scale-up and 'mission-oriented' public support instruments — such as Horizon Europe or Norwegian Financial Instruments — remain critical prerequisites for commercialization (Mazzucato, 2018; Skapste et al., 2025d).

CONCLUSION

This study demonstrates that *Furcellaria lumbricalis* digestate biostimulant can deliver a quantitatively significant triple-win effect at the farm level. Four key conclusions are drawn:

1. *Furcellaria lumbricalis* digestate biostimulant enhances crop yield by 17.9% (895 t additional production per 1,000 ha) and reduces mineral fertilisation costs by 15% (EUR 45,000 savings), generating a combined annual economic benefit of EUR 224,000 per 1,000 ha farm.
2. Nitrogen losses are reduced by 25% (from 30 to 22.5 kg N/ha), contributing to an effective reduction of approximately 1,500 kg N per year to Baltic Sea water bodies from a 1,000 ha area, directly supporting HELCOM Baltic Sea Action Plan eutrophication reduction targets.
3. The technology is particularly relevant for Cluster III Baltic Sea region countries (Latvia, Lithuania, Estonia, Poland), where the combination of low R&D investment and high export openness makes cost-competitive, sustainability-enhancing innovations strategically important; indicative cumulative benefits at 5–10% arable land coverage are EUR 440–880 million per year across the cluster.
4. Commercialization requires progress along three parallel tracks: field validation at Baltic Sea agro-ecological conditions, scale-up of Furcellaria biostimulant production to industrial scale (30,000 L reactor, scale factor 0.6), and integration into mission-oriented support instruments

(Horizon Europe, Norwegian Financial Instruments, EUSBSR Bioeconomy Action) to bridge the 'death valley' between pilot projects and commercial deployment.

ABSTRACT

This study evaluates modular plant activation strategies containing sodium nitrophenolate (SNP), sodium salicylate (SA-Na), the sodium salt of naphthaleneacetic acid (Na-NAA), forchlorfenuron (CPPU) and gibberellic acid (GA3), with respect to their potential contributions to rooting, stress management and fruit development. These compounds are associated, respectively, with photosynthetic activation and rapid physiological response, stress signalling and systemic resistance, adventitious rooting, cytokinin-like cell division and fruit enlargement, and gibberellin-related developmental regulation, including germination, shoot elongation and flowering. Integrating such compounds into fertilizer-related liquid formulations may create considerable product value; however, this compound group also represents the most regulation-sensitive family addressed in this line of work, given concerns related to dosage, phenological timing, residue levels and phytotoxicity. Rather than proposing a single combined formulation, this study outlines three separate modules: a stress management module, a rooting module, and a fruit enlargement and quality module. For peer-reviewed publication, each module should be supported by an independent dose-response trial and a corresponding safety evaluation.

Keywords: *plant growth regulator; sodium nitrophenolate; sodium salicylate; NAA; CPPU; GA3*

1. INTRODUCTİON

Plant growth regulators and physiological activators are compounds that, even at low doses, can direct plant developmental processes. Unlike conventional fertilizers, they do not act primarily by supplying nutrients; instead, they can influence photosynthesis, hormonal balance, root formation, flowering, fruit set and stress defence. For this reason, the boundary between a fertilizer formulation and a growth-regulator approach must be considered carefully from both a scientific and a regulatory standpoint.

In-house evaluation notes have assessed SNP, SA-Na, Na-NAA, CPPU and GA3 for distinct intended uses. SNP has been associated with rapid onset of action and support for photosynthesis; SA-Na with systemic resistance and stress management; Na-NAA with root development; CPPU with fruit enlargement; and GA3 with objectives such as germination, cluster elongation and fruit length.

The scientific value of this study lies not in combining these compounds into a single recipe, but in organising them into target-specific modules. In this way, distinct physiological objectives — rooting, stress management and fruit development — can be measured independently, and the resulting formulation claims become more scientifically defensible.

2. MATERİALS AND METHODS

2.1 Materials

The modular compound groups considered in this study are defined as follows: an SNP-based photosynthesis and growth activation group; an SA-Na-based stress and systemic resistance support group; an Na-NAA-based rooting group; a CPPU-based fruit-enlargement group; and a GA3-based germination, elongation and flowering group.

2.2 METHODS

For the stress management module, a control, a micronutrient/amino-acid base product, an SA-Na-containing product, and an SA-Na + SNP combination are compared.

For the rooting module, seedling or cutting trials are used to measure rooting percentage, root number, root length and root dry weight.

For the fruit-enlargement module, CPPU and GA3 applications are tested at separate doses according to phenological stage; fruit size, firmness, dry matter, soluble solids content, acidity and possible residue risks are monitored.

Rather than disclosing a complete recipe for each module, the active-ingredient class, application window, dose range and safety criteria should be reported in the publication text. Compliance with residue limits and relevant regulations must be explicitly addressed for ethical and regulatory reasons.

2.3 Statistical Analysis

Regression analysis is used for dose-response relationships, analysis of variance (ANOVA) for treatment group comparisons, and appropriate ordinal-data methods for phytotoxicity scores. Multivariate principal component analysis (PCA) may additionally be applied to fruit quality datasets.

3. RESULTS

The target physiological effects of SNP, SA-Na, Na-NAA, CPPU and GA3 have been clearly defined; however, field efficacy or dose-response results are not yet available in the current documentation. These compounds carry high potential for product development, but confirmatory field data remain to be generated.

The literature indicates that NAA/auxin applications can support adventitious root formation; that CPPU applications can be effective on fruit size and quality parameters; that GA3 applications have been studied in citrus and other fruit species in relation to flowering and fruit set; and that salicylic acid and nitrophenolate compounds may contribute to mechanisms associated with stress tolerance and photosynthesis.

Table 1. Proposed publication framework for the modular activation groups.

Module	Compound Class	Main Target	Measurable Output
Stress management	SA-Na + SNP	Antioxidant defence and photosynthesis	SPAD, Fv/Fm, electrolyte leakage
Rooting	Na-NAA + amino acid/phosphorus support	Adventitious root formation	Rooting %, root number, root length
Fruit enlargement	CPPU + Ca/B support	Cell division and fruit growth	Fruit weight, diameter, firmness
Flowering/elongation	GA3 module	Shoot, flower and fruit development	Cluster length, fruit set, quality

4. DİSCUSSİON

This compound group carries high publication value, yet it is simultaneously the most sensitive topic addressed in this line of work. Compounds such as CPPU, GA3 and NAA-type substances may fall under plant-growth-regulator or pesticide/registration regimes in many countries. For

this reason, in the academic text, the product group should be defined not as a "fertilizer" claim, but as a "controlled physiological activation module," and regulatory compliance should be noted separately.

Compounds such as SNP and SA-Na can be positioned more compatibly with stress-management products. The Na-NAA rooting module and the CPPU/GA3 fruit-development module should be tested separately from one another. Combining a large number of growth-regulating compounds within a single formulation complicates scientific interpretation; a modular approach improves both publication quality and product safety.

5. CONCLUSION

If properly modularised, the SNP, SA-Na, Na-NAA, CPPU and GA3 compound group has the potential to yield at least one comprehensive full-length article, together with two additional application-focused technical articles, produced within an in-house research and development framework. At the current stage, the literature basis is strong; however, definitive efficacy claims should not be made until field and dose-response data are completed

Declarations

Ethics Approval: This study is a laboratory-scale fertilizer and plant activation formulation development study and does not involve human or animal experimentation. If a field trial is conducted on living plant material, internal institutional permits and relevant local regulatory records should be obtained prior to submission.

POTENTIAL OF A MICRONUTRIENT, AMINO ACID AND PLANT SIGNALING COMPOUND-BASED LIQUID FERTILIZER FOR FROST AND POST-STRESS NUTRITION

Gökhan Yaşar[1]*, Burcu Köse[1], Ahmet Akbulut[1], Hatice Deniz Öncel[1]

ABSTRACT

This manuscript evaluates a liquid fertilizer concept containing micronutrients, amino acids and plant signaling compounds, developed for frost and post-stress nutrition. The formulation combines Zn, Mn, Fe, Cu, B and Mo, an amino acid fraction, ammonium nitrogen, and low-dose nitrophenolate/salicylate-based activators. Laboratory-scale preparation indicated that the formulation could be positioned for orchard recovery after frost, protection of chlorophyll-related functions, reduction of micronutrient-limitation risk, and mitigation of stress-induced physiological decline. The literature supports the relevance of foliar nutritional strategies for frost tolerance, the stress-regulatory role of salicylic acid, and the photosynthesis-promoting effects of nitrophenolate-based biostimulants. The manuscript frames the product as a field-trial-ready formulation concept rather than a final efficacy claim.

Keywords: *liquid fertilizer; frost stress; micronutrients; amino acids; sodium nitrophenolate; sodium salicylate*

1. INTRODUCTİON

With climate change, late spring frosts, temperature fluctuations, drought and salinity have become major risks limiting yield and quality, particularly in fruit growing and protected cultivation. Low-temperature injury in plants is associated with disruption of membrane integrity, increased reactive oxygen species, suppression of photosynthesis, and disturbance of mineral nutrient balance. For this reason, pre- and post-frost nutrition strategies should be regarded not merely as a fertilization practice but as a physiological recovery management approach.

Micronutrients play a critical role in enzyme activity, chlorophyll synthesis, oxidative stress management and reproductive development. Zinc is involved in protein synthesis and auxin metabolism; manganese in photosystem II and enzymatic reactions; iron in chlorophyll and electron transport; copper in redox enzymes; boron in cell wall integrity, flowering and fruit

set; and molybdenum in nitrogen metabolism. Balanced micronutrient application can support the plant's recovery capacity, particularly during stress periods.

Protein hydrolysates and free amino acids form an important group within plant biostimulants. Beyond serving as a nitrogen source, these compounds are considered signaling molecules or precursor metabolites that may influence osmotic regulation, nutrient uptake, root development and stress response. The addition of low-dose salicylate- and nitrophenolate-based activators to this structure aims to give the product a physiologically supportive function in addition to its nutritional role.

2. MATERİALS AND METHODS

2.1 Materials

The liquid fertilizer family addressed in this study combines micronutrients, an amino acid fraction and plant signaling compounds. For reasons of commercial confidentiality, exact recipe proportions are not disclosed in the manuscript; components are described in functional groups. The laboratory equipment used included a mixing vessel, a precision balance and measuring vessels.

2.2 Methods

In laboratory preparation, micronutrient salts were added to the mixing vessel in a controlled sequence; after homogenization was achieved, the amino acid fraction and the low-dose physiological activator components were added. The visual homogeneity, sedimentation tendency, application suitability and product positioning of the mixture were evaluated.

For field validation, a three-stage protocol is proposed: a pre-frost protective application, a post-frost recovery application, and a control/comparison application. The main parameters to be measured are leaf chlorophyll index, electrolyte leakage, visual frost-damage score, shoot vitality, fruit set, leaf micronutrient analysis, and final yield/quality parameters.

2.3 Statistical Analysis

Once field data are available, analysis of variance should be performed using a factorial design incorporating treatment, dose and time factors; means should be compared using Tukey's or Duncan's test; non-parametric tests should be used where necessary for ordinal measures such as the frost-damage score.

3. RESULTS

In the laboratory mixture, micronutrients, amino acids and activator components were successfully combined within a single product family. Internal evaluation notes indicated a favourable assessment of the product's potential use in frost-related and post-stress nutrition in orchards. This finding is not sufficient on its own to support a commercial efficacy claim, but it provides a technical feasibility signal for initiating field trials.

The literature review supports three scientific rationales for this approach. First, foliar mineral applications may have measurable effects on low-temperature tolerance. Second, salicylate signaling is associated with antioxidant defence and stress-related gene expression. Third, nitrophenolate-based compounds have been linked to photosynthetic pigments and carbon assimilation. Designing these three mechanisms together with micronutrient- and amino-acid-based nutrition distinguishes this liquid fertilizer approach from conventional micronutrient fertilizers.

Table 1. Scientific rationale and proposed validation parameters for the formulation.

Component Group	Expected Function	Proposed Validation Parameter
Micronutrients	Enzyme activity, chlorophyll and nutrient balance	Leaf Zn, Mn, Fe, Cu, B, Mo analysis
Amino acid fraction	Post-stress nitrogen and metabolic support	Free amino acids, total N, growth measurements
Salicylate-based component	Antioxidant defence and stress signaling	MDA, SOD/CAT/POD, electrolyte leakage
Nitrophenolate-based component	Photosynthesis and growth activation	SPAD, Fv/Fm, biomass, shoot development

4. DİSCUSSİON

The formulation addressed in this study can be interpreted as a hybrid approach combining mineral nutrition with a biostimulant strategy. Because membrane stability, osmotic adjustment and antioxidant defence come to the forefront under frost stress, products based solely on macronutrient application may not be sufficient under all conditions. For this reason, using micronutrients together with amino acid and signaling components may provide broader physiological targets for post-stress recovery.

At the same time, salicylate, nitrophenolate and similar activator compounds are sensitive components with respect to dose, phenological timing and product regulation. In the

manuscript, these components should be addressed under the assumption of controlled, low-dose and regulation-compliant use. For peer-reviewed publication, the product's effect must be demonstrated through comparison of a control, micronutrients alone, amino acids alone, and the combined formulation.

5. CONCLUSİON

This study shows that a liquid fertilizer combining micronutrients, amino acids and plant signaling compounds can be developed into a publishable manuscript addressing frost and post-stress nutrition. The current laboratory data are sufficient to support the skeleton of a full research article, but field data are required for any efficacy claim. The strongest publication framework would be a frost/stress trial comparing the combined formulation against micronutrient-only and control treatments.

Declarations

Ethics Approval: This study is a laboratory-scale fertilizer and plant nutrition formulation development study and does not involve human or animal experimentation. If a field trial is conducted on living plant material, internal institutional permits and relevant local regulatory records should be obtained prior to submission.

İGSAŞ Research and Development Unit, Türkiye

ABSTRACT

Urea ammonium nitrate (UAN) solutions are widely used liquid nitrogen fertilizers because they combine urea, ammonium and nitrate nitrogen in a homogeneous fluid phase and permit accurate metering in soil and fertigation systems. Their technical performance, however, is governed by two independent but interacting issues: nitrogen transformation after application and phase stability during storage. The urea fraction may hydrolyze rapidly and contribute to ammonia volatilization under unfavorable surface-application conditions, whereas concentrated UAN solutions can crystallize when temperature falls below their salt-out temperature. This study develops an integrated formulation and validation framework for UAN-28, UAN-32, UAN-33 and UAN-34 products designed to delay urea-N transformation while maintaining acceptable low-temperature stability. The formulation strategy is based on nitrogen mass balance, controlled urea/ammonium nitrate ratio, optional ammonium thiosulfate (ATS) addition, and evaluation of stabilizing or urease-inhibiting auxiliaries. A 5% ATS-supported design matrix calculated with 35% N ammonium nitrate, 46.6% N urea and 12% N ATS produced theoretical total N values of 32.25, 33.28 and 34.62% for the UAN-32, UAN-33 and UAN-34 candidates, respectively. The calculations show that increasing N grade is achieved mainly by reducing water from 15.77 to 9.87%, which simultaneously narrows the solution-stability window. Literature data indicate that conventional UAN-28 has a substantially lower salt-out temperature than UAN-32, while urease inhibitors such as NBPT and, under some conditions, ATS can reduce or delay ammonia loss from surface-applied UAN. Accordingly, the paper proposes a validation sequence based on ISO 23381 salt-out testing, total-N analysis, density, pH, visual clarity, cold-storage and re-dissolution observations, soil incubation, ammonia-volatilization measurements, and plant uptake/yield tests. The framework distinguishes a stabilized or enhanced-efficiency UAN from a true controlled-release fertilizer: a slow-release claim should only be made after release or transformation kinetics are experimentally demonstrated. The resulting approach provides a technically defensible basis for pilot-scale optimization of concentrated UAN products combining nitrogen-use-efficiency objectives with improved storage reliability.

Keywords: UAN, liquid nitrogen fertilizer, enhanced-efficiency fertilizer, slow release, urease inhibition, ammonium thiosulfate, nitrogen use efficiency, salt-out temperature, crystallization

INTRODUCTION

Nitrogen (N) is one of the principal nutrients controlling crop yield and quality, yet fertilizer-N efficiency is determined not only by the amount applied but also by the chemical form of N, the rate of transformation in soil, placement, moisture, temperature, pH, residue cover and the timing of crop demand. Urea-containing fertilizers are particularly sensitive to post-application hydrolysis. Urease catalyzes the conversion of urea to ammoniacal forms; during this process, transient alkalization around the fertilizer zone can increase the proportion of gaseous ammonia

and therefore the risk of N loss. This mechanism is especially relevant when urea-containing fertilizers are left on the soil surface without sufficient rainfall, irrigation or mechanical incorporation (Cantarella et al., 2018; Liu et al., 2019).

Urea ammonium nitrate solution is a useful platform for N management because it contains three agronomically relevant N pools in a single liquid product. Approximately one-half of the N in conventional UAN is commonly associated with urea, while the ammonium nitrate fraction supplies both ammonium and nitrate. The nitrate fraction is immediately mobile and plant available, ammonium can be retained temporarily by soil exchange sites before nitrification, and urea undergoes hydrolysis before entering the ammonium pool. This multi-form distribution provides flexibility for injection, banding and precise liquid application, but also means that the product cannot be evaluated as a single chemical species.

The agronomic objective of a delayed-N UAN formulation is to extend the period during which a portion of the urea-derived N remains available for crop uptake and to reduce avoidable losses. In liquid UAN, this goal is more appropriately approached through stabilization of N transformation than through a physical coating, because the product is already an aqueous solution. Urease inhibitors can temporarily slow urea hydrolysis; nitrification inhibitors can affect the subsequent conversion of ammonium to nitrate. Their performance depends strongly on soil and environmental conditions. Cantarella et al. (2018) reported that NBPT is one of the most established urease inhibitors and can substantially reduce ammonia losses from urea-based fertilizers. UAN-specific studies have also shown reductions in volatilization with NBPT-containing treatments, although the magnitude of the benefit is affected by application method and environment (Grant et al., 1996; Goos, 2013; Liu et al., 2019).

Ammonium thiosulfate (ATS) is technologically interesting because it adds both N and sulfur and can also interact with urea hydrolysis. Sullivan and Havlin (1992) demonstrated that thiosulfate oxidation products, particularly tetrathionate, can contribute to urease inhibition in soil. In a greenhouse study with surface-applied UAN, Goos (2013) reported lower ammonia losses for several additive systems, including ATS, compared with unamended UAN. However, other field observations have shown a weaker ATS response than NBPT under particular soil and climatic conditions (Grant et al., 1996). ATS should therefore be treated as a multifunctional formulation component whose agronomic effect requires direct validation rather than as a universal urease-inhibitor substitute.

A second and independent challenge is the physical stability of concentrated UAN during storage and transportation. UAN is a concentrated salt solution, and its dissolved-solids capacity decreases as temperature falls. Below the salt-out temperature, urea and/or nitrate-containing crystals may precipitate, producing sediment, concentration gradients, blocked transfer systems and non-uniform product application. Commercial guidance places the salt-out temperature of UAN-28 near -18 °C and conventional UAN-32 near approximately -2 to 0 °C, depending on composition and product specification. These data illustrate the fundamental trade-off: higher nutrient concentration reduces the quantity of water transported per unit N, but also decreases the margin against low-temperature crystallization.

For liquid fertilizers, ISO 23381:2020 specifically addresses determination of the salt-out (crystallization) temperature. This is more directly relevant to UAN product development than general freezing-point methods developed for other aqueous systems. An R&D program for high-analysis UAN should therefore separate the concepts of freezing, supercooling, first-crystal appearance, salt-out temperature and re-dissolution behavior. A formulation that remains visually clear for a short period at a target temperature may still crystallize during prolonged storage, while a product that forms crystals may remain commercially manageable if the crystals readily re-dissolve under defined recirculation and warming conditions.

The objective of the present study is to convert these agronomic and physicochemical requirements into a unified development framework for UAN-28, UAN-32, UAN-33 and UAN-

34. The specific aims are: (i) to establish a mass-balance approach for target N grades; (ii) to evaluate an ATS-supported composition matrix for UAN-32/33/34; (iii) to identify the consequences of decreasing water content on low-temperature stability; (iv) to define the analytical and agronomic tests required before a slow-release or enhanced-efficiency claim is made; and (v) to provide a pilot-scale decision structure suitable for subsequent laboratory and field validation.

MATERIAL AND METHOD

Materials and formulation components

The formulation framework uses urea, ammonium nitrate (AN) and process water as the principal UAN components. For calculation purposes, the theoretical N content of urea was taken as 46.6% and that of the AN raw material as 35.0%. ATS, when used, was treated as a 12% N sulfur-containing liquid component. Ammonium sulfate (AS) may be considered in exploratory low-temperature or sulfur-enrichment studies, but it was not included in the principal UAN-32/33/34 design matrix evaluated here. The actual certificate-of-analysis values of all raw materials should replace theoretical values before pilot production.

The slow-release concept was operationally defined as delayed N transformation rather than as a presumed release claim. Candidate auxiliaries can include urease inhibitors, nitrification inhibitors, or chemically compatible N-containing stabilizer systems. Because the present source dataset does not specify final commercial doses for these auxiliaries, no unverified dose is assigned in this manuscript. Each additive must instead be tested at its supplier-recommended active-ingredient range and evaluated for compatibility, storage stability, pH, phytotoxicity and agronomic response.

Table 1. Principal formulation components and their technical roles.

Component	Primary function	Development relevance
Urea	Amide-N source	Main N fraction targeted for delayed hydrolysis and improved N-use efficiency.
Ammonium nitrate	Ammonium- and nitrate-N source	Provides rapid-availability N forms and contributes strongly to ionic strength and salt-out behavior.
Process water	Solvent phase	Controls concentration, density, viscosity, heat balance and crystallization margin.
ATS	N + S liquid component	Provides sulfur and may influence urease activity; its effect on crystallization must be measured in the complete formulation.
AS (optional)	N + S solid component	Potential sulfur and ionic-composition modifier; requires separate solubility and salt-out evaluation.
Urease inhibitor / stabilizer	Delays urea hydrolysis	Candidate enhanced-efficiency component; must be validated by soil incubation and ammonia-loss tests.
Nitrification inhibitor (optional)	Delays NH4+ oxidation	Potential complementary strategy; should not be assumed to reduce ammonia volatilization.

Formulation design and nitrogen mass balance

The first design step was selection of the target nominal N grade. UAN-28 was used as the low-temperature reference class because its larger water fraction provides a wider solubility margin. UAN-32 represents the common high-analysis commercial grade, whereas UAN-33 and UAN-34 were treated as progressively more concentrated development targets. The total N content was calculated from the mass fraction and N assay of each N-bearing component according to Eq. (1):

$$Ntotal\ (\%) = 0.466 \cdot murea + 0.350 \cdot mAN + 0.120 \cdot mATS + fAS\text{-}N \cdot mAS$$

where m is the mass percentage of each component in the finished product and fAS-N is the measured N fraction of ammonium sulfate when AS is included. For AN, one-half of the AN-derived N was assigned to nitrate-N and one-half to ammoniacal-N for theoretical N-form distribution. ATS-derived N was assigned to ammoniacal-N. Final grade designation must be based on laboratory analysis rather than calculation alone.

Table 2. Starting composition matrix and theoretical total nitrogen. Values are wt.% of finished product.

Specification	NH4NO3	Urea	ATS	H2O	Theoretical total N
UAN-28 reference*	40.00	30.00	0.00	30.00	27.98
UAN-32 + ATS	45.43	33.80	5.00	15.77	32.25
UAN-33 + ATS	46.73	35.03	5.00	13.24	33.28
UAN-34 + ATS	48.66	36.47	5.00	9.87	34.62

**UAN-28 is shown as a conventional reference composition for comparison; the UAN-32/33/34 + ATS values are the source formulation matrix evaluated in this study.*

Table 3. Theoretical distribution of nitrogen forms in the starting matrix (percentage points of product mass).

Specification	Urea-N	Ammoniacal-N	Nitrate-N	Total N
UAN-28 reference	13.98	7.00	7.00	27.98
UAN-32 + ATS	15.75	8.55	7.95	32.25
UAN-33 + ATS	16.32	8.78	8.18	33.28
UAN-34 + ATS	17.00	9.12	8.52	34.62

Laboratory preparation sequence

Laboratory preparation is proposed as a controlled dissolution procedure. Process water is charged first and agitation is started. The solution is then brought to approximately 35-55 °C, avoiding unnecessary overheating. Urea is introduced gradually until a homogeneous solution is obtained, followed by controlled AN addition while temperature, visual clarity and pH are monitored. ATS and other compatible liquid auxiliaries are added only after the main UAN phase is fully dissolved. The batch is then adjusted to its target mass, mixed to homogeneity and filtered when required before analytical sampling.

For pilot work, the procedure should be managed under the facility's process-safety rules for ammonium-nitrate-containing systems. Raw-material contamination, incompatible metals, unintended organic contamination, local overheating and uncontrolled evaporation can alter

both safety and product composition. The purpose of the 35-55 °C range is to support dissolution, not to define a fixed industrial set point; the minimum temperature that provides complete dissolution and reproducible product quality should be preferred.

Low-temperature stability and crystallization testing

Salt-out temperature should be determined according to ISO 23381:2020, which is specifically intended for liquid fertilizers. For development screening, this measurement should be supplemented with fixed-temperature storage at selected temperatures relevant to the intended market. The original development plan proposes observations at 0, -5 and -10 °C. For each condition, the recorded endpoints should include time to first visible crystal, crystal abundance, sedimentation, phase separation, viscosity change, and the temperature/time required for complete re-dissolution after warming and recirculation.

The terms “freezing point” and “salt-out temperature” should not be used interchangeably in reporting. UAN can precipitate dissolved fertilizer salts before the bulk aqueous phase behaves as a fully frozen system. Accordingly, the primary product-development endpoint is salt-out/crystallization behavior. ASTM D1177 can provide a general conceptual reference for laboratory freezing-point observation in aqueous systems, but ISO 23381 is the more appropriate cited method for liquid fertilizer crystallization.

Nitrogen-transformation and agronomic validation

The enhanced-efficiency claim requires an untreated UAN control and at least one candidate stabilized formulation. Soil incubation should quantify the persistence of urea-N and the accumulation of ammoniacal and nitrate N over time. A parallel volatilization system should quantify cumulative ammonia loss. Closed or semi-closed chambers with acid traps may be used provided the method is validated and identical conditions are applied to all treatments. Measurements should be conducted under controlled soil moisture, temperature and pH conditions that are relevant to the intended use environment.

Pot or field trials should then compare plant N uptake, above-ground biomass, chlorophyll or canopy indicators when appropriate, final yield, and N-use-efficiency indices. Application method must be treated as a major factor because surface-applied UAN has a different volatilization risk than injected or incorporated UAN. A treatment that reduces ammonia loss under surface application may show little yield benefit when the same product is immediately incorporated into soil, as demonstrated in UAN field research (Liu et al., 2019).

Quality-control parameters and data evaluation

Table 4. Minimum analytical and performance validation plan for candidate UAN products.

Parameter	Purpose	Recommended evaluation
Total N (%)	Confirm grade and mass balance	Validated total-N method (e.g., Kjeldahl/Dumas or an equivalent fertilizer method).
Density at 20 °C	Batch consistency and logistics	Calibrated density measurement at controlled temperature.
pH	Chemical stability and application compatibility	Direct pH measurement with calibrated electrode.
Clarity / sediment	Single-phase quality	Visual assessment before and after cold storage; filtration record where applicable.

Parameter	Purpose	Recommended evaluation
Salt-out temperature	Primary cold-stability endpoint	ISO 23381:2020.
Cold-storage stability	Longer-term practical risk	Fixed-temperature holds at 0, -5 and -10 °C or market-specific conditions.
Re-dissolution behavior	Recoverability after crystallization	Record warming temperature, time and mixing requirement.
Urea hydrolysis	Evidence of delayed transformation	Controlled soil incubation versus untreated UAN.
NH3 volatilization	Evidence of N-loss reduction	Validated chamber/trap method versus untreated UAN.
Plant N uptake / yield	Agronomic confirmation	Pot or replicated field trial with suitable statistical analysis.

For replicated laboratory or agronomic trials, treatment means should be evaluated using an appropriate experimental design and inferential statistics. A randomized complete block design is suitable for many pot and field experiments, while completely randomized designs may be adequate for homogeneous laboratory incubations. Replication number, model structure, significance threshold and post-hoc comparison method must be reported with the actual dataset; they are not fixed in the present formulation-design dataset.

RESULTS AND DISCUSSION

Calculated formulation performance and nitrogen balance

The ATS-supported starting matrix produced theoretical total-N values of 32.25, 33.28 and 34.62% for the UAN-32, UAN-33 and UAN-34 candidates, respectively (Table 2). The UAN-32 and UAN-33 candidates are therefore close to their nominal grade designations on a theoretical basis. The UAN-34 candidate, however, calculates to 34.62% N with the assumed raw-material assays. This is an important formulation-development result: the candidate should either be rebalanced toward the desired nominal specification or intentionally treated as a higher-analysis experimental grade after laboratory confirmation. The value should not be silently rounded to 34.0% N.

The N-form calculations also show that approximately one-half of the total N remains in the urea pool across the matrix, while the remainder is divided between ammoniacal and nitrate N. In the UAN-32 + ATS candidate, the calculated urea-N, ammoniacal-N and nitrate-N values are 15.75, 8.55 and 7.95 percentage points, respectively. ATS contributes 0.60 percentage point N while increasing the ammoniacal fraction. This distribution retains the functional logic of UAN: an immediately available nitrate fraction, an ammonium fraction and a larger urea fraction that is the principal target for delayed hydrolysis.

The most consequential compositional trend is the reduction in water. From UAN-32 + ATS to UAN-34 + ATS, the water fraction decreases from 15.77 to 9.87%. This raises nutrient density but also increases dissolved-solids loading and decreases the thermodynamic margin against crystallization. Therefore, a high nominal N value cannot be treated as an independent optimization objective; the grade, cold stability, density, viscosity, pumpability and re-dissolution behavior must be optimized as a coupled system.

Low-temperature stability: implications of concentration and multicomponent formulation

Commercial reference data illustrate the expected concentration effect. UAN-28 is commonly reported with a salt-out temperature near -18 °C, whereas UAN-32 is typically near -2 to 0 °C, with the exact value depending on composition and product specification. The broader low-temperature margin of UAN-28 is therefore a useful reference when screening additives or process changes. In contrast, UAN-33 and UAN-34 cannot be assigned a reliable salt-out temperature from grade number alone; their values must be measured because small changes in water, AN/urea ratio and additional salts can substantially alter crystallization behavior.

The 5% ATS matrix is particularly important in this respect. ATS adds a third major dissolved salt system and contributes useful sulfur, but the UAN-32 + ATS formulation contains only 15.77% water, considerably less than a conventional UAN-32 reference composition. Consequently, any favorable multicomponent/eutectic effect of ATS must be large enough to offset the reduced water fraction if a lower crystallization temperature is to be achieved. The formulation therefore should not be described as cold-stable merely because ATS is present. Its actual salt-out temperature and storage behavior are experimental questions.

Historical liquid-fertilizer work shows that modifying the ionic composition can lower crystallization temperature in some UAN-containing systems. Sulfur-containing UAN formulations based on ammonium sulfate have been reported with lower crystallization temperatures when the overall composition and water content were appropriately balanced, and urea-formaldehyde-containing solutions have also been described as depressing salt-out temperature in certain high-N liquid blends. Such examples support the feasibility of formulation engineering, but they cannot be transferred directly to the present system without testing because the phase behavior is composition specific.

Table 5. Low-temperature interpretation framework for the UAN development series.

Grade / candidate	Reference or design information	Development interpretation
UAN-28	Literature salt-out approximately -18 °C	Useful low-temperature reference; larger water fraction gives broader stability margin.
Conventional UAN-32	Literature salt-out approximately -2 to 0 °C	Commercial benchmark for concentrated UAN.
UAN-32 + 5% ATS	15.77% water; 32.25% theoretical N	Must be measured: added salt complexity may help or hurt crystallization depending on full composition.
UAN-33 + 5% ATS	13.24% water; 33.28% theoretical N	Narrower expected stability window; prolonged cold-storage testing required.
UAN-34 + 5% ATS	9.87% water; 34.62% theoretical N	Highest crystallization-risk candidate in the present matrix; grade balance and salt-out behavior are critical.

Delayed urea transformation and ammonia-loss control

The agronomic part of the concept is supported by a substantial body of work on urease inhibition. NBPT delays urea hydrolysis and thereby reduces the rapid local increase in ammoniacal N and pH that promotes ammonia volatilization. A broad review by Cantarella et al. (2018) reported a strong average reduction in ammonia loss from NBPT-treated urea,

although the response varied with crop and environment. The mechanism is especially relevant to UAN because a major fraction of its N is urea-N.

UAN-specific evidence confirms that formulation additives can alter ammonia loss. Goos (2013) compared several additives in greenhouse studies and reported average 14-day ammonia-loss reductions relative to untreated UAN of 40% with ATS, 40% with calcium thiosulfate, 51% with an NBPT-containing product and 65% with NBPT plus calcium thiosulfate. However, the literature is not uniform. Grant et al. (1996) found NBPT effective with UAN under zero-till conditions while ATS had little influence in their particular field microplots. These contrasting results emphasize that ATS efficacy depends on soil and environmental conditions and that formulation screening must be followed by site-relevant validation.

The chemistry proposed for ATS is also different from direct NBPT inhibition. Sullivan and Havlin (1992) showed that thiosulfate itself did not directly inhibit purified urease to the same extent as oxidation products formed in soil and identified tetrathionate as an important inhibitory species. This helps explain why ATS performance can vary with soil moisture, temperature, pH and oxidation conditions. In practical product development, ATS should therefore be evaluated simultaneously as a sulfur nutrient, an ionic formulation component and a potentially variable contributor to delayed urea hydrolysis.

Slow-release versus stabilized UAN: claim definition

A key scientific issue is terminology. A liquid UAN containing a urease inhibitor does not automatically become a classical controlled-release fertilizer in the same sense as a coated granule or a slowly soluble N compound. The more defensible initial classification is an enhanced-efficiency or stabilized UAN with delayed N transformation. The term “slow-release characteristic” can be used as a development objective, but a final slow-release claim requires time-resolved evidence showing that the relevant N fraction is transformed or becomes plant available more slowly than the untreated control.

This distinction improves the quality of the research design. If the only demonstrated result is reduced ammonia volatilization, the supported claim is N-loss mitigation. If soil incubation additionally demonstrates slower urea disappearance or delayed mineral-N conversion, the supported claim expands to delayed transformation. If plant and release-kinetic data show prolonged N availability without yield or phytotoxicity penalties, a stronger slow-release or controlled-availability claim may then be justified. The manuscript therefore treats claim strength as an evidence hierarchy rather than as an assumption built into the formulation name.

Table 6. Evidence required for progressively stronger product claims.

Claim level	Minimum evidence	Interpretation
Physically stable UAN	N grade, pH, density, clarity, salt-out/cold-storage data	Supports product handling and storage specification only.
Stabilized / enhanced-efficiency UAN	Above + lower NH3 loss and/or altered N-transformation kinetics vs. untreated UAN	Supports reduced-loss or delayed-transformation positioning.
Slow-release characteristic	Above + time-resolved release/transformation and plant-availability evidence	Supports a measured slower availability profile under defined conditions.

Claim level	Minimum evidence	Interpretation
Agronomically superior product	Above + replicated plant uptake, yield and NUE response	Supports crop-performance claims for the tested use conditions.

Integrated product-development decision path

The results of the calculation and literature assessment support a sequential rather than one-step development strategy. First, each candidate must meet its N-grade target after real raw-material assays are inserted into the mass balance. Second, the candidate must remain chemically and physically compatible at ambient temperature. Third, salt-out temperature and extended cold-storage behavior must be determined. Only formulations that pass these physical screens should proceed to detailed N-transformation and agronomic testing. This order prevents resources being spent on biologically promising additives that produce an unstable commercial liquid.

UAN-28 is well suited to early compatibility and inhibitor screening because its higher water content reduces the risk that a negative result is caused only by inadequate solubility. UAN-32 should then serve as the principal commercial benchmark. UAN-33 and UAN-34 should be treated as advanced high-analysis variants and should not advance unless their cold stability, re-dissolution behavior and analytical N values remain acceptable. Within this sequence, ATS-containing and non-ATS controls are required to separate sulfur-nutrition effects from urease-inhibition and phase-stability effects.

The final product decision should be based on a multi-criteria matrix rather than on a single freezing or N-value result. A technically successful candidate should combine: target total N; reproducible N-form distribution; acceptable pH and density; low sediment formation; sufficiently low salt-out temperature for the intended logistics chain; complete and practical re-dissolution after cold exposure; reduced ammonia loss or delayed urea transformation versus untreated UAN; and no adverse effect on crop performance or application equipment.

CONCLUSIONS

This study converts an initial UAN formulation concept into a full technical framework for developing UAN-28, UAN-32, UAN-33 and UAN-34 liquid nitrogen fertilizers with delayed N transformation and improved low-temperature reliability. The calculated ATS-supported matrix gives 32.25, 33.28 and 34.62% total N for the UAN-32, UAN-33 and UAN-34 candidates, respectively. The UAN-34 candidate therefore requires particular attention to grade adjustment and analytical confirmation rather than simple nominal labeling.

The formulation calculations identify water content as the central physical trade-off. Increasing the target N grade from UAN-32 to the high-analysis UAN-34 candidate reduces water from 15.77 to 9.87%, which is expected to narrow the crystallization-stability window. ATS may provide agronomic sulfur value and may influence urea hydrolysis, but its net effect on cold stability cannot be inferred from composition alone. Salt-out temperature must be measured on the finished formulation, preferably using ISO 23381:2020, and complemented by prolonged cold-storage and re-dissolution tests.

From an agronomic perspective, the literature supports the use of urease-inhibition strategies to reduce ammonia loss from urea-containing fertilizers, including UAN, but treatment response is sensitive to soil, climate and application method. The most scientifically defensible development pathway is therefore to describe early candidates as stabilized or enhanced-efficiency UAN and reserve a slow-release claim for formulations that demonstrate delayed transformation/release kinetics and sustained plant availability in comparative experiments.

For subsequent pilot and field development, the highest-priority measurements are real total N, density, pH, salt-out temperature, 0/-5/-10 °C storage behavior, re-dissolution, urea-hydrolysis kinetics, cumulative ammonia volatilization, plant N uptake and yield. Integrating these endpoints provides a robust decision basis for selecting a commercially viable UAN formulation that improves nitrogen-use efficiency without sacrificing storage and handling performance.

DEVELOPMENT OF NOVEL FERTILIZER SYSTEMS FROM DOLOMITE BY NITRIC ACID AND MAGNESIUM-BASED PROCESSING ROUTES

Gökhan Yaşar, Ahmet Akbulut, Deniz Öncel, Burcu Köse & Halit Duran

İGSAŞ Research and Development Unit, Türkiye

ABSTRACT

Dolomite [CaMg(CO3)2] is an abundant carbonate mineral that can serve not only as a liming material but also as a local feedstock for soluble calcium- and magnesium-containing fertilizers. This paper develops a process-oriented framework for converting dolomite into value-added fertilizer intermediates through two complementary routes: direct nitric-acid digestion of raw dolomite to obtain mixed calcium-magnesium nitrate liquor, and a calcination-assisted route designed to facilitate selective magnesium hydroxide recovery and subsequent magnesium oxide production. The source process concept combines particle-size control, optional calcination, nitric-acid dissolution, pH-controlled precipitation, filtration, recycle of nitrate-containing mother liquor, and final liquid or suspension formulation. Stoichiometric calculations for pure dolomite show that 100 kg of CaMg(CO3)2 requires 136.69 kg pure HNO3 and can theoretically generate 88.98 kg anhydrous Ca(NO3)2 and 80.43 kg anhydrous Mg(NO3)2 while releasing 47.73 kg CO2. Complete calcination would yield approximately 30.41 kg CaO and 21.86 kg MgO equivalents per 100 kg pure dolomite. These calculations are design values and must be corrected for ore purity, acid excess, free water, hydration state and process losses. Recent literature demonstrates that uncalcined dolomite can be digested with nitric acid and subsequently neutralized with ammonia to produce liquid N-Ca-Mg fertilizers, while earlier patent literature shows that nitrate-containing slaking media can improve magnesium hydroxide filterability in dolomite-based separation processes. On this basis, the paper proposes an experimental matrix covering raw versus calcined dolomite, particle size, acid stoichiometry, reaction temperature, pH, residence time, precipitation reagent, cake washing and mother-liquor recycle. Recommended validation includes XRD, XRF/ICP-OES, TGA/DSC, SEM-EDS, total N, Ca, Mg, heavy metals, density, pH, crystallization behavior, filtration rate and agronomic tests. The resulting framework provides a technically defensible basis for laboratory and pilot-scale development of nitrate-based liquid fertilizers, magnesium hydroxide suspensions and MgO precursors from dolomite without presenting unverified target values as experimental results.

Keywords: Dolomite, nitric acid, calcium nitrate, magnesium nitrate, magnesium hydroxide, liquid fertilizer, filtration, calcination, process development

INTRODUCTION

Calcium (Ca) and magnesium (Mg) are essential plant nutrients with distinct physiological roles. Magnesium is the central atom of chlorophyll and participates in enzyme activation, energy transfer and carbon assimilation, whereas calcium contributes to cell-wall structure, membrane stability, root development and the quality of many horticultural crops. The agronomic value of Ca and Mg therefore depends not only on total nutrient content but also on mineral solubility, delivery route and the chemical environment in which the nutrients are applied.

Dolomite is a double carbonate commonly represented as CaMg(CO3)2. Pure dolomite contains, on a theoretical oxide-equivalent basis, approximately 30.41% CaO and 21.86% MgO, with the remainder corresponding largely to CO2 released during complete thermal decomposition (Olszak-Humienik & Jablonski, 2015). Natural ores deviate from this ideal composition because calcite, silica, iron-bearing phases, aluminosilicates and trace elements may be present. These impurities are important for fertilizer development because acid digestion can transfer both nutrients and undesirable elements into solution.

Natural dolomite can be applied directly as a liming or soil-conditioning material, but the carbonate lattice dissolves comparatively slowly under many soil conditions. Chemical conversion offers a route to transform the mineral into more soluble nitrate salts or into Mg(OH)2/MgO products with controlled particle properties. Acid-leaching studies have already demonstrated that dolomite can be converted to magnesium salts, while Turkish work by Yildirim and Akarsu (2010) showed that high-purity MgO can be produced through a leach-precipitation-pyrohydrolysis route. Sulfuric-acid processing has likewise been used to produce magnesium sulfate heptahydrate, with particle size, acid ratio, temperature and filtration identified as critical variables (Rashad & Baioumy, 2005).

Nitric acid is particularly attractive in a fertilizer-oriented flowsheet because nitrate introduced during mineral dissolution remains a plant nutrient rather than a non-fertilizer counter-ion. Recent research demonstrated the production of liquid nitrogen-calcium-magnesium fertilizers by digesting finely ground, uncalcined dolomite with nitric acid, neutralizing the acidic liquor with ammonia and adding nitrogenous components (Didžiulytė & Šlinkšienė, 2025). Historical patent literature also describes the simultaneous production of magnesia and calcium nitrate from dolomite and highlights a persistent industrial challenge: Mg(OH)2 precipitates may be difficult to filter unless slurry conditioning, particle size and the ionic composition of the mother liquor are controlled (DE830943C; DE1912865A1; US2912306A).

The present work therefore treats dolomite conversion as a fertilizer-process design problem rather than as a single reaction. The objective is to define a laboratory-to-pilot framework for (i) direct production of Ca/Mg nitrate fertilizer liquor, (ii) selective recovery of magnesium hydroxide as a suspension or MgO precursor, and (iii) integration of the calcium- and nitrogen-rich mother liquor into fertilizer products. The study expands the initial project draft with stoichiometric mass balances, a route-comparison matrix, analytical requirements, a filtration strategy, process risks and a structured experimental validation plan. Because the project is still at the process-development stage, calculated and literature-supported values are clearly distinguished from future experimental results.

MATERIAL AND METHOD

Materials and raw-material characterization

The primary raw material is dolomite ore. Before reaction testing, each ore lot should be homogenized, dried to constant mass where appropriate, crushed and milled to defined size fractions. The minimum characterization set should include XRF or wet-chemical major-element analysis, loss on ignition (LOI), XRD phase identification and ICP-OES or equivalent analysis for Ca, Mg, Fe, Al, Mn and regulated trace elements. TGA/DSC is recommended to identify the actual decomposition profile of the selected ore because calcination behavior depends on impurity content, particle size, CO2 partial pressure and heating history.

Process reagents include nitric acid, deionized water, ammonia solution and/or sodium hydroxide for pH control and Mg(OH)2 precipitation. Calcium nitrate solution or nitrate-rich wash water is included as a potential slaking/conditioning medium for the calcined route. Antifoam may be used during carbonate digestion because rapid CO2 evolution can cause

severe foaming. Flocculant should be screened only after baseline filtration behavior has been established so that any improvement can be attributed to a defined mechanism.

Table 1. Main materials and their intended process functions.

Material	Primary role	Critical quality / control point
Dolomite ore	Ca and Mg source	CaO/MgO equivalent, mineralogy, LOI, Fe/Al/Si, heavy metals, particle size
Nitric acid	Carbonate/oxide dissolution and nitrate source	Assay, density, acid feed rate, stoichiometric excess
Ammonia solution	Neutralization and Mg(OH)2 precipitation option	NH3 assay, pH endpoint, residual ammonium
Sodium hydroxide	Alternative Mg(OH)2 precipitant	NaOH assay, Na introduction into product liquor
Calcium nitrate liquor / wash water	Slaking or slurry-conditioning medium	Ca(NO3)2 concentration, recycle impurity build-up
Deionized water	Dissolution, washing and formulation	Conductivity and water balance
Antifoam / flocculant	Optional process aids	Compatibility, dose-response and fertilizer acceptability

Particle-size preparation

The source process draft proposes comparison of controlled particle-size fractions and cites a sub-0.84 mm target for some calcined-dolomite filtration concepts. The experimental plan should therefore include at least three fractions rather than treating a single grind as optimal. A practical screening set is <0.25 mm, 0.25-0.50 mm and 0.50-0.84 mm. Finer material should increase reactive surface area during acid digestion, but excessive fines can increase slurry viscosity and produce compact, poorly permeable filter cakes. Particle size must consequently be optimized jointly with reaction conversion and filtration rate.

Route A: direct nitric-acid digestion of raw dolomite

For the direct fertilizer route, raw dolomite is charged to a temperature-controlled, agitated reactor and nitric acid is added gradually to control foaming and heat release. The main idealized reaction is:

$$CaMg(CO3)2 + 4HNO3 \rightarrow Ca(NO3)2 + Mg(NO3)2 + 2CO2\uparrow + 2H2O \quad (1)$$

The reaction should be operated as an acid-digestion experiment with measured rather than assumed endpoints. Variables include acid concentration, acid/dolomite stoichiometric ratio, temperature, particle size and residence time. The initial source draft proposed 50-75 °C as a reaction window. A recent fertilizer study provides a useful lower-temperature reference: uncalcined dolomite (<0.25 mm) was decomposed with 45% HNO3 for approximately 50 min with the maximum temperature kept below 50 °C, followed by filtration and ammonia neutralization (Didžiulytė & Šlinkšienė, 2025). Accordingly, the present paper treats 35-75 °C as a screening space rather than declaring one temperature as optimum before testing.

Route B: calcination-assisted conversion and magnesium separation

The calcination-assisted route is intended to increase reactivity and create an oxide-rich intermediate. Complete idealized decomposition is represented by:

$$CaMg(CO3)2 \rightarrow CaO + MgO + 2CO2\uparrow \quad (2)$$

The original process draft proposed 1150-1450 °C as a screening range. This high-temperature range should not be adopted uncritically as the default operating condition. Thermal literature shows that dolomite decomposition is strongly dependent on atmosphere and mineralogy and that oxide formation occurs at substantially lower temperatures in many systems; temperatures that are unnecessarily high may increase energy demand and sintering. Therefore, the recommended laboratory design is to determine the ore-specific TGA/DSC decomposition profile first and then compare a lower calcination window (for example 800-1050 °C) with a limited high-temperature condition from the original project concept. The key output is not furnace temperature itself, but conversion, residual carbonate, oxide reactivity, specific surface behavior and downstream filtration performance.

Calcined solids can be slaked or conditioned in water, calcium nitrate solution or recycled nitrate-containing wash liquor. Historical dolomite patents report that nitrate-containing slaking media can alter the physical form of hydrated solids and improve Mg(OH)2 filterability. This concept will be treated as an experimental hypothesis rather than as an assumed benefit.

Nitric-acid conversion of calcined dolomite

The idealized reaction of the calcined CaO-MgO mixture with nitric acid is:

$$CaO + MgO + 4HNO3 \rightarrow Ca(NO3)2 + Mg(NO3)2 + 2H2O \quad (3)$$

Compared with raw-carbonate digestion, the calcined route eliminates reaction CO2 during the acid step but shifts CO2 release to the furnace and adds a substantial energy requirement. This trade-off should be quantified experimentally through acid consumption, conversion, residence time, filtration behavior and product concentration.

Selective magnesium hydroxide precipitation

Magnesium can be recovered from nitrate liquor by increasing pH. With sodium hydroxide, the simplified precipitation reaction is:

$$Mg(NO3)2 + 2NaOH \rightarrow Mg(OH)2\downarrow + 2NaNO3 \quad (4)$$

NaOH provides straightforward pH control but transfers sodium nitrate to the liquid phase. For a fertilizer plant this may be undesirable depending on the final product specification and sodium limits. Ammonia therefore deserves parallel evaluation because it introduces nitrogen rather than sodium. A simplified representation is:

$$Mg(NO3)2 + 2NH3 + 2H2O \rightarrow Mg(OH)2\downarrow + 2NH4NO3 \quad (5)$$

The ammonia route can create an ammonium-nitrate-rich mother liquor with direct fertilizer value, but precipitation chemistry is affected by ammonium concentration, ionic strength and pH. The process must therefore be optimized experimentally. The source draft proposed pH 8.5-10.5; this range is retained as a screening interval, with pH titration curves and dissolved Mg/Ca analyses used to determine the actual selectivity window.

Theoretical mass balance

Stoichiometric calculations were performed for ideal CaMg(CO3)2 using molar masses of 184.399 g mol−1 for dolomite and 63.012 g mol−1 for HNO3. These values provide a transparent basis for acid planning and theoretical yields, but do not account for ore impurities, incomplete conversion, hydrates, entrained mother liquor or process losses.

Table 2. Theoretical material balance for 100 kg of pure dolomite.

Item	Theoretical value	Interpretation
Pure HNO3 requirement	136.69 kg	4 mol HNO3 per mol dolomite
56% HNO3 solution equivalent	244.08 kg	Stoichiometric solution mass; operating excess not included

Item	Theoretical value	Interpretation
65% HNO3 solution equivalent	210.29 kg	Stoichiometric solution mass; operating excess not included
Ca(NO3)2, anhydrous equivalent	88.98 kg	Theoretical calcium-nitrate salt basis
Mg(NO3)2, anhydrous equivalent	80.43 kg	Theoretical magnesium-nitrate salt basis
CO2 released in raw-acid route	47.73 kg	Gas load from carbonate decomposition
CaO after complete calcination	30.41 kg	Oxide-equivalent fraction of pure dolomite
MgO after complete calcination	21.86 kg	Oxide-equivalent fraction of pure dolomite
Total calcined oxides	52.27 kg	Ideal residual solid after complete CO2 removal
Mg(OH)2 theoretical precipitate	31.63 kg	If all Mg is selectively recovered as Mg(OH)2
Pure NaOH for full Mg precipitation	43.38 kg	Stoichiometric value for Eq. 4
Pure NH3 for full Mg precipitation	18.47 kg	Stoichiometric value for Eq. 5

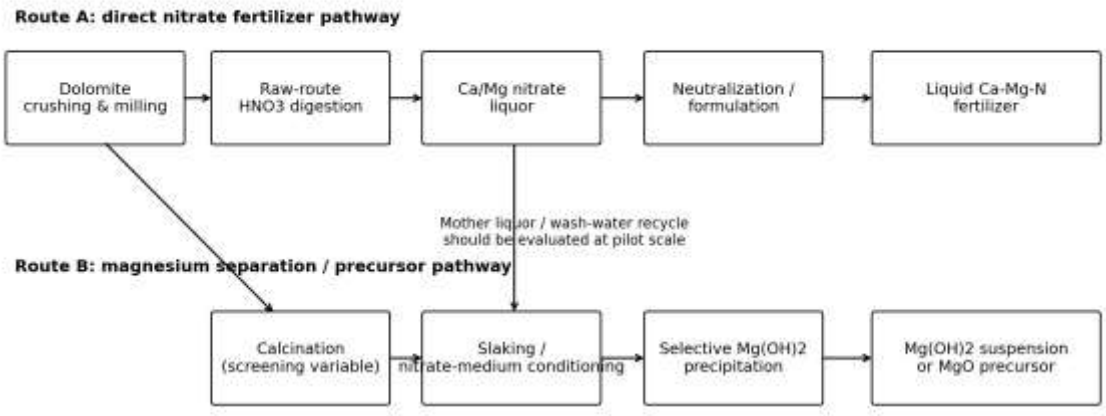

Figure 1. Proposed integrated process routes for dolomite-derived fertilizer products. Route A prioritizes direct nitrate-fertilizer liquor; Route B adds calcination/slaking and selective magnesium recovery.

Experimental design and process variables

The project should be executed as a staged design rather than a full-factorial experiment from the first batch. Stage 1 establishes raw-material variability and direct-acid baseline behavior. Stage 2 compares raw and calcined routes. Stage 3 focuses on Mg(OH)2 selectivity and filtration. Stage 4 integrates the best conditions into fertilizer formulations and agronomic validation. Each quantitative laboratory condition should be performed with sufficient replication for statistical evaluation after the screening stage.

Table 3. Proposed laboratory screening matrix.

Factor	Suggested screening levels	Primary responses
Dolomite condition	Raw; calcined at ore-specific lower window; selected high-temperature condition	Conversion, acid demand, Ca/Mg recovery
Particle size	<0.25; 0.25-0.50; 0.50-0.84 mm	Dissolution time, slurry rheology, filtration
HNO3 concentration	45%; 56%; 65% or plant-available grades	Reaction control, final concentration, safety
Acid stoichiometry	100%; 110%; 120-140% of calculated demand	Residual solids, free acidity, impurity dissolution
Reaction temperature	35; 50; 65; 75 °C screening	Conversion, foaming, residence time
Residence time	15; 30; 50/60; 90 min	Approach to dissolution plateau
Precipitation reagent	NaOH; NH3 solution	Mg recovery, Ca carryover, mother-liquor value
Precipitation pH	8.5; 9.0; 9.5; 10.0; 10.5	Mg(OH)2 yield/selectivity and filterability
Slaking medium	Water; Ca(NO3)2 solution; recycled wash liquor	Particle morphology and filter rate
Cake washing	0; 1; 2 wash stages	Nitrate removal, CaO impurity, yield loss

Analytical methods and performance criteria

ICP-OES should be used to quantify dissolved Ca, Mg and trace metals in reaction liquors and wash streams. XRF is suitable for rapid major-oxide analysis of raw and calcined solids, while XRD should be used to identify dolomite, calcite, CaO, MgO, Mg(OH)2 and other crystalline phases. TGA/DSC provides the thermal decomposition profile and supports selection of a calcination window. SEM-EDS is recommended for comparing raw mineral morphology, calcined porous structures and precipitated Mg(OH)2 agglomerates.

For fertilizer products, total nitrogen, nitrate-N and ammoniacal-N should be measured with validated fertilizer methods appropriate to the formulation. Density, pH, conductivity, viscosity, insoluble matter and crystallization/low-temperature stability should be characterized for liquid products. For Mg(OH)2 and MgO products, MgO equivalent, CaO contamination, moisture, LOI and particle-size distribution are important quality attributes. Heavy-metal screening is essential because nitric acid can solubilize trace elements originally present in the ore.

Table 4. Recommended analytical package for process validation.

Sample / product	Analyses	Purpose
Raw dolomite	XRF, XRD, ICP-OES, LOI, TGA/DSC, particle size	Feedstock composition and variability
Calcined dolomite	XRD, XRF, LOI, TGA check, particle size	Carbonate conversion and oxide formation
Acid digestion liquor	ICP-OES (Ca/Mg/impurities), free acidity, pH, density	Dissolution efficiency and impurity transfer
Mg(OH)2 cake	MgO eq., CaO impurity, moisture, XRD, SEM-EDS	Selectivity, morphology and product quality
Mother liquor	Ca, Mg, nitrate-N, ammoniacal-N, Na where relevant	Recycle and fertilizer integration
Liquid fertilizer	Total N, CaO/MgO eq., pH, density, viscosity, insolubles, crystallization	Commercial-formulation quality
Agronomic samples	Plant biomass/yield, tissue Ca/Mg/N, soil available Ca/Mg	Nutrient-use performance

RESULTS AND DISCUSSION

Stoichiometric potential of dolomite as a fertilizer feedstock

The theoretical balance in Table 2 illustrates why dolomite is attractive for integrated fertilizer processing. One hundred kilograms of pure mineral contains the equivalent of 30.41 kg CaO and 21.86 kg MgO, and complete reaction with nitric acid converts these alkaline-earth components into nitrate salts while introducing fertilizer N from the acid. On an anhydrous salt basis, the ideal mixed Ca(NO3)2-Mg(NO3)2 product contains approximately 17.93% N, 17.95% CaO equivalent and 12.90% MgO equivalent. Actual liquid products will contain water, excess acid or neutralization products, so their nutrient analysis will be lower and must be determined experimentally.

The same balance also identifies the dominant process load in the raw-dolomite route: CO2 evolution. The theoretical release is 47.73 kg CO2 per 100 kg pure dolomite. At laboratory scale this primarily affects foaming and reactor headspace; at pilot and industrial scale it becomes a gas-handling, ventilation and capacity issue. Controlled acid addition, adequate freeboard and antifoam screening are therefore process-design requirements rather than optional operational details.

Direct digestion versus calcination-assisted processing

The two routes serve different product objectives. Direct nitric-acid digestion avoids the thermal-energy penalty of calcination and is well suited to liquid Ca-Mg-N fertilizer development. The 2025 Sustainability study is particularly relevant because it demonstrated a direct sequence of dolomite → nitric acid → ammonia water → urea → ammonium nitrate and reported stable liquid fertilizer formulations after further nitrogen enrichment. By contrast, the calcination-assisted route becomes more attractive when selective Mg(OH)2 or MgO is the priority, because conversion to reactive oxides and controlled slaking can create a solid-liquid separation pathway not available in a simple mixed nitrate solution.

Table 5. Technical comparison of the two principal process routes.

Criterion	Route A: raw dolomite + HNO3	Route B: calcination-assisted
Primary target	Liquid Ca-Mg nitrate fertilizer liquor	Mg(OH)2 / MgO plus nitrate-rich co-product
Energy demand	Lower; no calcination furnace	Higher; furnace and gas handling required
Gas evolution	CO2 during acid digestion	CO2 mainly during calcination
Reaction rate	Controlled by mineral dissolution and particle size	Potentially faster oxide-acid reaction after calcination
Solid-liquid separation	Mainly insoluble-gangue filtration	Critical Mg(OH)2 precipitation and cake filtration
Main risk	Foaming, excess acidity, impurity dissolution	Sintering, energy use, filterability, Ca carryover
Fertilizer integration	Directly favorable	Requires mother-liquor/product integration
Best initial use	Fast laboratory proof of concept	Second-stage route for higher-value Mg products

Calcination temperature should be treated as an optimization variable

A key improvement over the initial process draft is the treatment of calcination temperature as a measured optimization variable rather than a fixed 1150-1450 °C requirement. Olszak-Humienik and Jablonski (2015) showed that the thermal decomposition of natural dolomite is strongly condition-dependent and confirmed complete conversion to CaO and MgO under suitable thermal conditions. Didžiulytė and Šlinkšienė (2025) explicitly avoided a 1050 °C calcination step in their fertilizer route because of its energy demand. These observations do not invalidate high-temperature testing; they indicate that very high temperatures should be justified by downstream benefits such as reactivity, phase purity or filtration. Excessive firing may promote sintering and reduce the reactive surface of the oxide product. TGA/DSC-guided furnace trials are therefore a more defensible development strategy.

Acid stoichiometry, concentration and impurity control

The ideal reaction requires four moles of HNO3 per mole of dolomite. Real ores require an operational allowance because non-dolomite carbonate phases and acid-consuming impurities may be present, while incomplete mixing or passivation can prevent stoichiometric acid from reaching full conversion. The recent direct-fertilizer study used an acid charge stated as 140% of the stoichiometric amount for its specific dolomite. This supports testing controlled acid excess, but it should not be copied as a universal recipe. Excess acid can increase Ca/Mg recovery yet also dissolve more Fe, Al and trace metals, increase neutralization demand and lower the nutrient concentration of the finished fertilizer if large amounts of neutralizing solution are then required. The optimum is therefore the minimum acid excess that provides reproducible nutrient recovery and an acceptable impurity profile.

Magnesium hydroxide precipitation and filtration as the decisive separation step

Mg(OH)2 precipitation is chemically simple but industrially demanding because fine precipitates can form gelatinous or low-permeability cakes. Historical patent DE830943C emphasized the practical importance of generating a more filterable precipitate and described slaking burned dolomite in calcium-nitrate-containing solution before reaction with nitrate liquor. The related US2912306A patent reported a lime-poor magnesia product and improved filtration when nitrate-conditioned slaking was used. DE1912865A1 similarly described the

conversion of MgO-containing dolime solids to Mg(OH)2 in chloride-containing mother liquor. Although these documents are old, they highlight a modern process-development principle: precipitation yield alone is not sufficient; particle morphology, cake permeability, wash demand and mother-liquor recovery determine the economic feasibility of the separation.

For the present project, pH should therefore be increased stepwise while measuring dissolved Mg and Ca, rather than simply targeting the upper end of the 8.5-10.5 screening range. Filterability should be quantified as filtrate volume per unit area per unit time, cake moisture and wash-water demand. SEM-EDS and particle-size analysis can then be used to connect operating conditions with precipitate morphology. The best precipitation condition is the one that balances Mg recovery, low Ca contamination and practical filtration.

Product-development opportunities

Table 6. Dolomite-derived product families and proposed development logic.

Product family	Principal chemistry	Development objective	Key validation
Liquid Ca-Mg-N fertilizer	Ca(NO3)2 + Mg(NO3)2, optionally NH4NO3/urea	High-solubility Ca/Mg with nitrogen	N/Ca/Mg analysis, pH, density, crystallization, crop compatibility
Mg-rich liquid fertilizer	Mg(NO3)2-rich separated liquor	Rapid Mg supply via fertigation/foliar routes	Mg concentration, Ca selectivity, phytotoxicity
Mg(OH)2 suspension	Mg(OH)2 dispersed phase	Suspension fertilizer / soil-pH functionality	Particle size, sedimentation, redispersibility, Mg availability
MgO precursor	Dried/calcined Mg(OH)2	Higher-purity Mg product for agricultural or industrial use	MgO assay, CaO impurity, LOI, surface/reactivity
Calcium nitrate co-product	Ca(NO3)2-rich mother liquor	Fertilizer integration and Ca value recovery	Ca/N ratio, Mg carryover, crystallization behavior
Organomineral product	Dolomite-derived solids/liquors + organic matrix	Slower nutrient release / soil-conditioning concept	Nutrient release, stability, agronomic trial

For the first laboratory milestone, the direct liquid Ca-Mg-N route is the lowest-complexity product because it avoids selective separation. A second milestone should focus on Mg(OH)2 recovery only after the nitrate liquor and impurity profile are characterized. Product diversification should follow measured process behavior rather than forcing all product families through one flowsheet.

Process safety, environmental control and scale-up

Nitric-acid digestion requires corrosion-resistant equipment, controlled reagent addition, temperature monitoring and effective ventilation. The carbonate reaction itself primarily generates CO2, but nitric acid handling and contact with reducing contaminants or inappropriate materials can create additional hazards. Industrial design should therefore include closed or semi-closed reaction equipment, scrubber capacity where required, materials-of-construction review and procedures that prevent contamination of nitrate-rich liquors with incompatible organic or combustible materials.

Calcination shifts a large portion of the environmental burden from the wet reaction to the furnace. Energy use and direct process CO2 must be included in route comparison. Mother-liquor and wash-water recycle can reduce wastewater and recover nitrate value, but repeated recycle can also concentrate Na, Cl, Fe, Al or other impurities. A purge strategy should be defined from measured impurity accumulation rather than assumed closed-loop operation.

Pilot-scale decision criteria

Table 7. Recommended stage-gate criteria before pilot scale.

Stage	Decision question	Minimum evidence before progression
1. Feedstock	Is the dolomite sufficiently consistent?	Representative XRF/XRD/ICP data from multiple lots; impurity and heavy-metal profile
2. Direct digestion	Can Ca and Mg be recovered reproducibly?	Mass balance, residual solids, acid consumption, reaction time and foam control
3. Product liquor	Is a stable fertilizer-grade liquid feasible?	N/Ca/Mg analysis, pH, density, viscosity, crystallization and storage observations
4. Mg separation	Can Mg(OH)2 be recovered selectively and filtered?	Mg recovery, Ca impurity, cake rate/moisture, washing requirement
5. Recycle	Can mother liquor/wash water be reused safely?	Ion accumulation profile, product quality after repeated recycle cycles
6. Agronomy	Does chemical availability translate to crop response?	Replicated greenhouse or field response versus commercial/reference fertilizers
7. Economics	Does the selected route justify scale-up?	Reagent, energy, water, filtration, drying and waste-management balance

Limitations of the present study

The present manuscript is a process-development paper based on the project draft, stoichiometric calculations and published literature/patent evidence. The target conditions listed in Tables 3-7 are experimental design ranges, not measured optima. No experimental recovery percentage, filtration rate, impurity level or agronomic response is claimed for the İGSAŞ dolomite project until the corresponding laboratory data are generated. This distinction is essential for scientific publication and will allow future measured results to replace the design targets without rewriting the conceptual framework.

CONCLUSIONS

Dolomite can be treated as a strategic Ca-Mg feedstock for fertilizer-process development rather than only as a low-solubility liming mineral. The most direct route is nitric-acid digestion of finely ground raw dolomite, producing a mixed Ca/Mg nitrate liquor that can be neutralized and formulated as a liquid fertilizer. This pathway minimizes thermal energy demand and is supported by recent experimental literature on liquid N-Ca-Mg fertilizer production.

A calcination-assisted route is justified when the project objective expands to selective Mg(OH)2 recovery or MgO production. However, calcination temperature should be selected from ore-specific TGA/DSC and downstream performance rather than fixed at the highest temperature. The separation challenge is not merely chemical precipitation: Mg recovery, Ca contamination, particle morphology, cake permeability, washing and mother-liquor recycle must be optimized together.

The theoretical balance establishes a transparent baseline: per 100 kg pure dolomite, the stoichiometric requirement is 136.69 kg pure HNO3, with theoretical formation of 88.98 kg Ca(NO3)2 and 80.43 kg Mg(NO3)2 and release of 47.73 kg CO2. These values must be corrected with actual ore assay, acid excess and process losses before scale-up.

The recommended development sequence is therefore: feedstock characterization → direct nitric-acid digestion baseline → calcination comparison where needed → selective precipitation/filtration study → fertilizer formulation and low-temperature stability → mother-liquor recycle assessment → greenhouse/field validation → techno-economic evaluation. This staged approach can generate the measured process data required for a final peer-reviewed article and can also identify potentially protectable process know-how for the PYP 75-3120-026 “Dolomitten Farklı Gübre Üretim Projesi”.

ACKNOWLEDGEMENTS

This manuscript was prepared within the scope of the planned PYP 75-3120-026 “Dolomitten Farklı Gübre Üretim Projesi”. The authors acknowledge the planned contributions of the İGSAŞ R&D team and collaborating analytical laboratories. Experimental data and institution-specific funding information should be updated before journal or congress submission.

ABSTRACT

Water scarcity driven by climate change, population growth, and irregular rainfall patterns has made efficient water use in agriculture a critical issue for sustainable food production. Agricultural activities account for a large share of global freshwater consumption, and a significant portion of irrigation water is lost through evaporation, surface runoff, and deep percolation. Consequently, the need for technologies that can increase soil water retention capacity and improve irrigation efficiency is growing steadily. In recent years, hydrogel-based superabsorbent polymers have emerged as promising materials due to their ability to absorb large amounts of water and release it in a controlled manner to the plant root zone when needed. In this study, a water-retentive hydrogel formulation with properties comparable to commercial agricultural hydrogels was developed, and its potential agricultural performance was evaluated. The formulation was prepared using superabsorbent polymeric structures, organic stabilizers, and cross-linking agents. Laboratory- and pot-scale trials were planned to determine the water absorption capacity, swelling behavior, soil moisture retention performance, and effects on plant growth of the developed hydrogel recipe. Different hydrogel doses will be applied to the soil under controlled irrigation conditions, and the results will be compared with control groups. The developed hydrogel formulations are expected to reduce soil moisture loss, extend irrigation intervals, and support plant growth by providing a more stable moisture environment in the root zone. The system developed is also expected to contribute to sustainable agricultural practices by improving irrigation efficiency in arid and semi-arid regions. This study is expected to provide a basis for controlled-release fertilizer systems, biodegradable hydrogel technologies, and climate-resilient agricultural practices.

Keywords: Hydrogel, Water retention capacity, Sustainable agriculture, Superabsorbent polymer, Irrigation efficiency, Soil moisture

INTRODUCTION

Due to global climate change and increasing water consumption, the water resources available for agricultural production are steadily decreasing. The agricultural sector accounts for approximately 70% of total freshwater use worldwide, and significant water losses occur in current irrigation systems. In agricultural activities carried out particularly in arid and semi-arid regions, the inefficient use of water leads to yield losses and increased economic damage.

Superabsorbent polymers (SAPs), which enable water to be retained in the soil for longer periods, have become one of the key research areas in sustainable agricultural practices in recent years. These polymers can absorb hundreds of times their own weight in water and release the stored water back to the plant root zone in a controlled manner. Guilherme et al. (2015) reported that hydrogel applications reduce water stress and positively affect plant growth. Montesano et

al. (2015) reported that controlled water release provides a reduction in irrigation frequency and an improvement in plant growth. In addition, Ekebafe et al. (2011) stated that superabsorbent polymers improve the soil-water relationship under arid conditions.

However, the high cost of existing commercial hydrogel products, the low biodegradability shown by some products, and their variable performance under different soil conditions make it necessary to develop new formulations. For this reason, developing more economical, environmentally friendly, and high-performance water-retentive hydrogel systems is of great importance.

The main objective of this study is to develop a new hydrogel formulation that can be used in agricultural applications and to evaluate the effects of the developed formulation on water retention capacity and plant growth.

MATERIAL AND METHOD

In this study, superabsorbent polymer, organic additives, cross-linking agents, and stabilizer components are used in the preparation of the hydrogel formulation. A polyacrylate-based superabsorbent material is preferred as the main polymeric structure. Cellulose derivatives are utilized to increase the mechanical strength of the formulation.

The agricultural soil to be used in the trials will be homogenized, sieved, and used under standard moisture conditions. Fast-growing test plants have also been selected for the pot trials.

In preparing the hydrogel formulation, superabsorbent polymer, organic additive, and cross-linking agent will be mixed at determined ratios. The mixture will be homogenized under controlled temperature and left to cure for a specific period. The resulting hydrogel structure will be dried and converted into granular form.

The following parameters will be examined to evaluate the performance of the prepared formulations:

Water absorption capacity

Swelling ratio

Water release time

Stability in soil

Resistance to repeated wetting-drying cycles

Controlled pot trials will be conducted to determine hydrogel performance. The trial groups are planned to be formed as follows:

Control group: soil without hydrogel

Trial group 1: soil containing 0.2% hydrogel

Trial group 2: soil containing 0.5% hydrogel

Trial group 3: soil containing 1.0% hydrogel

The following measurements will be taken at specific intervals:

Soil moisture percentage

Irrigation frequency

Plant height

Number of leaves

Fresh and dry biomass amount

RESULTS AND DISCUSSION

It is anticipated that the developed hydrogel formulations will retain water in the soil for longer periods compared to the control group. In particular, formulations with high absorption capacity are expected to extend irrigation intervals and reduce water losses.

In the hydrogel-treated groups, plant height, leaf development, and biomass amount are predicted to be higher than in the control group.

The results to be obtained are anticipated to demonstrate that superabsorbent hydrogel applications can provide significant advantages in agricultural water management. In line with studies in the literature, the developed formulation is expected to increase soil moisture retention capacity.

The positive effects of hydrogel applications on plant growth are particularly important in terms of reducing water stress. It is thought that the reduction in irrigation frequency could both decrease water consumption and reduce production costs.

Formulations containing organic additives are considered to offer advantages in terms of environmental sustainability and could be integrated with controlled-release fertilizer systems.

CONCLUSIONS

Within the scope of this study, the water-retentive hydrogel formulation developed is considered to be a significant material that can improve agricultural irrigation efficiency. It is thought that the developed formulation could reduce irrigation frequency and support plant growth by retaining soil moisture for longer periods.

In future studies, it is recommended that greenhouse and open-field trials be conducted to evaluate performance under different climate and soil conditions. In addition, new formulation development studies using biodegradable raw materials could be carried out.

ABSTRACT

Maintaining a clean and healthy environment is directly linked to the preservation of ecosystems and biodiversity. In this context, the use of eco-friendly materials is gaining increasing importance in the construction sector. Energy efficiency, resource utilization, and material selection are among the fundamental assessment criteria in widely used green building certification systems. Energy efficiency improves as the level of naturalness of construction materials increases and the extent of their processing decreases. Research indicates that prioritizing the use of plant-based materials in building design and construction is essential for minimizing energy consumption. Plant-based construction materials—particularly those derived from renewable sources and possessing low embodied energy—represent a significant alternative to traditional materials; consequently, the use of bio-based and biocomposite materials is rising within the industry as part of a sustainability-oriented approach. Plant-based materials stand out due to their natural, eco-friendly, and sustainable characteristics; they hold significant global potential in the construction materials sector thanks to their renewability, ability to reduce carbon footprints, contribution to occupant health, and excellent insulation performance. For these reasons, plant-based construction materials are viewed as a crucial step toward achieving sustainability goals in the construction industry. Researching, developing, and promoting the use of these materials is of great importance for sustainable building design. This study aims to evaluate the effectiveness of plant-based construction materials in terms of resource and energy efficiency. Within this scope, the study examines the role of plant-based construction materials in sustainable building production and their relationship with the life cycle assessment approach. The potential contribution these materials can make to the sustainable construction sector is being examined by analyzing their role within national and international regulations, green building certification systems (BREEAM, LEED, CASBEE, GBTool, etc.), and life cycle assessment tools.

Keywords: Plant-based building materials, Life cycle assessment, Green building certificate systems, Energy use, Embodied energy.

INTRODUCTION

Driven by population growth, industrialization, and urbanization, the construction sector is characterized by high energy and raw material consumption and significant environmental impact. Regarding the sectoral distribution of energy consumption in Türkiye as of 2024, the largest shares belong to the industrial (32.2%) and transportation (28.5%) sectors. These are followed by the residential sector (23.8%) and the agriculture and livestock sector (10.8%) (ghg-turkiye.com, 2024). Assessing the environmental performance of buildings requires

considering not only energy requirements during the operational phase but also the entire life cycle of building materials, spanning from pre-production to disposal. Furthermore, chemicals, volatile organic compounds (VOCs), and formaldehyde—utilized or generated during raw material sourcing, production, and transportation—can pose risks to indoor air quality and human health (Zorlu, 2019). Consequently, it is crucial to consider environmental criteria such as low embodied energy, the use of renewable raw material sources, recyclability, and low water consumption when evaluating materials. In particular, the European Union's targets to reduce carbon emissions by 55% by 2030 and achieve climate neutrality by 2050 are driving efforts toward more efficient resource and energy use within the construction sector (eu.immib.org, 2023). The environmental issues and consumption patterns associated with the construction sector necessitate the consideration of sustainable materials that enhance energy and resource efficiency while minimizing environmental impact. Plant-based building materials offer an alternative to conventional materials due to their derivation from renewable sources, low embodied energy potential, carbon sequestration capabilities, and thermal and acoustic insulation performance. An examination of international examples reveals that various raw materials—such as wood, bamboo, hemp, straw bales, cork, mycelium, flax fiber, and rice husks—are utilized in diverse building types, ranging from residences and educational facilities to cultural centers and high-rise structures. These global applications demonstrate the technical, environmental, and economic viability of plant-based building materials, thereby serving as a guide for future initiatives in Türkiye. Figure 1 illustrates the geographical distribution of selected buildings worldwide that utilize plant-based building materials. The examples examined show that a variety of plant-based materials are employed across diverse building typologies, including educational facilities, cultural centers, residences, pavilions, and high-rise structures.

Figure 1. Examples of buildings worldwide that utilize plant-based construction materials.

Information regarding the examples shown on the map is presented in Table 1. These examples demonstrate the applicability of plant-based building materials across various climatic conditions and building types.

Table 1. Selected examples of buildings worldwide utilizing plant-based construction materials and their characteristics.

Figure 2 illustrates the geographical distribution of traditional practices involving the use of plant-based building materials in Türkiye. Depending on local conditions, wood is observed to be widely used in various regions, particularly in Safranbolu Houses and the Eastern Black Sea Region. While straw is utilized as an additive in adobe construction in the Central Anatolia Region, reed is traditionally used for roofing and shading structures along the Mediterranean coast. These examples demonstrate that plant-based building materials are employed in Türkiye, particularly within the context of traditional building culture.

Figure 2. Examples of traditional buildings in Türkiye that utilize plant-based construction materials.

MATERIAL AND METHOD

This study investigates the role of plant-based building materials in sustainable building production and their relationship with the life cycle assessment (LCA) approach; it also examines the criteria for their use and evaluation within green building rating systems, as well as the approaches employed within the LCA framework. Based on the data obtained, the study analyzes the potential of plant-based building materials to reduce resource and energy consumption, prevent waste, and contribute to sustainable building production**.**

The study seeks to answer the following research questions:
What is the potential of plant-based building materials to reduce resource, energy, and waste consumption in architecture?

What is the role of plant-based building materials within green building rating systems?

CLASSIFICATION OF BUILDING MATERIALS AND RELEVANT REGULATIONS

"Construction material" refers to the various elements—defined by their specific properties—that constitute the physical environment and structural components essential for human life (Eriç, 2002). While material properties are generally examined under two main categories—intrinsic and extrinsic properties (Bayraktar, 2010)—materials are classified based on various criteria such as intended use, production method, origin, form, and physical and chemical characteristics (Şimşek, 2003). In addition to traditional materials like stone, wood, and brick, technological advancements have led to the use of a wide range of construction materials, including steel, concrete, plastics, composites, biomaterials, and smart materials. Plant-based construction materials are those in which at least one of the primary components is derived from renewable biological sources, plant biomass, or agricultural waste (Le et al., 2023). Plant fibers, starches, oils, and various agricultural wastes can be utilized in their production. Lignocellulosic sources—such as sugarcane, bamboo, jute, kenaf, rice stalks and husks, wheat, corn, hemp, straw, and flax—are among the primary raw materials that can be utilized in the production of construction materials (Youngquist et al., 1994). The quantities of global fiber sources are presented in Table 2.

Table 2. Quantity of global fiber sources (arastirma.tarimorman.gov., 2024; Yazıcı, 2024)

Fiber sources in the world	Quantity (tons)
Barley	143,3 million
Jute (2022)	3.503,448
Coconut (2022)	1.939,429
Flax (2022)	875,995
Hemp (2021)	274,883
Kenaf (2022)	224,926
Sisal (2022)	213,305
Sunflower	52,048
Cotton	51,8
Ramie (2022)	7,625

The diversity and widespread nature of agricultural production in Turkey facilitate the generation of various plant-based wastes and allow them to be utilized as raw material sources for the production of building materials. Table 3 shows the status of agricultural wastes in Turkey—specifically those suitable for use as fibers. Such materials, derived from renewable resources, can be classified as green building materials because, under appropriate production and usage conditions, they contribute to reducing environmental burdens and enhancing the comfort of building occupants.

Table 3. Production quantities of fiber sources in Türkiye (arastirma.tarimorman.gov., 2024; tuik.gov., 2025)

Turkey's fiber sources	Annual (Million Metric Tons)
Wheat	17,9
Corn	8,5

Barley	6
Cotton	2.2
Sunflower	1,8
Rice	1,19
Oats	0.3
Rye	0.2

The use of renewable resources and the repurposing of agricultural waste in the construction sector allow plant-based materials to be addressed within the framework of resource efficiency and the circular economy. The fibers used in the production of these materials can be classified as natural or man-made, depending on their method of extraction. Natural fibers offer significant advantages in construction materials due to their low cost, low specific gravity, ease of processing, low energy requirements, and favorable thermal and acoustic properties. However, they also possess characteristics that must be taken into account, such as low resistance to moisture and fire, property fluctuations due to weather conditions, and susceptibility to biological degradation.

LEGAL REGULATIONS ON BUILDING MATERIALS

In Turkey, the construction materials sector encompasses various product groups such as concrete, cement, steel, wood, glass, ceramics, and insulation materials. Technical standards and conformity requirements form the basis for the production and use of construction materials, with these standards established by the relevant national authorities (Bringas, 2004). Amidst growing environmental concerns, the resource and energy efficiency of construction materials, as well as their environmental impacts, are gaining increasing importance within the scope of regulations and standards. The Construction Products Regulation mandates that construction products meet seven basic requirements: mechanical resistance and stability; safety in case of fire; hygiene, health, and the environment; safety and accessibility in use; protection against noise; energy economy and heat retention; and the sustainable use of natural resources (Construction Products Regulation, 2013). While the Energy Efficiency Law and the Regulation on Energy Performance in Buildings establish criteria for reducing energy consumption and improving energy performance in buildings, the Environmental Impact Assessment (EIA) Regulation aims to evaluate the potential environmental impacts of projects. Furthermore, the Waste Management Regulation sets out principles for waste reduction, reuse, recovery, and disposal without harming the environment. Regulations concerning air, water, and soil pollution also support the control of environmental impacts that may arise from the production processes of construction materials. When these regulations are considered collectively, it becomes evident that the selection of construction materials requires taking into account not only technical performance but also energy consumption, resource utilization, emissions, waste generation, and environmental impacts throughout the material's life cycle. Various approaches—such as TSE and ISO standards, Environmental Product Declarations (EPD), eco-labeling, green building certification systems, and Life Cycle Assessment (LCA)—are utilized to evaluate the environmental impacts of construction materials. These systems enable the determination and comparison of energy and resource consumption, emissions, waste generation, and environmental impacts from the production stage through to the end of the material's service life. LCA, in particular, serves as a crucial tool for sustainable material selection by facilitating a systematic evaluation of environmental impacts arising throughout the material's life cycle. In this context, the aforementioned standards, evaluation methods, and

certification systems provide a fundamental framework for assessing plant-based construction materials in terms of resource and energy efficiency.

LIFE CYCLE ASSESSMENT-LCA and BUILDING CERTIFICATION SYSTEMS

As environmental impacts have increasingly intensified worldwide, awareness regarding environmental consciousness and sustainability has also grown. In this context, it is crucial to address the principles and strategies underpinning sustainable architecture in a manner that ensures their compatibility and mutual reinforcement. Life Cycle Assessment (LCA)—one such approach—serves as a systematic method enabling the combined evaluation of qualitative and quantitative data to determine the environmental impacts of structures and building materials. LCA is a method used to assess the environmental performance of a product or material. While the traditional "cradle-to-grave" approach in life cycle assessments covers the processes spanning from raw material sourcing to the end of a product's service life, the "cradle-to-cradle" approach prioritizes the reuse and recovery of materials rather than treating them as waste after use. Developed by McDonough and Braungart, this approach offers a sustainable design philosophy that supports the circular use of resources, renewable energy, and environmental health (McDonough & Braungart, 2016). Within this approach, evaluating the energy requirements associated with the production and use of building materials is just as important as the efficient use of resources throughout their life cycle. Embodied energy refers to the total energy consumed by a building material throughout its life cycle—spanning raw material sourcing, production, transportation, construction, use, maintenance, reuse, recycling, and disposal (Cabeza et al., 2014). As a key criterion for assessing the environmental performance of building materials, embodied energy plays a significant role in sustainable material selection by helping to reduce energy consumption and carbon emissions. Plant-based materials represent a significant alternative in sustainable building design, as they are derived from renewable sources and—in the case of certain types—possess the potential for carbon storage alongside low production energy requirements.

There are numerous certification systems used by various countries around the world to assess the environmental impact of buildings. Brief information regarding the most widely used certification systems is presented in Table 4.

Table 4. Green building systems used in different countries

Certificate	Country	Publication Year	Number of Certified Buildings	Reference Year
LEED	ABD	1998	107.319 (usgbc.org, 2025b)	2025
BREAM	England	1990	More than 1.045,000 (breeam.com, 2025a)	2025
GREEN STAR	Australia	2003	More than 5.500 (gbca.org.au, 2025)	2025
DGNB	Germany	2009	12.900 (dgnb.de, 2"024)	2024
CASBEE	Japan	2001	More than 5.105 (ibecs.or.jp, 2026)	2026
SBTOOL	Canada	1998		

BEAM PLUS	Hong Kong	1996	2165 (beamsociety.org, 2025)	2025
B.E.S.T.	Türkiye	2013	23 (dilekasan.com, 2022)	2022
YeS –TR	Türkiye	2021	Resmi veri bulunmamaktadır	2021
IGBC	India	2001	More than 18.620 (igbc.in, 2026)	2026

To outline the assessment approaches of certification systems regarding construction materials, material categories, their sub-categories, and assessments concerning plant-based materials were examined separately and compared in Table 5.

Table 5. Comparison of Material Categories in Green Building Certification Systems

Certification System	**Material Category**	**Score/Weight of the Material Category**	**Subcategories of the Material Category and Evaluation of Plant-Based Materials**	
LEED (usgbc.org, 2025a)	Materials and Resources	18 Point	Zero Waste Operations Planning	Precondition
			Quantify and Evaluate Embodied Carbon	Precondition

In green building certification systems, materials are evaluated based on general criteria such as "sustainable building materials," "use of environmentally friendly materials," and "low-emission materials." However, the unique characteristics of plant-based materials—such as renewability, low embodied energy, carbon storage, biodegradability, and resource efficiency—are not directly addressed. Therefore, it is important to develop specific and distinguishing criteria within certification systems to make the environmental advantages of plant-based building materials more visible.

CONCLUSIONS

The creation of the built environment and the production of building materials result in the consumption of natural resources and energy. The study demonstrates that sustainable building production does not depend solely on material selection; rather, proper design, appropriate construction techniques, and conscious usage must be addressed holistically.

To promote the widespread use of plant-based materials, it is crucial to utilize rapidly renewable plants—cultivable with low energy and water consumption—and agricultural waste in the production of building materials. Sustainability criteria such as carbon footprint, recyclability, life-cycle performance, and reusability need to be more extensively integrated into standards and assessment systems. Furthermore, the adoption of material and digital product passports will strengthen resource efficiency and the circular economy approach by enabling the monitoring of material composition, service life, environmental impacts, and potential for reuse.

Future research should conduct a detailed analysis of the life cycle of plant-based building materials—spanning production, usage, and disposal—in terms of energy consumption, carbon

footprint, and resource utilization. It is important to compare the environmental and technical performance of various materials—such as hemp, straw, bamboo, flax, and fungi—against traditional building materials, and to evaluate properties like mechanical strength, fire resistance, moisture behavior, and thermal performance under varying climatic conditions. Furthermore, the application of BIM, energy simulations, and digital modeling methods can help predict how these materials perform in different types of structures. Additionally, research is needed on aspects such as cost, production capacity, supply chains, and the use of local resources when scaling up from laboratory studies to industrial production. Beyond the economic and sectoral barriers affecting the widespread adoption of these materials, it is also crucial to examine the levels of awareness and acceptance among designers, practitioners, and end-users. Finally, increasing interdisciplinary research will contribute to a more comprehensive understanding of the environmental, technical, and economic potential of plant-based building materials.

ABSTRACT

Plant genetic resources (PGR) constitute a fundamental component of agricultural biodiversity and include genetic material of actual or potential value for food and agriculture. Their effective conservation and sustainable utilization require not only appropriate storage conditions but also a reliable, standardized and continuously updated documentation system. The Bulgarian system for plant genetic resources documentation was developed as an integrated information framework supporting the conservation, management, characterization, evaluation, exchange and utilization of germplasm maintained in the National Genebank at the Institute of Plant Genetic Resources "Konstantin Malkov" – Sadovo. The documentation system integrates passport information, taxonomic and geographical data, collecting and acquisition information, biological status, storage conditions, regeneration, evaluation and characterization data, as well as information related to the distribution and use of accessions. Its structure follows the FAO/Bioversity Multi-Crop Passport Descriptors and the requirements of the European Search Catalogue for Plant Genetic Resources (EURISCO), thereby providing compatibility and interoperability with European and international information networks. The system incorporates functional modules for accession registration, passport data management, expedition documentation, accession searching, storage and regeneration management, and controlled data access. An important feature of the system is the distinction between a public interface for researchers and other users and a protected management environment for authorized genebank specialists. Open access to passport information, including mobile access, increases the visibility and usability of Bulgarian plant genetic resources. The system also supports the National Inventory of plant genetic resources and the transfer of validated and harmonized data to EURISCO. The documentation framework provides traceability of accessions from acquisition and registration through storage, regeneration, characterization and distribution. Its implementation contributes to the modernization and digitalization of genebank management and strengthens the role of the Bulgarian National Genebank as a national and international information centre for plant genetic resources.

Keywords: Accession, GeneBankSystem, Descriptors, Expedition, Introduction, Crop breeding.

INTRODUCTION

Plant genetic resources for food and agriculture represent an essential component of agricultural biodiversity and provide the genetic basis for crop improvement, adaptation and sustainable food production. The diversity of crops, traditional varieties, landraces, breeding materials and crop wild relatives provides genetic variation that may be valuable for adaptation to changing environmental conditions, emerging pests and diseases, and new production systems. The

conservation of this diversity is therefore directly associated with long-term food security and the resilience of agricultural systems (Salgotra & Chauhan, 2023).

Modern agriculture relies increasingly on a relatively limited number of high-performing cultivars. This tendency may contribute to genetic erosion and the loss of traditional varieties and locally adapted populations. Landraces and traditional populations may contain valuable characteristics associated with adaptation to local environmental conditions, disease resistance, quality traits and specific consumer preferences. Consequently, their conservation in genebanks, combined where possible with in situ and on-farm conservation, is an important component of sustainable management of agricultural biodiversity (Raggi et al., 2021).

Ex situ conservation in genebanks provides an effective mechanism for the long-term preservation of plant genetic resources. However, the biological material alone is insufficient to ensure its effective future use. The scientific and practical value of an accession depends strongly on the availability, accuracy and completeness of information associated with it. Documentation has to allow the identity, origin, biological status, storage history, reproduction, characterization and utilization of each accession to be traced throughout its conservation cycle. The documentation of plant genetic resources is therefore an integral part of genebank management (FAO, 2013; ECPGR, 2021).

The Bulgarian National Genebank, located at the Institute of Plant Genetic Resources "Konstantin Malkov" – Sadovo, maintains collections comprising local populations, traditional varieties, modern cultivars, breeding lines, genetic stocks and crop wild relatives. The collections are managed through a specialized documentation system that integrates information generated during accession acquisition, registration, conservation, regeneration, characterization, evaluation and distribution. The system was developed through long-term interdisciplinary cooperation between researchers from IPGR-Sadovo and computer scientists (Stoyanova-Doycheva et al., 2020; Malinov et al., 2025).

The development of a standardized documentation framework in Bulgaria is also closely related to European and international initiatives for harmonization and exchange of plant gene pool information (Goritschnig et al., 2024). The Bulgarian National Genebank participates in the European Search Catalogue for Plant Genetic Resources (EURISCO) and coordinates the maintenance of the Bulgarian National Inventory. The system applies the FAO/Bioversity Multi-Crop Passport Descriptors, which provide a common structure for passport information and facilitate data exchange between national and international information systems.

The importance of interoperable documentation systems has increased with the development of digital infrastructures for plant genetic resources. Standardized information enables data aggregation, validation, searching and dissemination, while open access increases the potential for researchers, breeders and other stakeholders to identify and use conserved germplasm. Digitalization is therefore not simply a technical transformation of records into databases, but a means of improving the quality, accessibility, interoperability and long-term value of plant genetic resources information (Mendel et al., 2017; Cicova et al., 2026).

The objective of this study was to describe the design, structure and current status of the Bulgarian plant genetic resources documentation system, with particular emphasis on the information architecture of the GeneBankSystem at IPGR-Sadovo, the implementation of standardized descriptors, the documentation of enrichment of collections, data management and the integration of national information with EURISCO.

MATERIAL AND METHOD

Source of information

The study was based on the methodological framework for plant genetic resources enrichment and documentation developed for the Bulgarian National Genebank at IPGR-Sadovo. The

documentation procedures, database structure, passport descriptors, expedition records, GeneBankSystem modules and principles of data exchange were analyzed.
The methodological framework follows international standards, particularly the FAO/Bioversity Multi-Crop Passport Descriptors (FAO/Bioversity, 2017), the FAO Genebank Standards for Plant Genetic Resources for Food and Agriculture (FAO, 2013), and the documentation and quality-management principles promoted by European program (ECPGR).
Structure of accession documentation
The basic documentation unit is the accession. Each accession receives a unique identification – catalogue number (COLLNUMB) at registration, which remains associated with the genetic resource throughout its storage, evaluation, regeneration and utilization.
The national accession number (ACCENUMB) is generated according to the established registration system and is not reused for another genetic resource.
The passport database is structured according to the FAO/Bioversity MCPD and EURISCO standards. The main groups of descriptors include:
taxonomic identification;

accession identification;

origin and acquisition;

collecting information;

geographical coordinates;

elevation;

biological status;

breeding and ancestral information;

collecting/acquisition source;

donor information;

storage conditions;

access and exchange status;

additional identifiers and remarks.

Four core fields – NICODE (National Inventory code), INSTCODE (Institute code), ACCENUMB and GENUS, provide the essential identification structure of an accession within the EURISCO framework. Their combination is intended to ensure uniqueness of the record and reduce duplication.
The system also supports the use of persistent unique identifiers PUID (Digital Object Identifier from FAO), which provide the possibility of unambiguous identification of a genetic resource at the global level.
Documentation of collecting expeditions
Expeditions constitute an important mechanism for enriching the Bulgarian genebank collections, particularly through the collection of local varieties, landraces, farmer populations and crop wild relatives. During collecting missions, seed or vegetative material is collected

together with information concerning geographic location, environmental conditions, local names, cultivation practices and traditional uses.
The documentation system includes a dedicated expedition module. It records the participants, financing organization, project, geographic and ecological characteristics of the area, and the collected accessions. Search filters facilitate retrieval of expedition records according to different criteria.
A standardized questionnaire has also been developed for interviews with farmers maintaining local varieties. The questionnaire includes expedition identification, collection date, collector, geographic location, environmental characteristics, information about the farmer, taxonomic information and local accession name, as well as information about farm size, reasons for growing the accession, production destination, seed sources and traditional uses.
GenaBankSystem (https://genbank.uni-plovdiv.net/) architecture
The Bulgarian genebank documentation system is a web-based platform designed for integrated management of information associated with the conservation, study and distribution of plant genetic resources. It consists of two interconnected functional environments.
The public component provides external users with access to accession information and searching by passport data. The protected component is available to authorized users through authentication and is intended for documentation specialists and collection curators responsible for managing accessions in the active and base collections.
The system integrates several functional modules, including:
registration of new accessions;

passport-data management;

accession searching;

expedition documentation;

storage and regeneration information;

characterization and evaluation data;

accession distribution;

data administration and updating.

This modular structure allows information associated with an accession to be maintained as a continuous record rather than as isolated datasets.
Data quality, updating and protection
Data quality is maintained through continuous updating, validation and correction. Curators are responsible for maintaining reliable information for the collections under their responsibility, while documentation specialists are responsible for the quality of passport information introduced during accession registration.
When information for a particular descriptor is unavailable and cannot be established from other sources, the field remains unfilled rather than being populated with unsupported information. Data entered into the system must remain compatible with the European exchange format to facilitate automated transfer to international information networks.
The system also provides data protection and continuity through electronic registration and archival copies maintained on primary and backup servers.

RESULTS AND DISCUSSION

Integrated documentation framework

The analysis demonstrates that the Bulgarian documentation system has evolved from a MS Access database register Phyto 2000 into an integrated digital framework for the management of plant genetic resources. GeneBankSystem connects accession identity with information generated at different stages of the conservation process.

The documentation starts with accession acquisition and registration and continues through storage, regeneration, evaluation, characterization and distribution. Consequently, the accession record represents not only a passport description but also a dynamic information resource reflecting the history and status of the genetic material.

The main categories of operational data include evaluation and characterization results, germination information, regeneration and multiplication records, storage type and distribution to users. Regular updating of these records supports the reliability and traceability of the collections. This approach corresponds to the principle that documentation should support the complete management cycle of a genebank accession rather than only its initial registration.

Standardization of passport data

One of the main strengths of the Bulgarian system is its alignment with the FAO/Bioversity Multi-Crop Passport Descriptors and EURISCO. Standardization makes it possible to describe accessions using a common taxonomy and data structure.

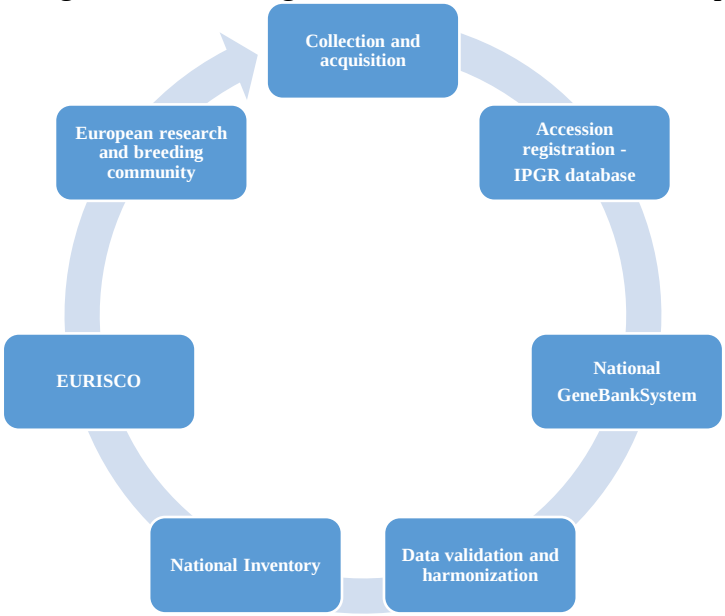
The database contains descriptors for taxonomic identity such as GENUS, SPECIES, SPAUTHOR, SUBTAXA and CROPNAME. Origin and collecting descriptors include COLLNUMB, COLLCODE (Collecting institute code), ORIGCTY (Country of origin), COLLSITE (Location of collecting site), COLLDATE (Collecting date) and COLLSRC (Collecting/acquisition source). Geographic information is represented through latitude, longitude and elevation.

The biological status descriptor SAMPSTAT (Biological status) allows accessions to be differentiated as wild material, traditional cultivars/landraces, breeding and research material, genetic stocks, and advanced or improved cultivars. This provides an important basis for distinguishing different categories of genetic resources within the national collection.

The system also documents storage categories, including seed collections, medium- and long-term storage, field collections, *in vitro* collections.

Such standardization is particularly important when national data are incorporated into international catalogues. EURISCO uses standardized passport descriptors to enable data exchange and facilitate access to information on European genebank collections.

Unique identification and traceability



Traceability is a central principle of the Bulgarian documentation system. Each accession receives a unique national accession number, while additional identifiers may link it to collecting institutions, donor institutions, previous catalogue numbers or other databases. The ACCENUMB identifier is assigned at registration and cannot subsequently be reused for another accession. The system therefore preserves the identity of an accession even if the original biological material is lost. This approach provides continuity between physical germplasm and its digital representation. It also supports the identification of duplicates, the management of regeneration activities and the interpretation of research data associated with individual accessions. The use of additional identifiers, donor accession numbers and persistent identifiers creates opportunities for linking national records with other institutional and international information resources.

Documentation of plant genetic resources

A specific strength of the Bulgarian system is its capacity to document local plant genetic resources collected directly from traditional agricultural systems. Local varieties and landraces are frequently maintained by small-scale farmers and gardeners outside formal breeding programmes. Their documentation therefore requires information that goes beyond

conventional passport descriptors. The expedition questionnaire developed within the methodological framework records not only the identity and geographical origin of the accession but also farmer-related information, cultivation practices, reasons for maintaining the material, production destinations, seed sources and traditional uses. This additional information increases the cultural, historical and practical value of the accession record. It can also support future research on the relationship between genetic resources, traditional knowledge, agricultural practices and local food systems. The inclusion of collecting-site information and geographic coordinates also creates opportunities for analysis. Geographic descriptors can be used to identify areas of concentration of particular genetic resources, support future collecting missions and contribute to analyses of adaptation and diversity.

In essence, the introduction activity of international free germplasm exchange, which is carried out by the genebank in Sadovo using SMTA (FAO, 2006), serves the crop improvement programs of the breeding institutes in Bulgaria. Accessions are introduced upon special requests

with diverse geographical origins for study in the conditions of the country and for use as donors of valuable traits as ecological plasticity, resistance to a given pathogen, high productivity, etc. The main partners of the National Genebank in the exchange are: GRIN (USA), ICARDA, NordGen, IPK (Germany), INRA (France), John Innes Center (Great Britain).

The genebank conserves seeds of Bulgarian advanced varieties and breeding lines, the result of crop improvement programs, for long-term storage, which are registered in the GeneBankSystem with data on pedigree, breeding institution and access level.

Integration of the National Inventory with EURISCO

The Bulgarian National Genebank is presented in EURISCO and performs a coordinating role in relation to the Bulgarian National Inventory. The National Inventory integrates passport information from collections maintained by different Bulgarian scientific institutions. The National Focal Point is responsible for collecting, validating, harmonizing and periodically submitting information to EURISCO Intranet. Thus, the documentation system functions not only as an institutional database but also as a national information infrastructure connecting different plant genetic resources collections. The national-to-European data transfer is represented on the Figure 1.

Figure 1. Integration of the Bulgarian National Inventory with European plant genetic resources community system

Such interoperability increases the international visibility of Bulgarian plant genetic resources and facilitates their identification for scientific research, breeding and conservation activities. According to Mendel et al. (2026), improved data management and documentation contribute to the visibility and usability of genebank collections. The integration with EURISCO further strengthens this role by providing a standardized European environment for accessing passport information.

Open access and user-oriented information services

The transition from an internal database to a web-based information environment represents an important development in the Bulgarian GeneBankSystem. The public interface provides external users with access to accession information, while the protected component enables professional management of the collections.

Open access is available in both Bulgarian and English, and a mobile application has been developed to facilitate access by external users.

This approach is consistent with the broader development of digital infrastructures for genebank and responds to the increasing demand for accessible and interoperable information. Open access does not replace the physical conservation of germplasm; rather, it increases the visibility of conserved material and enables potential users to identify resources before requesting biological material.

The availability of standardized passport information is particularly important for breeders and researchers because it allows them to search collections according to crop, taxonomic identity, geographical origin, biological status and other characteristics.

Data security and quality management

The implementation of data backup and controlled access is another important element of the system. Information is maintained in electronic registers and backed up on primary and secondary servers, reducing the risk of data loss and supporting continuity of genebank operations. Data quality is further supported by defined responsibilities among documentation and conservation specialists and collection curators. Information may be corrected or supplemented when new evidence becomes available. This is particularly important for historical accessions, for which passport information may initially be incomplete. The system therefore follows a dynamic model of documentation in which accession records are considered continuously improvable rather than static records created only at the time of acquisition.

Current status and development potential

The current documentation framework provides an integrated digital environment for managing accession information in the Bulgarian National Genebank. Its main achievements include standardized passport documentation, unique accession identification, expedition documentation, integration of storage and regeneration information, evaluation and characterization records, public access and interoperability with EURISCO.

According to ECPGR (2023) and Velcheva et al. (2026) the system provides a foundation for further digital development. The GeneBankSystem explicitly defines the documentation framework as a dynamic structure that is expanded and updated with innovative techniques by IS-PGR-SADOVO public financed project. Future development is focus on increasing the interoperability of phenotypic datasets, improving geospatial functionality, strengthening links between passport and characterization data, expanding and implementing additional mechanisms for data validation and quality control. An important future direction is also the integration of more detailed characterization and evaluation datasets. While passport data provide the identity and origin of accessions, characterization and evaluation data provide the information needed to assess their actual value for breeding, research and sustainable agriculture.

CONCLUSIONS

The Bulgarian GeneBankSystem represents an integrated digital framework for the management of information associated with the national germplasm collections maintained at the National Genebank of IPGR-Sadovo.

The system combines accession registration, standardized passport documentation, collecting and expedition information, geographical data, biological status, storage and regeneration records, characterization and evaluation information, and distribution data. The use of FAO/Bioversity Multi-Crop Passport Descriptors and alignment with EURISCO provide an internationally compatible structure for data exchange and interoperability.

A major achievement is the introduction of a unique and traceable accession identification system that maintains the connection between the physical genetic resource and its digital record throughout the accession conservation process. The expedition module enables the documentation of local varieties and landraces together with information on their traditional cultivation and utilization.

The integration of the Bulgarian documentation system with the National Inventory and EURISCO increases the visibility of Bulgarian plant genetic resources and facilitates their discovery and potential use by researchers, breeders and other stakeholders. The public web interface and mobile access further support the open-access principle.

The system provides mechanisms for data quality control, updating, backup and controlled access, which are essential for the long-term reliability of genebank documentation.

Overall, the Bulgarian GeneBankSystem demonstrates that digital documentation is an essential component of modern germplasm management. By connecting physical conservation with standardized, interoperable and accessible information, the system strengthens the capacity of the Bulgarian National Genebank to conserve, document, study and promote the sustainable use of plant genetic resources. Its modular and dynamic structure provides a basis for further integration of new data types, innovative technologies and European and international information infrastructures.

ACKNOWLEDGEMENTS

The research work was carried out under the project IS-PGR-SADOVO “Intelligent system for managing Bulgarian plant gene pool, conserved in the genebank of IPGR-Sadovo” with the financial support of the Ministry of Education and Science, Contract number KP-06-H86/9/09.12.2024 of Bulgarian National Science Fund.

ABSTRACT

The long flowering period in carrots, starting with the flowers from the central umbel and continuing with those from the umbels on the branches of the I, II and III order, leads to the formation and maturation of seeds at different stages of the mother plant. This determines the different quality of the seeds, as well as the presence of heteroblasty in the resulting seed production. The main objective of the present study is to investigate the influence of the nutrient regime and the order of the umbels on the quality of the seeds in carrots. Three levels of NPK were studied, as follows: N – 0, 50, 70, 90 kg.ha^{-1}, P – 0, 90, 140, 190 kg.ha^{-1} and K – 0, 100, 150, 200 kg.ha^{-1}, applied once and twice. The share of individual umbels in the formation of the total seed yield, the linear dimensions of the seed – length, width and thickness, mass of 1000 seeds, the quality of the seeds by determining the germination energy, germination, mean germination time and uniformity of germination, as well as the morphological features of the seedlings – length of the embryo root and hypocotyl, and fresh and dry mass of the seedlings were determined. The different nutrient regime affects the quality of the seeds and the morphological parameters of the seedlings in carrots, helping to reduce the quality difference. This is most clearly observed when fertilizing with $N_{90}P_{90}K_{200}$, as well as with $N_{90}P_{190}K_{100}$ (once application) and $N_{90}P_{90}K_{200}$ (twice application), where the differences in germination energy and germination between seeds from individual orders are the smallest.

Key words: *Daucus carota* L., heteroblasty, germination, seed, vigour, yield

INTRODUCTION

Flowering in carrots begins with the flowers from the central umbel and continuing sequentially with the umbels on the first, second, and third order branches. This period is characterized by a long duration, with seeds forming and ripening at different stages of the mother plant's development and under different climatic conditions. This leads to the formation of seeds with different quality (Panayotov, 2005). A number of authors Manimurugan et al., (2017), Thakur et al. (2015), Panayatov (2010), Pereira et al. (2008) point out the importance of umbel order on carrot seed quality. Sutradhar et al. (2017) claim that seeds from the central umbel are with the highest quality, followed by those obtained from umbels I, II and III orders. A similar opinion is expressed by Kumar et al. (2017), who found a decrease in seed viability with increasing umbels order. All of this clearly shows the presence of heteroblasty in carrot seeds. There are various approaches that help reduce differences in seed quality. One of them is optimizing the nutritional regime when growing carrot seed plants. According to Noor et al.

(2019) and Kano et al. (2012), seed vigour increased after application of higher levels of phosphorus and potassium. In attempts to optimize the nutritional regime in carrot seed production, Iqbal et al. (2023) indicated that fertilization with $N_{150}P_{125}K_{65}$ kg.ha^{-1} resulted in an increase in seed yield and quality, as well as a decrease in their heteroblasty. In their studies, Ilyas et al. (2013) and Panayotov (2015) express the opinion that phosphorus plays an important role in better insemination of plants and obtaining seeds of equal quality. A similar conclusion ware reached by Lefarmo et al. (2019).

For successful carrot seed production is essential importance the control of carrot fly (Psila rosae Fabr.). This pest is widespread in Europe, North America and New Zealand (Collier & Finch, 1996; Ramert & Ekbom, 1996; Sivasubramaniam, 1996). In the 1950s, chemical control with the pest was carried out using organochlorine compounds (Wright & Coaker, 1968). In modern plant protection practice, insecticides from the group of synthetic pyrethroids are widely used to control of carrot fly.

The main objective of the present study was to determine the differences in carrot seed quality depending on the fertilization regime and umbel order.

MATERIAL AND METHOD

The experiments were carried out during the period 2017-2019 in the Experimental Field and Laboratory of the Department of "Horticulture" at the Agricultural University - Plovdiv, Bulgaria with carrots, variety Tushon. Seed production was carried out using the technology adopted in Bulgaria by preliminary production of stecklings (Murtazov et al., 1984). The stecklings were produced by sowing at the end of June and harvesting in mid-November, after which they were placed for storage during the winter period in a pit. Soil preparation was carried out by deep autumn plowing and furrow profiling in the spring. The stecklings were planted in mid-March according to a scheme of 80x30 cm. Each variant was presented in four replicates with a experimental plot size of 7 m^2 and a explored area of 6 m^2 (Barov, 1982).

Two fertilization regimes were studied: 1. Once fertilization, by applying the entire amount of phosphorus and potassium fertilizers in the fall before deep plowing and nitrogen during planting; 2. Double fertilization - half of the phosphorus and potassium fertilizers were applied before autumn deep plowing, the other half in the spring before planting, and nitrogen fertilizer - half before planting, and the other part during the growing season at the beginning of flowering. The following variants with different fertilization levels in kg.ha^{-1} and application term were studied:: once fertilization: 1.$N_0P_0K_0$ – control; 2.$N_{70}P_{140}K_{150}$ (recomended); 3.$N_{50}P_{90}K_{100}$; 4.$N_{50}P_{90}K_{200}$; 5.$N_{50}P_{190}K_{100}$; 6.$N_{50}P_{190}K_{200}$; 7.$N_{90}P_{90}K_{100}$; 8.$N_{90}P_{90}K_{200}$; 9.$N_{90}P_{190}K_{100}$; 10.$N_{90}P_{190}K_{200}$ and twice fertilization: 11.$N_{50}P_{90}K_{100}$; 12.$N_{50}P_{90}K_{200}$; 13.$N_{50}P_{190}K_{100}$; 14.$N_{50}P_{190}K_{200}$; 15.$N_{90}P_{90}K_{100}$; 16.$N_{90}P_{90}K_{200}$; 17.$N_{90}P_{190}K_{100}$; 18.$N_{90}P_{190}K_{200}$. The different fertilizer rates are determined based on the recommended fertilization for carrot seed production in Bulgaria $N_{70}P_{140}K_{150}$ (Madzharova, 1968; Kolev et al. 1977).

The following fertilizers were used: ammonium nitrate (N 34%), triple superphosphate (P2O5 46%) and potassium sulfate (K2O 50%). During the vegetation of the seed plants, all necessary cultural practices were carried out for their normal development. The seed production was harvested when 60-70% of the seeds were fully mature, and the rest were waxy ripe. The seed stalks were placed for 10 days for post-harvest ripening of the seeds. The seeds from the umbels of the individual orders – central (king), I, II and III, were cleaned separately, after which their linear dimensions – length, width and thickness – were determined (Panayotov, 2015), the mass of 1000 seeds was determined according to the requirements of ISTA (2013). The percentage contribution of individual umbels to the total seed yield was calculated. The germination energy and germination of the seeds from the central umbel and umbels I, II and III order were determined according to the requirements of ISTA (2013). The mean germination time was

calculated using the formula proposed by Battle and Whittington (Wellington, 1972). The uniformity of germination was determined using the Strona method described in detail in Panayotov (2015). The vigor index was calculated using the "Initial vegetative productivity of seeds" method (Panayotov, 2013). The length of the embryo root and hypocotyl was determined on the day of germination determination, by measuring 10 seedlings in four replicates. The fresh mass of one seedling was assessed by measurement of each developed seedling from the three replicates on scale accurate to the third digit and divided into the number of these seedlings. The dry mass of the seedling was determined using a drying oven according to the method described by Black et al. (2008).

During the period of steckling production and the cultivation of seed plants yellow sticky traps were placed to detect the presence of the carrot fly (*Psila rosae* Fabr.).

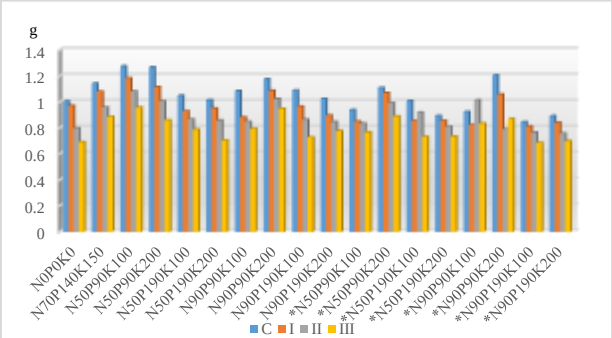
If an infestation is detected, various insecticides from the synthetic pyrethroid group will be used for control.

Due to the similarity in trends over the three years of the experiment, the results shown are the average three-year data.

The data from the study were subjected to analysis of variance (Fowel and Cohen, 1992), and the least significant differences between the individual variants were calculated using the Fisher test at $p = 0.05$, according to the ANOVA method.

RESULTS AND DISCUSSION

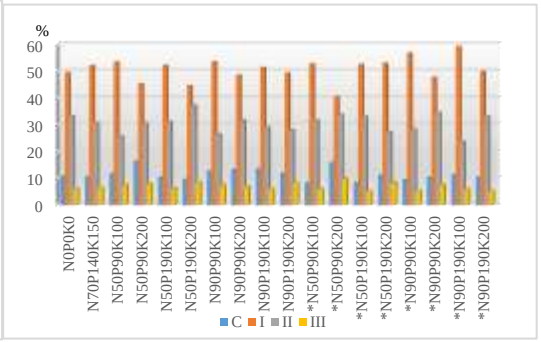
The formation of high and quality seed yields in carrots depends of many factors with ecological and agrotechnological character. For the normal development of seed plants, correct plant protection is essential, especially against pests. During the vegetation period, when field experiments were carried out, no pests with an economic threshold of harmfulness were observed. Carrot seed plants are characterized by a specific morphology, which determines the different participation of individual umbels in the formation of the yield. On average for all tested variants, the share of first-order umbels is 50.61%, followed by second-order umbels with 30.57% (Figure 1). This is due to the larger number of umbels that develop along the branches from first and second order. The umbels from the last III order and the umbels from the central stems are characterized by the least participation. A similar opinion is expressed by Panayotov (2010) and Mengistu and Yamoah (2010), who point out that despite the largest size of the central umbel, as well as the largest weight of the seeds formed in it, the first-order umbels have a major share in the yield, which is related to their greater number.



The participation of the central umbel in productivity is highest after once and twice fertilization with the $N_{50}P_{90}K_{200}$ combination - 16.24 and 15.67%, respectively. The share of first-order umbels increases more significantly after the application of $N_{90}P_{90}K_{100}$ (once) and $N_{90}P_{190}K_{100}$ (twice). A once application of $N_{50}P_{190}K_{200}$, as well as a twice application of $N_{90}P_{90}K_{200}$ and $N_{50}P_{90}K_{200}$ leads to a more significant increase in the percentage share of umbels from second and third order in the total seed yield.

The mass of 1000 seeds is an important indicator that is closely related and depends on the size and density of the seeds. Its importance is also determined by the fact that it directly participates in determining the seeding rate (Mihov et al., 2014).

In carrots, the mass of 1000 seeds decreases smoothly with increasing umbel order. For unfertilized plants, i.e. when developing without additional impact, compared to that of the central umbel, it decreases by 3.38% for the first order and significantly more for the second and third, respectively 19.30 and 27.82% (Figure 2).



In the central umbel, this indicator has the highest value for the option fertilized once with $N_{50}P_{90}K_{100}$ – 1.276 g, followed by $N_{50}P_{90}K_{200}$ and $N_{90}P_{90}K_{200}$ again applied once – 1.269 and

1.178 g, respectively. When applying mineral fertilizers twice, an increase was recorded for the combinations $N_{90}P_{90}K_{200}$ – 1.206 g and $N_{50}P_{90}K_{200}$ – 1.110 g.

* twice fertilization; C – central umbel; I, II, III – orders;

Figure 2. Mass of 1000 seeds depending on the fertilization regime and umbel order, (g)

Seeds from the first-order umbels are characterized by a maximum absolute mass after once application of $N_{50}P_{90}K_{100}$ – 1.184 g, which represents an increase of 0.103 g compared to the fertilized control and 0.249 g compared to the zero control. Fertilization with $N_{50}P_{90}K_{200}$ and $N_{90}P_{90}K_{200}$ leads to produce seeds with the highest mass at the other time of application of mineral fertilizers – 1.071 g and 1.060 g, respectively. A similar pattern was observed for the seeds of the last two orders – II and III.

The applied fertilization levels reduce the existing heteroblasty in carrot seeds. This applies especially to seeds of the III and II order compared to the central umbel and the I order. This decrease is stronger observed in most variants with twice fertilization and compared to the unfertilized dcontrol it is more than doble compared to all previous orders. The reduction in heteroblasty between seeds from the central umbel and from the first order is weaker.

The linear dimensions of seeds have important practical significance for seed cleaning, sorting and mechanized sowing (Panayotov, 2015; Black et al., 2008). The seeds from the central umbel are characterized by the highest values of the three linear dimensions, followed by those from the first-order umbel (Table 1).

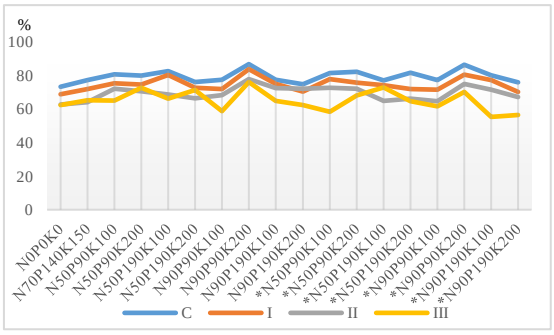
L – length; W – width; T – thickness; C – central umbel; I, II, III – order;



A more significant decrease in length, width and thickness is found in seeds from umbels of the II and especially III order. Panayotov (2010) also reaches a similar conclusion. Fertilizing the carrot seed plants with $N_{50}P_{90}K_{200}$ and $N_{90}P_{90}K_{200}$ at both terms leads to an increase in the linear dimensions of the seeds in individual umbels. A stronger decrease in heteroblasty of the seeds, however, is observed after the application of $N_{50}P_{190}K_{100}$ (once) and $N_{50}P_{190}K_{100}$ and $N_{50}P_{190}K_{200}$ (twice).

To determine the quality of seeds, the most important thing is to establish the basic vital indicators - germination energy and germination. The highest germination energy for all orders was recorded for the variant with single fertilization $N_{90}P_{90}K_{200}$, with the exception of the first order where it was with a twice fertilization. For the central umbel it reaches 83.44% and decreases by 4.12% for seeds of the first order, by 8.78% for those of the second order and by 13.0% for those of the third order (Figure 3). A similar trend was observed for germination (Figure 4).

* twice fertilization; C – central umbel; I, II, III – orders;

Figure 3. Germination energy of carrot seeds depending on the fertilization regime and umbel order, (%)

* twice fertilization; C – central umbel; I, II, III – orders;

Figure 4. Germination of carrot seeds depending on the fertilization regime and umbel order, (%)

From this it can be assumed that seeds that were formed at an earlier stage of the development of the mother plants ripen better, accumulate more nutrients and are characterized by higher quality. A similar opinion is expressed by Sutradhar et al. (2017).

Depending on the applied nutritional regime, the heteroblasty in germination energy and seed germination decreases, and this is observed more clearly in seeds from the first-order umbels compared to those from the central umbel, especially well expressed after once fertilization with $N_{90}P_{90}K_{200}$ and $N_{90}P_{190}K_{100}$, as well as twice with $N_{90}P_{90}K_{100}$ and $N_{90}P_{90}K_{200}$.

Mean germination time is an important indicator that better determines the vital status of seeds (Panayotov, 2015).

The number of days required for germination of seeds from the central umbel and the first-order umbels is about 4 (Table 2). Regardless of the small differences, it can be noted that the seeds from the central umbel germinate faster, with the shortest period was recorded for the combination $N_{90}P_{190}K_{200}$, applied twice (3.32 days). For seeds from first-order umbels, mean germination time decreases significantly after twice fertilization with $N_{90}P_{90}K_{100}$ (3.79 days).

Seeds from the second-order umbels and especially from the third-order umbels germinate much more slowly. The most days for this – 6.05 and 6.31, were required, respectively, for once fertilization with $N_{50}P_{90}K_{100}$ for the second umbel and for a twice fertilization with $N_{90}P_{90}K_{100}$ for the third order seeds, which is approximately 3 days more than the values for the central umbel.

It can be pointed out that the seeds of the last, third order, which are characterized by the lowest quality, germinate almost twice slowly compared to the seeds from the central stems and the umbels of the first-order branches.

The heteroblasty between the seeds from the central umbel and the first umbels is higher only for the variant $N_{90}P_{90}K_{100}$, applied once, while for $N_{50}P_{190}K_{200}$ in the same regime and for $N_{50}P_{190}K_{200}$ when applied twice, it is almost absent.

The differences in mean germination time between seeds of the first and second order are also insignificant, increasing slightly with a twice application of the higher fertilizer rates, and compared to the central umbel, the differences reach almost one day, but are lower compared to the control.

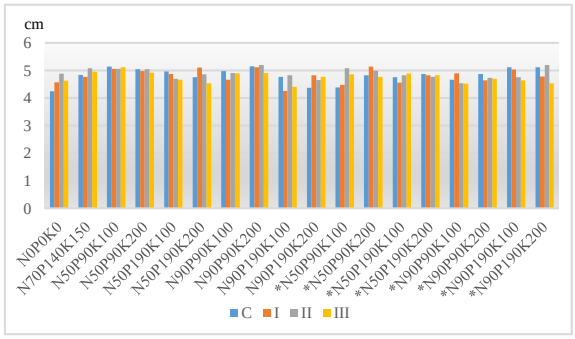
C – central umbel; I, II, III – orders;



The strongest heteroblasty was recorded for the seeds from the third order, compared to those from the central stems, with the difference for the fertilized and unfertilized controls being approximately two days, while with the optimization of the nutritional regime it decreases, especially for $N_{90}P_{190}K_{200}$ and $N_{50}P_{190}K_{200}$ (once) and $N_{50}P_{190}K_{200}$ and $N_{90}P_{190}K_{100}$ (twice).
According to Copeland and McDonald (2001), uniformity of seed germination is essential for better crop establishment.
Most uniformity germinate the seeds from central umbel, follow from umbels with higher order – I, II and III. A higher percentage of uniformity germinated seeds from the central umbel was found in the fertilized control – 15.70%. Close to this result are the variants fertilized with $N_{50}P_{90}K_{200}$ (15.17%) and $N_{90}P_{90}K_{100}$ (15.16%) applied once, as well as with twice fertilization with maximum amounts of the three fertilizers $N_{90}P_{190}K_{200}$ (15.06%).
Germination efficiency decreases with increasing umbel order, reaching it's minimum in seeds of the last third order. However, optimizing the nutritional regime improves seed quality, which is particularly evident when applying $N_{90}P_{90}K_{200}$ at both fertilization terms.
The heteroblasty between the seeds from the central umbel and those from the first-order umbels decreased more significantly after twice fertilization with $N_{90}P_{90}K_{100}$, as well as with the combination $N_{50}P_{90}K_{100}$, regardless of the method of application. Higher heteroblasty was reported between seeds of the second and third order, compared to those from the central umbel, with a decrease observed after fertilization with $N_{90}P_{90}K_{200}$.
The morphological characteristics of the seedlings are essential for determining the viability of the seeds. Different fertilizer rates, as well as the method of fertilization, affect the length of the different parts of carrot seedlings.
The maximum length of the embryo root in the seeds from the central umbel was recorded after twice fertilization with $N_{90}P_{190}K_{100}$ – 2.54 cm (Figure 5). At the first application period of mineral fertilizers, it reaches a greater length in the variants $N_{50}P_{90}K_{100}$ and $N_{50}P_{90}K_{200}$ – 2.39 cm, followed by $N_{90}P_{90}K_{200}$ – 2.31 cm.
A more significant growth of the embryo root for the seedlings from first-order umbels was observed after twice fertilization with $N_{90}P_{90}K_{100}$ – 2.77 cm, in contrast to the zero control, where only 1.77 cm was recorded. Good results are also found for the variants $N_{90}P_{190}K_{100}$ (twice) and $N_{50}P_{190}K_{100}$ (once), 2.48 cm and 2.51 cm, respectively.
A relatively shorter embryo root, in most of the tested fertilization methods, develops the seeds of the second and especially the third order. In the first case, once fertilization has the strongest effect at levels $N_{90}P_{190}K_{100}$, $N_{90}P_{90}K_{200}$ and $N_{50}P_{90}K_{100}$, and when applying fertilizer rates twice, the maximum length is recorded for the variant $N_{50}P_{190}K_{100}$. Once fertilization with $N_{90}P_{90}K_{100}$ and twice fertilization with $N_{50}P_{90}K_{200}$ causes the development of seedlings with the longest embryo root in the seeds of the last third order. The difference in seed quality from different umbels decreases more significantly after once application of $N_{50}P_{90}K_{200}$ and twice application of $N_{50}P_{190}K_{100}$.
Different levels of N, P and K, as well as their frequency of application, have weak effect on hypocotyl length in carrot seedlings. A more significant increase in the values of the monitored

indicator for the seeds of all orders was recorded after a once fertilization with $N_{90}P_{90}K_{200}$, as well as after $N_{90}P_{190}K_{200}$ for the twice method of the applying mineral fertilizers (Figure 6).
This indicator is less affected by heteroblasty. Nevertheless, optimizing the nutrient regime leads to it's reduction, and this is more significantly observed in the variants fertilized once with $N_{90}P_{90}K_{100}$ and with $N_{90}P_{90}K_{200}$, and twice with $N_{50}P_{190}K_{200}$.

Figure 6. Length of the hypocotyl of carrot seedlings depending on the fertilization regime and umbel order, (cm)

Seedling fresh mass is a main parameter in many tests to determine seed vigour (Copeland and McDonalds, 2001; Black et al, 2008; Panayotov, 2015). This determines it's importance for a more complete characterization of the vital status of vegetable seeds.
The fresh mass of the seedlings from the seeds from the central umbel increased significantly in the variant fertilized twice with $N_{90}P_{90}K_{200}$ (13.25 mg) (Table 3). This represents an increase of 27.89% compared to the unfertilized control and 12.67% compared to the fertilized control. At the first term of application of mineral fertilizers increase increase in mass was observed at $N_{50}P_{90}K_{100}$ – 12.85 mg.
The mass of one seedling in the seeds of I order umbels is highest after application of $N_{50}P_{90}K_{100}$ (once) – 12.30 mg, as opposed to the zero and fertilized controls, where it is 10.50 mg and 11.57 mg, respectively.
For seeds from secondary umbels, the weight of the pods for most of the tested combinations is around 10 mg. A more significant increase was found with the fertilizer rate $N_{90}P_{90}K_{200}$ (once application) – 11.37 mg, which is represent with 0.93 mg and 1.37 mg more than the recommended rate and when growing plants without fertilization.
The values obtained for the seeds from the last, third order, are in range from 7.87 mg for $N_{90}P_{90}K_{100}$ (twice) to 10.30 mg for $N_{50}P_{90}K_{100}$ and $N_{90}P_{90}K_{200}$, again applied twice.
Good results have also been reported for $N_{50}P_{90}K_{200}$ regardless of the method of application. A more significant reduction in differences between seeds from individual orders is found for $N_{50}P_{90}K_{200}$ at both application terms, as well as for $N_{90}P_{190}K_{100}$ (once).

Table 3. Morphological characteristics of carrot seedlings depending on the fertilization regime and umbel order

C – central umbel; I, II, III – orders;

Determining the parameters of the absolute dry mass of the seedlings makes it possible to gain an idea of the physiological status of the seeds. The presence of higher values also determines the suitability subsequently from these seeds to be formed a better plants.

The seedlings from the central umbel developed a higher absolute mass after twice fertilizations with maximum amounts of the three fertilizers – 4.55%. A good result is also reported for the combination $N_{50}P_{90}K_{100}$ – 4.33%. At the first application period, the highest percentage was reported for the fertilizer rate $N_{50}P_{190}K_{100}$ (4.21).

The absolute dry mass for the seedlings from the first-order umbels for most of the variants is about 4%. A weak decrease was found in once application of $N_{50}P_{190}K_{100}$.

A more significant increase in the values of the monitored indicator in the second-order canopies was found for the variant fertilized twice with $N_{90}P_{90}K_{100}$ (3.66%), which represents an increase of 0.78% compared to the zero control and 0.44% compared to the fertilizer rate used to the moment in carrot seed production.

For the umbels of the last III order, the data obtained are in range from 2.66% for $N_{50}P_{190}K_{200}$ to 4.22% for $N_{50}P_{90}K_{200}$ and $N_{90}P_{190}K_{200}$ applied twice.

In this indicator, the heteroblasty between seeds from umbels with different orders is less affected by the applied nutritional regime. Regardless of this, it can be noted that a decrease is observed after fertilization with $N_{90}P_{190}K_{100}$ (once) and $N_{90}P_{90}K_{100}$ (twice).

CONCLUSIONS

The seed yield of carrots is formed primarily from the seeds from the first-order and second-order umbels. Once fertilization with $N_{90}P_{90}K_{100}$ and double fertilization with $N_{90}P_{190}K_{100}$ lead to an increase in the percentage participation of these umbels in the formation of the total seed yield.

As a result of the applied fertilization levels and regimes, heteroblasty between seeds from umbels with different order were reduced in most indicators. This is most significantly observed when fertilizing with $N_{90}P_{90}K_{200}$, as well as with $N_{90}P_{190}K_{100}$ (once) and $N_{90}P_{90}K_{200}$ (twice), where the differences in germination energy and germination between seeds from individual orders are the smallest.

The highest absolute mass and linear dimensions were found for seeds from the central umbel and they decreasing with increasing umbel order. A more significant increase in their values and a decrease in the heteroblasty was reported after fertilization with $N_{50}P_{90}K_{100}$, $N_{50}P_{90}K_{200}$ and $N_{90}P_{90}K_{200}$.

The length of the embryo root in seeds of all orders increased after twice fertilization with $N_{90}P_{90}K_{100}$ and $N_{90}P_{190}K_{100}$, while that of the hypocotyl increased more significantly as a result of a once fertilization with $N_{90}P_{90}K_{200}$, as well as with $N_{90}P_{190}K_{200}$ for the twice method of applying of the mineral fertilizers.

The fresh mass of one seedling increases after fertilization with $N_{50}P_{90}K_{100}$ and $N_{90}P_{90}K_{200}$, regardless of the method of application. The seedling developed higher absolute dry mass as a result of twice fertilizations with $N_{90}P_{190}K_{200}$ and $N_{50}P_{90}K_{200}$, as well as and once fertilization with $N_{50}P_{190}K_{100}$. These two indicators are weakly influenced by umbel order.

ABSTRACT

Rising fertilizer consumption coupled with declining nutrient use efficiency has emerged as a major challenge for sustainable agriculture. Conventional NPK fertilizers suffer from substantial nutrient losses following soil application due to mechanisms such as leaching, volatilization, and fixation. Nitrogen loss via ammonia volatilization and nitrate leaching, in particular, leads to both economic inefficiency and environmental hazards. Consequently, interest in slow-release fertilizer technologies capable of releasing nutrients in a controlled manner aligned with crop demand has grown significantly. In this study, a slow-release NPK fertilizer formulation was developed using polymer coating systems and stabilizing additives to regulate nutrient release dynamics and enhance fertilizer use efficiency. The formulation aims to attenuate rapid dissolution in soil and ensure sustained nutrient availability within the root zone. Laboratory and soil incubation experiments were designed to evaluate nutrient release kinetics, granule crushing strength, water stability, and controlled-release performance. Furthermore, various coating ratios and formulation combinations will be investigated to identify the optimal release profile. Pot trials were planned to examine the effects of the developed fertilizer on plant growth parameters, nutrient uptake, and crop-water relations. The developed slow-release NPK formulation is expected to minimize nutrient losses, boost fertilizer efficacy, and contribute to sustainable agricultural production while mitigating environmental pollution risks associated with over-fertilization. This study serves as a foundational reference for biodegradable coating technologies, controlled-release nutrient delivery systems, and next-generation smart fertilizer applications.

Keywords: Slow-release fertilizer, NPK fertilizer, Controlled nutrient release, Sustainable agriculture, Polymer coating, Fertilizer efficiency

INTRODUCTION

With the rapid increase in world population, achieving high yields in agricultural production has become imperative. This has led to increased use of chemical fertilizers; however, the low use-efficiency of conventional fertilizers has brought about significant environmental and

economic problems. A substantial portion of applied fertilizers is lost from the soil or dispersed into the environment before being taken up by plants.
Ammonia volatilization and nitrate leaching, in particular, significantly reduce the use-efficiency of nitrogenous fertilizers. In phosphorus fertilizers, the amount of phosphorus available for plant uptake remains limited due to the problem of soil fixation. For this reason, the development of slow-release fertilizer systems capable of releasing nutrients in a controlled manner has become an important area of research for sustainable agriculture.
The literature indicates that polymer-coated fertilizers reduce nutrient losses and have a positive effect on plant growth. Shaviv (2001) reported that controlled-release fertilizers increase plant nutrition efficiency. Trenkel (2010) stated that slow-release fertilizer technologies offer significant advantages in reducing environmental losses. Similarly, Azeem et al. (2014) noted that polymer-coated fertilizers improve fertilizer use-efficiency by enhancing controlled-release performance.
However, the high cost of existing commercial products, the environmental sustainability disadvantages of some coating materials, and their variable performance under different soil conditions necessitate the development of new formulations.
The aim of this study is to develop a slow-release NPK fertilizer formulation using polymer coating technologies and to evaluate the effects of the developed system on controlled nutrient release and plant growth.

MATERIAL AND METHOD

Commercial fertilizer raw materials will be used as sources of nitrogen, phosphorus, and potassium in the study. The formulation was designed using biopolymer- and synthetic polymer-based coating agents in order to impart controlled-release properties. In addition, binding additives and stabilizers were used to increase granule strength.

The soil samples to be used in the trials are planned to be standardized and maintained under controlled moisture conditions. Fast-growing test plants were preferred for the pot trials.

NPK fertilizer granules will be prepared in specified ratios and coated using a controlled coating system. During the coating process, the polymer solution will be sprayed onto the granule surface, followed by a drying step at a specific temperature.

The following analyses are planned in order to determine the performance of the prepared formulations:

- Nutrient element release profile
- Granule strength
- Moisture absorption
- Coating homogeneity

Nutrient release behavior will be examined through soil incubation tests. Soil samples will be taken at different time intervals to analyze the release amounts of nitrogen, phosphorus, and potassium.

The following groups were established for the pot trials:

- Control group: Conventional NPK fertilizer

- Treatment group 1: Slow-release fertilizer with 0.5% coating ratio
- Treatment group 2: Slow-release fertilizer with 1% coating ratio
- Treatment group 3: Slow-release fertilizer with 2% coating ratio

The following parameters are planned to be measured throughout plant development:

- Plant height
- Leaf number
- Chlorophyll content
- Fresh and dry biomass
- Soil nutrient content

RESULTS AND DISCUSSION

The developed slow-release NPK formulations are expected to provide more controlled nutrient release compared to conventional fertilizers. In particular, granules with a higher coating ratio are thought to extend the nutrient release duration.

In the soil incubation tests, nitrogen losses are expected to be lower than those of the control group. Phosphorus is also expected to remain in a plant-available form in the soil for a longer period.

In the pot trials, plant growth parameters are expected to be higher in the groups treated with slow-release fertilizer. The increase in plant height, leaf development, and biomass is thought to result from the continuity of nutrient supply.

The results to be obtained indicate that NPK formulations providing controlled release could improve fertilizer use-efficiency. It is considered that slow-release systems could minimize environmental impacts, particularly by reducing nitrogen losses.

Consistent with studies reported in the literature, it has been determined that polymer coating systems control the rate of nutrient release and have a positive effect on plant growth.

The use of biodegradable coating materials may provide a significant advantage in terms of environmental sustainability. In addition, the use of the developed systems together with hydrogel and inhibitor technologies may offer important opportunities for next-generation smart fertilizer systems.

CONCLUSIONS

Within the scope of this study, it was evaluated that the slow-release NPK fertilizer formulation developed could improve fertilizer use-efficiency by providing controlled nutrient release. It is thought that the developed system, by reducing nutrient losses, could provide both economic and environmental advantages.

In future studies, it is recommended that open-field trials be conducted to evaluate performance under different climate and soil conditions. In addition, the development of new, environmentally friendly formulations using biodegradable polymer coating systems can be targeted.

ABSTRACT

Conventional tillage methods in clay and moisty soils lead to adverse effects such as soil compaction, plow pan formation, and excessive clodding. This complicates seedbed preparation and reduces field sprout emergence rates. In heavy clay soils with high moisture content and poor drainage, ridge sowing should be applied to protect the seeds from groundwater. A new prototype machine consisting of a lister and a rotary tiller has been designed for use in areas with these soil and climate characteristics. The ridges created by this machine were processed with the rotary tiller to prepare them for sowing. In the research, the performance of the prototype machine at an average soil moisture content of 25%, the minimum observable moisture level, was compared against conventional methods using physical and mechanical parameters such as bulk density, porosity, penetration resistance, and aggregate size distribution. As a result, no statistically significant difference was found between the plow + prototype tillage and the prototype tillage treatments. It was proven that the prototype machine can be used effectively on its own under clayey and humid conditions. By forming ridges in a single pass to protect seeds from groundwater—replacing the conventional 4-pass tillage system, this machine provides a significant advantage in terms of time, labor, and fuel consumption.

Keywords: Conventional tillage Ridge tillage, Poor drainage, Clay Soil

INTRODUCTION

Agricultural soils are frequently degraded as a consequence of intensive and improper management practices. Mitigating this degradation requires the adoption of appropriate tillage methods, enhancing soil organic matter content, preserving microbial populations, and transitioning toward sustainable agricultural systems. The incorrect application of conventional tillage practices often results in significant drawbacks, including soil compaction, plough pan formation, excessive soil pulverization, and rapid moisture loss (Alvarez et al.1995, Pierce,1983, Eckert, 1987).

In regions experiencing excessive soil moisture during the sowing period, seed germination is seriously affected. While tillage can facilitate drainage and reduce moisture levels in the root zone (Ketcheson, 1980) , ridge sowing offers an effective mechanical solution by elevating the seedbed. Ridges protect seeds from waterlogging and prevent decay (Fulton et al.1996), and

previous studies have demonstrated that ridge sowing can achieve yields comparable to conventional tillage (CT) in poorly drained soils (Erbach, 1982, Stone and Heslop, 1987).

Achieving optimal friability (mellowness) in heavy-textured clay soils is highly challenging when moisture levels are elevated. Heavy clay soils possess a high capacity for water and nutrient retention; however, internal water movement is slow, and soil aeration rates are low. Consequently, these soils must be tilled within a narrow, optimum moisture range. As moisture content increases, clay soil transitions into a plastic consistency, eventually becoming slurry-like and adhering strongly to tillage tools. Conversely, when these soils dry after improper tillage, large, hard clods are formed due to their dense aggregate structure. Breaking down these clods consumes excessive energy, making the preparation of an ideal seedbed extremely difficult (Canbolat et al., 2013).

Soil physical properties, climatic conditions, and topography are primary determinants of crop yield. Declining yields coupled with rising input costs threaten the economic viability of small-scale agricultural enterprises. A primary indicator of yield reduction in heavy clay soils is a low field sprout emergence rate, primarily driven by dense soil structures and rising groundwater levels following heavy rainfall. Even when sowing is mechanically feasible in wet soils, seeds are prone to rotting. Furthermore, seeds trapped beneath large clods suffer from poor seed-to-soil contact and fail to germinate, while emerging sprouts often lack the mechanical strength to penetrate the crusted surface. In poorly managed heavy clay soils, seedling emergence rates can drop by up to 40%, frequently necessitating costly and labor-intensive replanting. This results in wasted fuel energy, labor inefficiency, delays in the cropping calendar, and excessive seed consumption.

While conventional listers (Bernacki et al. 1972, Merfield et al.2020) and modified rotary cultivators (Mandal, 2013, Salokhe and Ramalingam, 2001,Destain and Houmy,1990) have been utilized for years, their operational designs have seen limited development for extreme conditions. When high soil moisture is combined with a heavy clay texture, soil adheres to the blades and clogs the spaces between rotary tines, rendering standard equipment inoperable. Currently, there is a critical lack of machinery capable of operating efficiently under high-moisture clay soil conditions.

The objective of this study was to evaluate the operational performance of a prototype soil-tilling machine developed for heavy-textured agricultural soils prone to high moisture levels from drainage problems under the lowest soil moisture conditions recorded in the field. Accordingly, performance was evaluated based on some physical and mechanical soil parameters during field trials conducted at an average soil moisture content of 25%.

MATERIALS AND METHODS

The field trials were conducted in a heavy-textured clay soil comprising 50.47% clay, 21.08% silt, and 28.45% sand. During the experiments, the average soil moisture content at the prototype machine's working depth of 100 mm was 25%. The technical specifications of the tractor used during the field trials are summarized in Table 1. In addition to the newly designed prototype machine, a conventional mouldboard plough and a tandem disc harrow were used for comparison.

Table 1. Technical specifications of the tractor utilized in field trials.

Power generation, kW (2270 min^{-1})	64.5 (88 BG)
Torque, (Nm) / Engine cycle (min^{-1})	335/1360
Max lifting force of the lifting arms mounted on the rear points, (kN)	33
Total weight (Kg)	3500
Front axle (Kg)	1190
Rear Axle (Kg)	2310

The prototype machine is an integrated implementation consisting of a specialized lister (ridger) and a rotary cultivator (Fig. 1). To overcome high soil hardness while minimizing energy consumption, the rotary cultivator was designed to process only the active sowing rows rather than the entire soil surface.

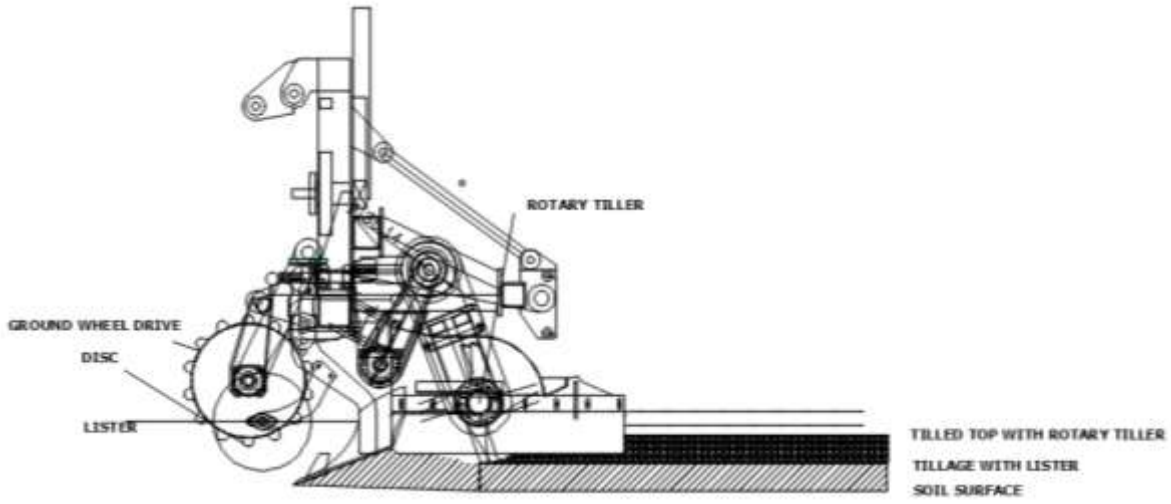

Figure 1. prototype machine

Preliminary field trials were conducted to determine the optimal ridge geometry capable of maintaining structural integrity without degrading until seedling emergence under heavy clay conditions (Fig. 2). The finalized ridge profile was configured with a 700 mm row spacing, a 350-400 mm ridge-top width, a 150-200 mm ridge height, and 45° side slope angles. Tillage along the ridges was executed by the rotary cultivator at an operational depth of 100 mm.

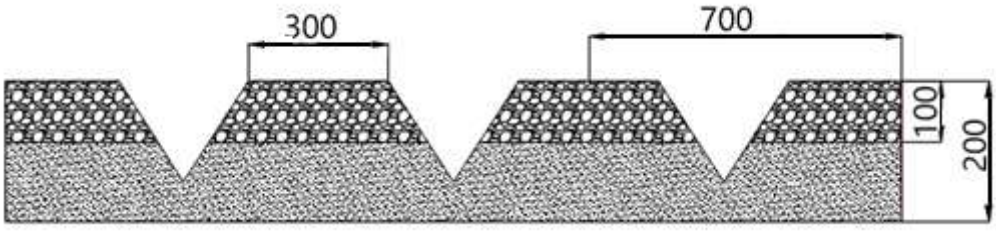

Figure 2. The ridge shape

The experimental layout was arranged in a Randomized Complete Block Design consisting of 24 plots, each measuring 10 x 5 m, arranged across eight rows.

Three distinct tillage treatments were evaluated; Conventional Tillage (CT): Mouldboard ploughing followed by disc harrowing (3 passes). Combined Tillage (Plough + Prototype): Mouldboard ploughing followed by direct seedbed preparation using the prototype machine. Direct Prototype Tillage (Prototype machine): Single-pass direct seedbed preparation using only the prototype machine.

To determine bulk density (BD) and total soil porosity (SP), undisturbed core samples were collected after tillage from two depths (0-100 mm and 100-200 mm) in three replicates per plot. BD and moisture content were determined gravimetrically according to standard methods (Blake and Hartge,1986), and total porosity was calculated from BD and particle density (Dursun, 2015).

Soil penetration resistance (PR) was measured using an Eijkelkamp hand-pushed electronic cone penetrometer (Kukal and Aggarwal, 2003). Soil particle size distribution following tillage was determined using a vibrating sieve set according to standard testing procedures (Keçecioğlu, 1967). The six initial size fractions (<1, 1-2, 2-4, 4-6.3, 6.3-8, and >10mm) were categorized into three primary agronomic clod size classes: 1 mm, 1<x<10 mm (ideal seedbed aggregate size), and >10 mm.

Statistical analyses were performed using SPSS v21 Base software. Analysis of variance (ANOVA) was conducted to evaluate the effects of the tillage treatments on soil physical properties. When significant differences were detected, treatment means were compared using the Least Significant Difference (LSD) test at a significance level of $P < 0.05$.

RESULTS AND DISCUSSION

Due to high regional precipitation, the experimental soil does not dry sufficiently during the spring sowing season. Prior to tillage operations, soil moisture was 25.69% and 32.81%, the baseline BD values at depths of 0-100 and 100-200 mm were 1.22g cm^{-3} and 1.26 g cm^{-3}, respectively, while baseline SP values were 53.96% and 52.45%.

Following tillage, significant differences in both BD and SP were observed among treatments at the 0-100 mm depth ($P < 0.05$), whereas no statistically significant differences were detected at the 100-200 mm depth (Table 3.1). At the surface layer (0-100 mm), the lowest BD (1.10 g cm^{-3}) and highest porosity (58.49% and 58.13%) were achieved by the Direct Prototype Tillage and Combined Tillage treatments, significantly outperforming CT (1.22g cm^{-3} BD and 53.64% porosity).

Table 3.1. Soil BD and SP values across different tillage treatments and depths.

Treatment	BD (g cm^{-3}) (100 mm)	SP (%) (100 mm)	BD (g cm^{-3}) (200 mm)	SP (%) (200 mm)
CT	1.22b	53.64b	1.23	53.41
Direct Prototype Tillage	1.10a	58.49a	1.28	51.48

Combined Tillage (Plough + Prototype)	1.10a	58.13a	1.24	52.99

Means within a column followed by different superscript letters are significantly different ($P < 0.05$)

BD values exceeding 1.60 g cm^{-3} are known to severely restrict root proliferation in general agricultural soils (Raper et al., 1999). However, in heavy clay soils (e.g., 45% clay content), root development can be hindered at thresholds as low as 1.39 g cm^{-3} (Pierce et al., 1983; Fulton et al., 1996). In the present study, all post-tillage BD values remained well below these critical thresholds, indicating that none of the tillage systems created physical barriers to plant growth. As BD decreased, SP increased predictably. Similar inverse relationships in clay soils have been reported by Kasap (2023), although the prototype machine achieved superior surface porosity compared to standard rotary treatments.

Soil penetration resistance values did not differ significantly among the tillage treatments across any of the measured depths ($P > 0.05$). The maximum penetration resistance recorded before and after tillage did not exceed 0.61MPa. The lowest penetration resistance was observed in plots processed with the Combined Tillage system (Plough + Prototype). Hakansson and Lipiec (2000) established that mechanical impedance exceeding 3.0 MPa completely halts root elongation. The values recorded in our trials are substantially lower than this critical limit, confirming optimal soil looseness. These findings align with Bulut (2015), who recorded a minimum penetration resistance of 0.78 MPa (0-150 mm) in heavy soils, and are consistent with the mechanization results of Karaağaç (2007).

The particle size distribution following seedbed preparation is a crucial indicator of tillage efficiency, particularly in plastic clay soils. The percentage of aggregates larger than 10 mm and within the ideal 1-10 mm range showed statistically significant differences among treatments ($P < 0.05$), while the fine fraction (<1 mm) showed no significant difference (Table 3.2).

Table 3.2. Post-tillage soil particle size distribution (%) across treatments.

Treatment	10<x	1<x<10	x<1
CT	83.88a	15.76b	1.20
Direct Prototype Tillage	60.01b	38.23a	1.74
Combined Tillage (Plough + Prototype)	55.78b	42.45a	1.76

Means within a column followed by different superscript letters are significantly different ($P < 0.05$)

CT resulted in an excessively coarse seedbed, with 83.88% of soil clods exceeding 10 mm and only 15.76% falling within the agronomically desirable 1-10 mm range. In contrast, Direct Prototype Tillage and Combined Tillage significantly reduced the proportion of large clods (>10 mm) to 60.01% and 55.78%, respectively, while more than doubling the fraction of ideal seedbed aggregates (1-10 mm to 38.23% and 42.45%).

This aggregate size distribution achieved by the prototype machine closely approaches the optimal soil fragmentation criteria required for rapid crop emergence in heavy soils (Dursun, 2015). Furthermore, the proportion of dust-like fine particles (<1 mm) remained below 2.00% across all treatments, indicating that the prototype machine successfully fragmented heavy clay without causing structural over-pulverization or increasing erosion risks. The proportion of seedbed-ready aggregates (<10 mm) obtained with the prototype was higher than the 13.55% (conventional) and 15.30% (rotary tillage) reported by Pınar (1992), and superior to the fragmentation ratios observed by Kasap (2023) in similar soil textures. Moreover, these findings reinforce Karaköse et al. (2026), who demonstrated that specialized ridge-rotary systems maintain superior clod fragmentation efficacy at moisture levels ranging from 25% to 37% compared to CT implements.

CONCLUSION

Field evaluations of the newly developed prototype machine, engineered specifically for poorly drained and heavy clay soils, demonstrated superior agronomic and mechanical performance compared to Conventional multi-pass tillage. At a challenging soil moisture content of 25%, the prototype successfully formed structurally stable ridges that maintained their geometry following rainfall, effectively elevating the seedbed and protecting seeds from groundwater saturation.

The prototype machine produced significantly better soil fragmentation and lower surface BD than conventional tillage. Importantly, statistical analyses revealed no significant difference in seedbed quality between the two-stage Combined Tillage (ploughing followed by the prototype) and the single-pass Direct Prototype Tillage. This confirms that the prototype machine can be operated independently as a primary and secondary tillage implementation in heavy clay soils. By consolidating a Conventional four-stage seedbed preparation process into a single pass, the prototype implement offers a sustainable agricultural solution that prevents deep soil compaction, reduces equipment wear, and maximizes both fuel and labor efficiency.

ABSTRACT

Many pathogens, including *Escherichia coli* causing serious infections, pose a significant risk to human health worldwide. *E. coli* is a commensal bacterium that is widely found in the human gastrointestinal tract. Some strains of *E. coli* can cause gastrointestinal and extraintestinal infections in humans due to the acquisition of pathogenetic factors through mobile genetic elements, such as plasmids, bacteriophages, pathogenicity islands, and transposons. Heavy metals are pollutants that cause serious harm to the environment and human health due to their toxicity, persistence in the environment, and bioaccumulative properties. Heavy metals contribute to antimicrobial resistance in bacteria through co-selection and cross-resistance. Although some metals, such as zinc, are crucial for microbes, they can be toxic at high concentrations or impose selective pressure on bacteria. The aim of this study was to investigate the resistance to heavy metal zinc in multidrug-resistant (MDR) *Escherichia coli* isolates using phenotypic analysis by the broth microdilution method and genotypic analysis by the PCR-based amplification of the *zntA* gene associated with zinc resistance. All MDR *E. coli* isolates had minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) values higher than 3200 µg/mL. Out of the zinc-resistant MDR isolates, 85.7% were positive for the *zntA* gene, encoding resistance to zinc. However, 14.3% of the MDR isolates with an MIC of >3200 µg/mL did not carry the *zntA* gene. The results of this study demonstrate the presence of zinc resistance both phenotypically and genotypically. The zinc-resistant MDR *E. coli* isolates from food in this study might constitute potential risks to human health.

Keywords: zinc resistance, *zntA* gene, *Escherichia coli,* minimum inhibitory concentration

INTRODUCTION

Escherichia coli is a Gram negative, short rod, aerobic, generally motile organism. Most of the strains are not pathogenic and exist in the intestinal tract of warm blooded animals (Bhunia, 2008). The pathogenic strains cause disease inside the intestinal tract and in the extraintestinal sites like hemolytic uremic syndrome, urinary tract infection, septicemia, and meningitis (Dworkin et al., 2006; Bhunia, 2008).

Pathogenic *E. coli* strains are categorized into different pathotypes according to their virulence characteristics and pathogenic mechanisms. In addition, pathogenic *E. coli* strains are serologically classified based on their capsular(K), somatic (O), and flagellar (H) antigens. The most important pathotypes clinically as they cause a serious threat to human health and are responsible for a large proportion of diarrhoeal diseases (Bhunia, 2008). Pathogenic strains of

E. coli colonise the intestinal epithelium and damage host cells through various virulence factors. These bacteria may affect the function of ion transport systems, cause excessive fluid loss, inhibit protein synthesis, alter the host cell cytoskeleton, and eventually induce cell death. Collectively, these pathogenic mechanisms lead to the development of a wide range of gastrointestinal infections (Meng et al., 2007; Bhunia, 2008).

Heavy metals are poisonous, persistent and bioaccumulative in nature. They are metallic and non-metallic materials. Certain heavy metals such as zinc, copper and nickel are essential for basic biological activities but can be hazardous when they cross permissible limits. Chromium, unlike other metals such as cadmium and lead, is very toxic to living things even in small quantities (Chen et al., 2018; Peshkov et al., 2025). Zinc occurs naturally and as a result of human activities in the environment. It can be naturally released into the environment by rock weathering, volcanic eruptions, air dust, and forest fires. On the other hand, anthropogenic sources of emission include industrial waste, burning of fossil fuels, and a number of industrial processes (Hussain et al., 2022; Peshkov et al., 2025). It is widespread in soil, water, atmosphere, plants, and living organisms (Hussain et al., 2022).

Humans can inhale heavy metals via contaminated air, ingest them via contaminated water and food, and absorb them via skin contact (Afolabi et al., 2023). Zinc is a transition trace metal and is an essential cofactor and key player in cell growth and development processes in most living organisms (Adekanmbi et al., 2020; Schuindt et al., 2026). Many fundamental biological processes, including transcription to translation and cell division to metabolism, depend on zinc (Schuindt et al., 2026). Its chemical properties allow for stable interactions with most proteins, supporting enzyme and protein functionality (Berg and Shi, 1996; Adekanmbi et al., 2020).

High amounts of zinc are potentially hazardous to humans, microbes and other living species. A high level of zinc release in the environment results in the disruption of microbial communities and the selection of zinc tolerant microorganisms (Hussain et al., 2022). Heavy metals exposure and their bioaccumulation may cause adverse health effects, such as weight loss, decreased immunity, cancer, hepatotoxicity, cardiovascular diseases and reproductive disorders (Halema et al., 2024; Peshkov et al., 2025). A high zinc concentration disrupts metal homeostasis, enters cells through non-specific transport systems, and inhibits enzyme activity and disrupts normal cell functions. For these reasons, intracellular zinc concentration must be controlled by zinc homeostasis systems such as the ZntA-mediated efflux system (Nies, 1999).

Bacteria have evolved methods to defend themselves from heavy metal exposure. Heavy metal resistance genes may be found on bacterial chromosomes, transposons, or plasmids. Their presence promotes horizontal gene transfer and the spread of heavy metal and antibiotic resistance genes (Halema et al., 2024). Bacteria have specific uptake and efflux systems to maintain zinc homeostasis (Hussain et al., 2022). The ZnuABC transporter system ensures proper zinc intake by increasing zinc uptake from exogenous sources. Alternatively, bacteria activate a detoxifying mechanism to prevent the build up of high zinc concentrations as intracellular zinc levels rise. The P-type ATPase zntA exports excess zinc from the cytoplasm. The CzcCBA efflux system, a resistant nodulation division transporter, regulates zinc export across the cell membrane (Nies, 1999; Hussain et al., 2022). These coordinated uptake and efflux systems maintain intracellular zinc levels, allowing bacteria to adapt under heavy metal stress conditions and resist zinc toxicity (Hussain et al., 2022).

Multidrug resistance refers to a bacterium exhibiting resistance to at least one antibiotic from more than three different classes of antimicrobials. Exposure to this bacterium risks human and animal health by complicating infection treatments. Furthermore, antibiotic resistance has emerged as a serious public health concern, as antibiotic use facilitates the spread of antibiotic resistance genes throughout the food chain. Furthermore, heavy metal-induced selective pressure in environmental reservoirs contributes to the spread and persistence of antibiotic resistance genes (Vats et al., 2022; Nguyen et al., 2025).

Water and soil are contaminated with heavy metals from both natural and anthropogenic sources (Gillieatt and Coleman, 2024). These hazardous metals may enter the human body as a result of heavy metal contamination in foods, particularly vegetables. The presence of heavy metal contaminants in the environment poses growing threats to food safety and human health. Moreover, heavy metals can cause and prolong antimicrobial resistance in food-borne bacteria (Mihdir et al., 2016; Vats et al., 2022). Therefore, the aim of this study is to investigate heavy metal zinc resistance among the multidrug-resistant (MDR) *E. coli* isolates from vegetables. The broth microdilution method was performed phenotypically to determine the minimum inhibitory concentration (MIC) for zinc. The *zntA* gene responsible for zinc resistance was detected genotypically by using PCR.

MATERIALS AND METHODS

Bacterial isolates

The reference strains *Escherichia coli* ATCC 35218, *E. coli* K-12, and seven multidrug-resistant (MDR) *E. coli* isolates previously isolated and identified from vegetables (Özdemir, 2024) were used in this study. All isolates stored in sterile Eppendorf tubes at -20 °C in Brain Heart Infusion broth (Merck) containing 20% glycerol in the stock bacterial culture collection were revived. The MDR *E. coli* isolates were activated from stock cultures using Brain Heart Infusion broth (37°C / 24 h). Then, the culture was streaked on Eosin Methylene Blue (EMB) (Merck, Germany) to obtain individual colonies showing characteristics of a metallic green sheen. These colonies were subcultured onto Brain Heart Infusion agar (Merck, Germany) and used for further study.

Phenotypic characterization

Determination of minimum inhibitory concentration of heavy metal zinc

The minimum inhibitory concentration (MIC) of heavy metal zinc quantitatively on a U-bottom sterile 96-well microtiter plate (LP Italiana) was determined by the broth microdilution method according to CLSI recommendations (CLSI, 2012). Heavy metal zinc ($ZnCl_2$) was obtained from Sigma-Aldrich. All multidrug-resistant (MDR) *E. coli* isolates were streaked on Eosin Methylene Blue (EMB) agar (Merck). The petri plates were incubated at 37°C for 24 h. Later, several colonies with a green metallic sheen from the EMB agar were selected and suspended on Mueller Hinton Broth (MHB). The bacterial suspension turbidity was adjusted to a 0.5 McFarland (around 10^8 colony forming units (CFU) / mL). Adjusted suspension was diluted at 1:150 ratio in MHB and inoculated to each well of a microtiter plate. Two-fold dilutions of the zinc metal were prepared in MHB on wells of the microtiter plates. Heavy metal zinc was tested at concentrations ranging from 3200 to 6.25 µg/ mL. Each test consisted of a sterility control well (only MHB) and a growth control well (MHB with bacterial culture but no zinc). The microtiter plates were incubated for 24 h at 37°C. After incubation, the MIC was defined as the lowest visible concentration of the heavy metal zinc that completely inhibited bacterial growth. The absorbance was determined at 600 nm using a Thermo Electron Corporation microplate reader. The tests were conducted in triplicates. In this study, the references *E. coli* K-12 and *E. coli* ATCC 35218 were utilized controls.

Detection of minimum bactericidal concentration of heavy metal zinc

After incubation (37°C/ 24 h), the minimum bactericidal concentration (MBC) is the lowest concentration of an agent that inhibits 99.9% of bacterial growth (CLSI, 2012). The MBC was determined, after reading, In order to detect viable cells, 10 µL of the first eight dilutions, ranging from 3200 to 25 µg/mL, were seeded as a spot inoculation onto MHB and incubated at 37°C for 24 h.

Genotypic characterization

Genomic DNA extraction

A single colony of the multidrug-resistant (MDR) *E. coli* was suspended in the 5 mL Brain Heart Infusion (BHI) broth and incubated for 24 h at 37°C. Later, 1.5 mL of culture suspension was transferred into a sterile microcentrifuge tube. After centrifugation, DNA of the MDR *E. coli* isolates was isolated using the cetyl trimethyl ammonium bromide (CTAB) method (Ausubel et al., 1991). The DNA was stored in TE buffer (10 mM Tris, 1mM EDTA) and kept at -20°C for further PCR analysis.

PCR identification of the *E. coli* isolates

For species-level identification, *uspA* gene (*E. coli* specific universal stress protein A) was amplified by PCR, as previously described (Chen and Griffiths, 1998). All PCR reactions were performed in a T100 thermocycler (Bio-Rad). A 50 µL The reaction mixture included 1.5 U Taq polymerase (Thermo Scientific), 5 µl 10X buffer, 4 mM $MgCl_2$, 0.2 mM dNTP mix (Amplicon), 0.4 µM primers, 4 µL template, and 31.7 µL PCR water. The cycles were 94°C/ 5 min for the first cycle; 94°C/ 2 min, 60°C/ 1 min, and 72°C/ 1 min for the next 30 cycles; and 72°C/ 10 min for the final cycle. The PCR products were determined on a 1% agarose gel and analyzed by agarose gel electrophoresis (Bio-Rad). *E. coli* ATCC 35218 strain was employed as a positive control.

PCR identification of the *zntA* gene

The *zntA* gene was detected using PCR, which encodes a zinc export protein that is responsible for heavy metal resistance, particularly zinc. The primers for the *zntA* gene were the forward primer, 5'-ATC GTC CGC TCG CTG TAT CTC T-3', and the reverse primer, 5'-CCG CCT TTT CCC CTC ACC CTA ACC-3' (Rensing et al., 1997). The predicted size was 2374 bp. The PCR amplification was performed in 50 µL as a final volume; 30.7 µL PCR water (AppliChem), 5 µL 10X buffer, 4 µL $MgCl_2$, 1 µL dNTP mix (Amplicon), 2 µL forward and reverse primer, 0.3 µL Taq DNA polymerase (Thermo Scientific), and 5 µL DNA template. PCR amplification was carried out in a Bio-Rad T100 thermal cycler under the following conditions: an initial denaturation at 94 °C for 8 min, followed by 35 cycles of denaturation at 94 °C for 1 min, primer annealing at 64 °C for 1 min, extension at 72 °C for 90 sec, and a final extension at 72 °C for 8 min. The amplified PCR products were separated by electrophoresis on a 1% agarose gel, stained with ethidium bromide and visualized (DNR Minilumi). A 100-bp DNA ladder (Vivantis) for DNA fragment size determination on gel electrophoresis was used. In all experiments, the reference strains, including *E. coli* K-12 and *E. coli* ATCC 35218, were used as positive controls.

RESULTS AND DISCUSSION

Nowadays, excessive and inappropriate use of antimicrobial drugs and heavy metals in aquaculture and animal farming may accelerate the spread of antimicrobial resistance through co-selection (Seiler et al., 2012). In this investigation, multidrug-resistant (MDR) *E. coli* isolates from vegetables were evaluated for resistance to heavy metal zinc ($ZnCl_2$) using both phenotypic and genotypic methods.

Table 1 displays the results of phenotypic and genotypic characterization for zinc resistance by the broth microdilution method and for the presence of Zn (II)-translocating P-type ATPase, encoded by the *zntA* gene, responsible for zinc resistance.

All MDR *E. coli* isolates from vegetable samples and tested reference strains, including *E. coli* K-12 and *E. coli* ATCC 35218, showed a minimum inhibitory concentration (MIC) for zinc greater than 3200 µg/ mL (Table 1). Furthermore, the minimum bactericidal concentrations (MBCs) for zinc were found to be higher than 3200 µg/mL for all MDR *E. coli* isolates and tested reference control strains, such as *E. coli* K-12 and *E. coli* ATCC 35218 (Table 1). Figure 1 illustrates a representative MBC image of *E. coli* K-12 and an MDR *E. coli* isolate from spinach (V11).

Table 1. Resistance to heavy metal zinc among the multidrug-resistant *E. coli* isolates

No	Isolate	Source	MIC (µg/mL)	MBC (µg/mL)	*zntA* gene
1	V10	Spinach	> 3200	> 3200	+
2	V11	Spinach	> 3200	> 3200	+
3	V13	Spinach	> 3200	> 3200	-
4	V17	Lettuce	> 3200	> 3200	+
5	V25	Lettuce	> 3200	> 3200	+
6	V26	Lettuce	> 3200	> 3200	+
7	V27	Lettuce	> 3200	> 3200	+
E. coli K-12			> 3200	> 3200	+
E. coli ATCC 35218			> 3200	> 3200	+

MIC, Minimum inhibitory concentration; MBC, Minimum bactericidal concentration.

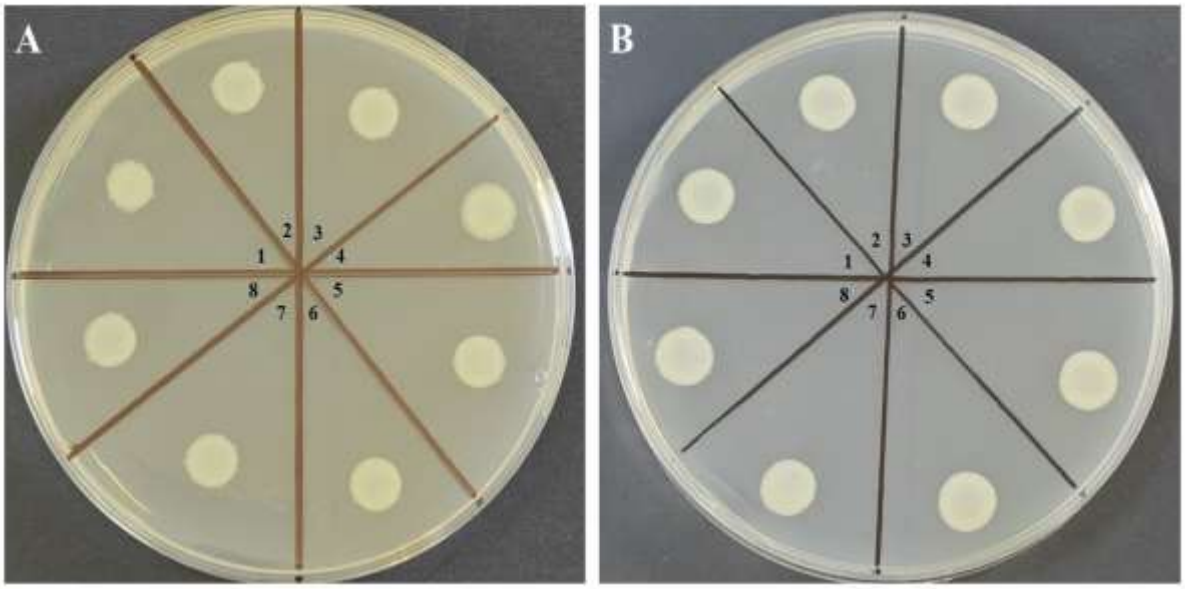

Figure 1. The agar plates represent the minimum bactericidal concentration (MBC) of heavy metal zinc against *E. coli* K-12 (A) and a spinach MDR *E. coli* isolate (B). The concentrations shown by the numerals 1-8 are 3200, 1600, 800, 400, 200, 100, 50, and 25 mg/mL.

The presence of the *zntA* gene associated with zinc resistance was performed by PCR amplification. Only six (85.7%) of the seven MDR *E. coli* isolates had the *zntA* gene identified by PCR (Table 1). The representative PCR products of the *zntA* gene in the MDR *E. coli* isolates from vegetables are shown in Figure 2.

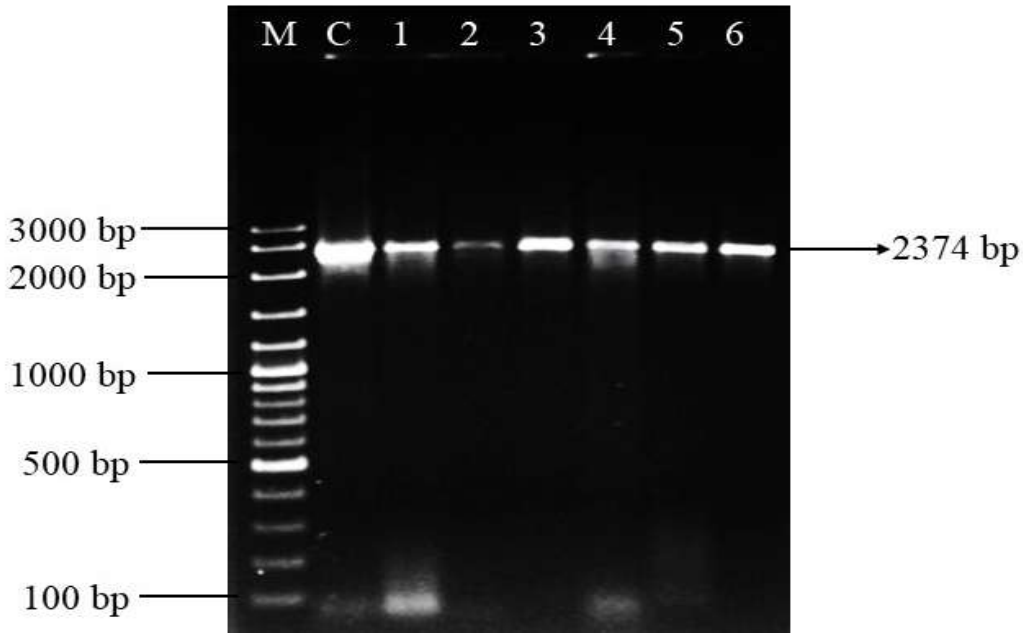

Figure 2. Agarose gel electrophoresis of the PCR amplification of the *zntA* gene (2374 bp) in six MDR *E. coli* isolates from vegetables, except the spinach *E. coli* isolate. M: 100 bp marker (Vivantis), C: positive *E. coli* K-12 strain, Lanes 1-7: MDR *E. coli* isolates in this study.

In this study, a high level (85.7%) of zinc resistance was observed among the seven multidrug resistant (MDR) *E. coli* isolates, suggesting a potential association between zinc and multidrug resistance. Similar observations were reported by Cufaoğlu et al. (2022), who reported that 89% of the *E. coli* isolates were resistant to at least three antibiotics. Among the eight heavy metals, zinc resistance was detected in 62%, with minimum inhibitory concentration (MIC) values reaching 3200 µg/mL. Additionally, PCR amplification of the Cufaoğlu et al. (2022) 20 isolates with high zinc MIC values revealed that 85% carried the *zntA* gene. In our study, PCR amplification indicated that the six MDR *E. coli* isolates (85.7%) carried the *zntA* gene (Figure 2). Yang et al. (2018) found that 77% of *E. coli* isolates contained the zntA gene, with MIC values ranging from 400 to 1600 µg/mL. Vidhyaparkavi et al. (2017) demonstrated that *zntA* expression increased in response to zinc exposure, confirming its importance in bacterial zinc tolerance. On the other hand, the mere presence of the *zntA* gene does not explain zinc resistance. For example, Adekanmbi et al. (2020) showed that some isolates of *E. coli* do not have the *zntA* gene, suggesting that maybe other mechanisms and systems contribute to zinc tolerance.

CONCLUSIONS

The present research revealed that the phenotypic and genotypic resistance characteristics of multidrug-resistant (MDR) *E. coli* isolates from vegetables to the heavy metal zinc. All MDR isolates were zinc resistant, and all except one carried the *zntA* gene, which is associated with zinc resistance. As a result, the existence and dissemination of heavy metal resistance in MDR *E. coli* isolates from vegetables might pose risks to human health and food safety.

ABSTRACT

Evaluating soil nutrient availability together with plant nutrient concentrations provides a comprehensive understanding of crop nutritional status. Accordingly, this study aimed to assess the macro- and micronutrient status of wheat grown in the Narlı Plain of Kahramanmaraş, Türkiye. Soil samples were collected from a depth of 0–30 cm, and flag leaf samples were collected immediately before heading from 11 wheat-growing fields. Soil samples were analyzed for pH, calcium carbonate ($CaCO_3$) and organic matter contents, available phosphorus (Olsen-P), exchangeable potassium (K), calcium (Ca), and magnesium (Mg), and DTPA-extractable iron (Fe), zinc (Zn), copper (Cu), and manganese (Mn). Plant samples were analyzed for P, K, Ca, Mg, Fe, Zn, Cu, and Mn concentrations. The soils were slightly to moderately alkaline, with organic matter contents ranging from 2.13% to 4.50% and $CaCO_3$ contents ranging from 19.84% to 41.09%. Soil Olsen-P concentrations varied between 7.98 and 35.38 mg kg^{-1}, while the mean DTPA-extractable Fe, Zn, Cu, and Mn concentrations were 11.73, 1.05, 1.50, and 9.65 mg kg^{-1}, respectively. The mean exchangeable K, Ca, and Mg concentrations were 339.55, 3461, and 1145 mg kg^{-1}, respectively. The mean P, K, Ca, and Mg concentrations in wheat flag leaves were 0.28%, 2.60%, 0.80%, and 0.18%, respectively, whereas the mean Fe, Zn, Cu, and Mn concentrations were 97.93, 21.84, 6.75, and 40.41 mg kg^{-1}, respectively. The results showed that wheat grown in the Narlı Plain was generally adequately supplied with the macro- and micronutrients examined. However, the variation in soil and plant nutrient concentrations among the sampled fields suggests that wheat nutrient status may be influenced by differences in soil nutrient reserves, fertilizer management, and other soil properties. These findings highlight the importance of evaluating soil and plant analyses together when developing field-specific nutrient management strategies for wheat production in the region.

Keywords: Calcareous soil, flag leaf, mineral nutrition, wheat.

INTRODUCTION

Determining the mineral nutritional status of wheat grown in calcareous soils represents an important diagnostic challenge because soil nutrient reserves do not necessarily correspond to the availability of these nutrients to plants. High soil pH and $CaCO_3$ content may restrict nutrient uptake by roots by altering nutrient speciation in the soil solution, adsorption–desorption equilibria, and precipitation reactions. Therefore, the presence of an adequate reserve of a particular nutrient in the soil does not necessarily indicate that the nutrient can be taken up by plants in sufficient amounts (Hinsinger, 2001; Marschner, 2012; Xue et al., 2016). Recent studies conducted in calcareous soils have also demonstrated that these conditions may affect nutrient uptake and fertilizer-use efficiency in wheat (Martínez-Ríos et al., 2024; Zaheri Abdehvand et al., 2024; Demirkaya & Gülser, 2025).

In calcareous and alkaline soils, P may form sparingly soluble compounds with Ca or become immobilized through retention on $CaCO_3$ surfaces. Similarly, high pH and the presence of carbonate and bicarbonate ions may reduce the solubility and root availability of Fe, Zn, Mn, and Cu. Zinc availability, in particular, is strongly influenced by interactions among soil pH, carbonate content, P status, organic matter, and clay minerals (Chen et al., 2019; Martínez-Ríos et al., 2024). Consequently, wheat grown in calcareous soils may exhibit marginal or latent nutrient deficiencies even in the absence of visible deficiency symptoms. However, the relationship between soil $CaCO_3$ content and plant nutritional status is not straightforward. Nutrient availability in the root zone is governed by the combined effects of soil pH and $CaCO_3$ content, as well as texture, organic matter, cation exchange capacity, soil moisture, and rhizosphere processes. Plant nutrient uptake may also vary depending on genotype, root-system characteristics, growth stage, fertilization history, and interactions among nutrients (White & Brown, 2010; Marschner, 2012). Therefore, $CaCO_3$ content alone may not provide an adequate basis for assessing plant nutritional status in calcareous soils.

Soil analyses provide information on the potential availability of nutrients and the nutrient-supplying capacity of the soil, whereas plant tissue analyses reflect the integrated outcome of soil–root processes as expressed in plant nutrient uptake. However, because elemental concentrations in plant tissues vary with the sampled organ and growth stage, the results should be interpreted using appropriate sampling times and established sufficiency ranges (Jones et al., 1991; Reuter & Robinson, 1997; Lemaire et al., 2019). Flag leaves collected immediately before heading constitute suitable diagnostic material for assessing the nutrient status of wheat. Accordingly, the combined use of soil and plant analyses enables a more comprehensive assessment of nutrient deficiencies and limitations to nutrient uptake.

The Narlı Plain, located south of Kahramanmaraş, is an important agricultural production area characterized by soils developed from alluvial and colluvial parent materials. Variations in topographic position and soil-forming conditions have resulted in considerable heterogeneity in the physical and chemical properties of the plain's soils (Yakupoğlu et al., 2012; Yakupoğlu & Demirci, 2013). Previous studies conducted in the region have shown that this variability is also reflected in soil pH, $CaCO_3$ content, and nutrient concentrations (Saltalı et al., 2018). Total and active $CaCO_3$ contents have also been reported to be associated with the availability of certain metallic micronutrients in the soils of the plain (Kadifeci et al., 2024). Nevertheless, field-based information on the extent to which soil nutrient levels are reflected in the nutritional status of wheat remains limited. Accordingly, this study aimed to determine selected physical and chemical properties of calcareous agricultural soils under wheat cultivation in the Narlı Plain and to evaluate the macro- and micronutrient status of wheat through combined soil and flag-leaf analyses. The relationships between soil $CaCO_3$ content and P, K, Ca, Mg, Fe, Zn, Cu, and Mn concentrations in wheat flag leaves were also investigated.

MATERIAL AND METHOD

Study area

The study was conducted in wheat-growing areas of the Narlı Plain, located within the administrative boundaries of Pazarcık district, Kahramanmaraş Province, southern Türkiye. Situated approximately 30 km southeast of Kahramanmaraş city center, the plain covers an area of approximately 26,500 ha and lies within a transitional zone between Mediterranean and continental climatic conditions (Saltalı et al., 2018).

The soils of the Narlı Plain have developed predominantly from alluvial and colluvial parent materials transported from the surrounding uplands and deposited across the plain. Variations in depositional environments and topographic positions have resulted in pronounced spatial

variability in the physical and chemical properties of these soils (Yakupoğlu et al., 2012; Yakupoğlu & Demirci, 2013). The soils of the region have generally been characterized as neutral to slightly alkaline and as having varying $CaCO_3$ contents. Moreover, their total and active $CaCO_3$ contents may influence the availability of metallic micronutrients (Kadifeci et al., 2024).

The study area comprised fields under wheat cultivation within the Narlı Plain. Eleven wheat-growing fields were selected to represent the spatial variability in soil properties and plant nutritional status across the plain. The geographical coordinates of the soil and flag-leaf sampling points were recorded during fieldwork. The location of the study area within Türkiye and Kahramanmaraş Province, together with the distribution of the sampling points across the Narlı Plain, is presented in Figure 1.

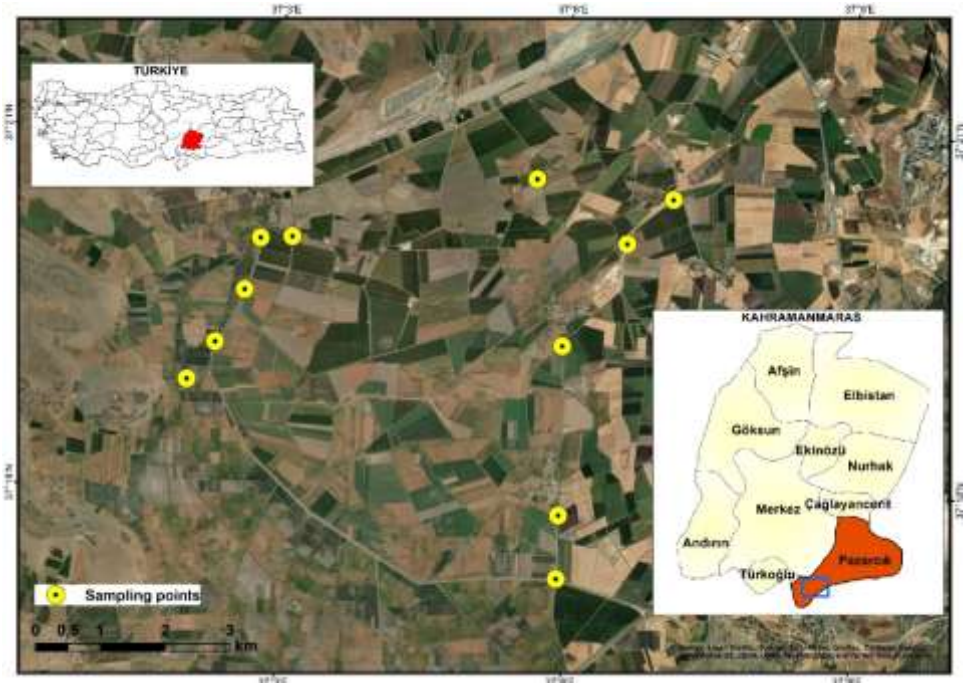

Figure 1. Location of the study area and distribution of soil and wheat flag-leaf sampling points in Narlı Plain

Soil and Plant Sampling and Preparation for Analysis

Soil samples were collected from a depth of 0–30 cm at 11 wheat-growing fields selected across the Narlı Plain, and the coordinates of the sampling points were recorded using a Global Positioning System (GPS). Composite soil samples representing each sampling point were transported to the laboratory, air-dried under ambient conditions, and passed through a 2-mm sieve. The prepared samples were labelled and stored in sealed plastic containers under cool and dry conditions until analysis (Richards, 1954).

Plant samples were collected simultaneously from the same fields where the soil samples were obtained. To assess the nutritional status of wheat, 25–30 representative flag leaves were collected from each field immediately before heading (Jones et al., 1991). The leaf samples were washed with distilled water to remove surface dust and other residues and subsequently oven-dried at 65 °C for 48 h. The dried plant material was ground and homogenized, transferred to labelled polyethylene bags, and stored under refrigerated conditions until chemical analysis (Jones & Case, 1990).

Soil and Plant Analyses

Soil pH and electrical conductivity (EC) were determined in saturated soil paste according to the methods described by Peech (1965) and Richards (1954), respectively. Total calcium carbonate ($CaCO_3$) content was measured using a Scheibler calcimeter (Loeppert & Suarez, 1996), whereas soil organic matter was determined using the Walkley–Black wet oxidation method (Nelson & Sommers, 1996). Available P was determined using the Olsen method based on extraction with 0.5 M $NaHCO_3$ at pH 8.5 (Olsen et al., 1954). Exchangeable K, Ca, and Mg were extracted with 1 N ammonium acetate (NH_4OAc) at pH 7.0 (Thomas, 1982). Plant-available Fe, Zn, Cu, and Mn were determined using the DTPA extraction method (Lindsay & Norvell, 1978). The concentrations of K, Ca, Mg, Fe, Zn, Cu, and Mn in the soil extracts were measured using an Agilent 240AA atomic absorption spectrophotometer (AAS).

A 0.50-g portion of each ground plant sample was wet-digested on a hot plate using a mixture of 5 mL HNO_3 and 4 mL $HClO_4$ until a clear solution was obtained (Jones & Case, 1990). Following digestion, the solutions were filtered and brought to a known volume with deionized water. Phosphorus concentration in the plant samples was determined spectrophotometrically using the vanadomolybdophosphoric yellow colour method. Potassium, Ca, Mg, Fe, Zn, Cu, and Mn concentrations were measured using an Agilent 240AA atomic absorption spectrophotometer.

Statisitical analyses

Minimum, maximum, mean, and standard deviation values for the soil and plant variables were calculated using Microsoft Office Excel. Relationships between soil $CaCO_3$ content and P, K, Ca, Mg, Fe, Zn, Cu, and Mn concentrations in wheat flag leaves were examined using two-tailed Pearson correlation analysis in IBM SPSS Statistics 23.0 (IBM Corp., Armonk, NY, USA). Statistical significance was accepted at $p < 0.05$, and graphical presentations of the results were prepared using Microsoft Office Excel.

RESULTS AND DISCUSSION

Characteristic Properties of the Study-Area Soils

Soil pH values ranged from 7.43 to 7.79, with a mean of 7.56. Electrical conductivity values varied between 303 and 501 µS cm^{-1}, averaging 349 µS cm^{-1}. Soil $CaCO_3$ contents ranged from 19.84% to 41.09%, with a mean of 27.95%, whereas organic matter contents varied between 2.13% and 4.50%, with a mean of 2.85%. Based on these results, the soils were generally characterized as slightly alkaline and non-saline, with high to very high $CaCO_3$ contents and moderate organic matter levels.

Table 1. Descriptive statistics of selected physicochemical properties of the study area soils

	pH	**EC**	**Lime**	**OM**
		(µS/cm)		%
Min	7,43	303	19,84	2,13
Mak	7,79	501	41,09	4,50
Ort	7,56	349	27,95	2,85

Macronutrient Status of the Study-Area Soils

Evaluation of the macronutrient contents of soil samples collected from the Narlı Plain revealed different sufficiency levels among the nutrients examined. According to Cottenie (1980), available P concentrations of 8–25 mg kg^{-1} are classified as sufficient, whereas concentrations of 25–80 mg kg^{-1} are considered high. Based on these thresholds, the mean available P concentration (22.5 mg kg^{-1}) was within the sufficient range; 54.5% of the samples were classified as sufficient and 45.5% as high. However, because the minimum concentration was close to the lower limit of the sufficiency range, the mean value should be interpreted together with the variability among sampling sites.

The mean exchangeable K concentration (340 mg kg^{-1}) exceeded the ≥161 mg kg^{-1} threshold above which Kaiser and Piotrowski (2024) did not recommend K fertilization for wheat under Minnesota conditions. While 63.6% of the samples reached or exceeded this threshold, 36.4% had K concentrations within the range of 95–160 mg kg^{-1}. Therefore, the high mean K concentration should not be interpreted as indicating a uniform K status across all sampling sites. Because this threshold was developed for a different region, it should be used as a comparative benchmark rather than directly applied to fertilizer recommendations for the Narlı Plain.

Regarding exchangeable Ca, 45.5% of the samples were classified as sufficient (1150–3500 mg kg^{-1}), whereas 54.5% were classified as high (3500–10,000 mg kg^{-1}). The mean Ca concentration (3461 mg kg^{-1}) was close to the upper limit of the sufficient range. Accordingly, the results did not indicate Ca deficiency in the investigated soils under the classification system used. For exchangeable Mg, 72.7% of the samples were classified as high (480–1500 mg kg^{-1}) and 27.3% as very high (>1500 mg kg^{-1}). The mean Mg concentration (1145 mg kg^{-1}) was within the high range, and all samples exceeded the sufficiency range, indicating that the soils generally had high exchangeable Mg concentrations (Cottenie, 1980).

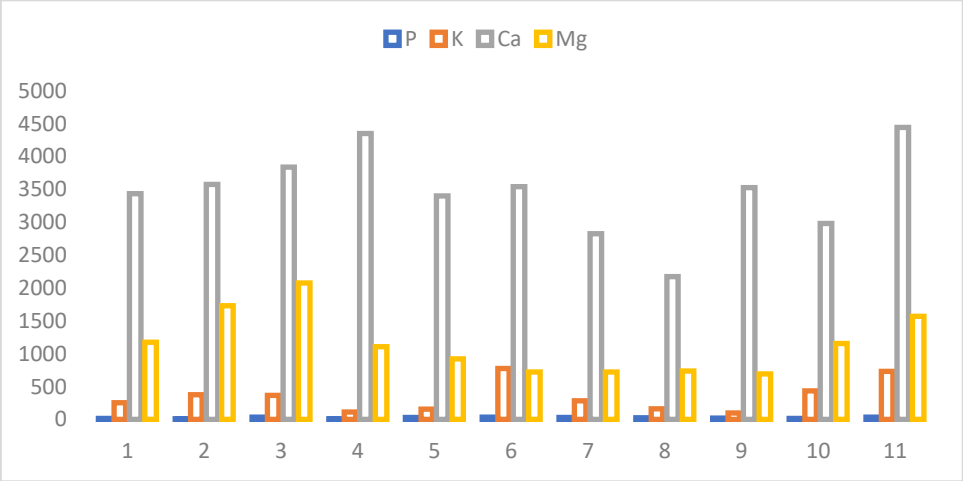

Figure 2. Distribution of available P and exchangeable cations

Micronutrient Status of the Study-Area Soils

The DTPA-extractable micronutrient concentrations of the soil samples collected from the Narlı Plain varied among the sampling sites (Figure 2). Iron (Fe) concentrations ranged from 8.88 to 23.52 mg kg^{-1}, with a mean of 11.73 mg kg^{-1}. Zinc (Zn) concentrations varied between 0.54

and 2.90 mg kg^{-1}, averaging 1.05 mg kg^{-1}. Copper (Cu) concentrations ranged from 1.08 to 2.20 mg kg^{-1}, with a mean of 1.50 mg kg^{-1}, whereas manganese (Mn) concentrations varied between 3.36 and 28.80 mg kg^{-1}, averaging 9.65 mg kg^{-1}. The mean concentrations of the micronutrients followed the order Fe > Mn > Cu > Zn.

Soil micronutrient status was evaluated using the critical levels reported for maize by Lindsay and Norvell (1978) as comparative benchmarks. In all samples, Fe, Cu, and Mn concentrations exceeded their respective critical levels of 4.5, 0.2, and 1.0 mg kg^{-1}. Thus, according to these thresholds, no indication of Fe, Cu, or Mn deficiency was identified in the investigated soils. However, the critical values reported for Mn and Cu were proposed tentatively and should therefore be interpreted with caution.

Based on the critical Zn level of 0.8 mg kg^{-1}, 45.5% of the samples were classified as deficient and 54.5% as sufficient. Although the mean Zn concentration (1.05 mg kg^{-1}) exceeded the critical threshold, the occurrence of concentrations below this value in 45.5% of the samples demonstrates that soil Zn status should not be evaluated solely on the basis of the mean. Zinc was the only micronutrient for which values below the critical level were detected, indicating a potential Zn deficiency at some sampling sites that warrants further investigation. Nevertheless, because the thresholds used were originally established for maize, definitive conclusions regarding wheat nutritional status should be supported by plant tissue analyses and crop-specific sufficiency criteria.

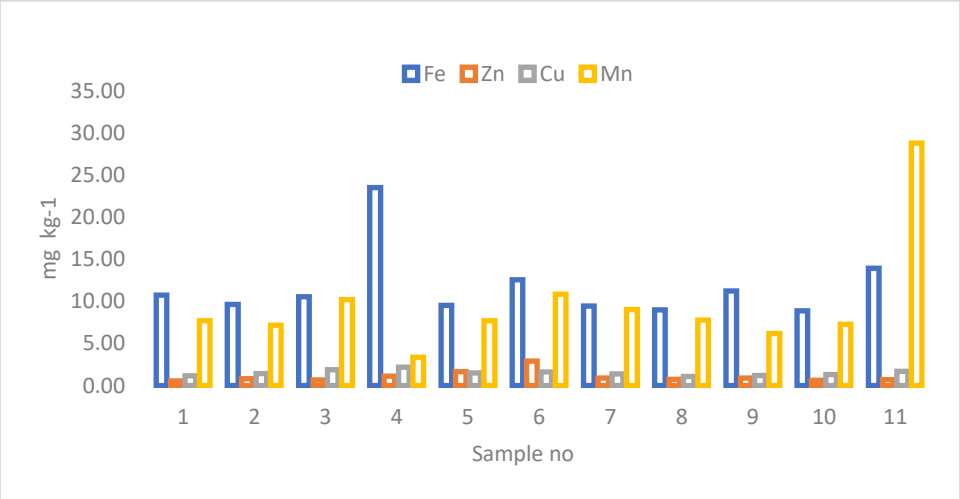

Figure 3. Distribution of DTPA-extractable Fe, Zn, Cu, Mn and Ni concentrations

Flag-Leaf Macronutrient Concentrations in Wheat

Macronutrient concentrations in wheat flag leaves varied among the sampling sites. Phosphorus concentrations ranged from 0.21% to 0.38%, with a mean of 0.28%. Potassium concentrations varied between 2.13% and 3.33%, averaging 2.60%. Calcium concentrations exhibited a relatively wide variation, ranging from 0.40% to 1.61%, with a mean of 0.80%. Magnesium concentrations ranged from 0.14% to 0.24%, with a mean of 0.18% (Figure 5). Among the macronutrients examined, K had the highest mean concentration, whereas Mg had the lowest.

The plant analysis results indicated that wheat grown in the study area generally had an adequate macronutrient status. When compared with the critical concentrations and sufficiency ranges reported for wheat, P and K concentrations were considered sufficient at all sampling sites (Jones et al., 1991; Reuter & Robinson, 1997; Plank & Donohue, 2000). In particular, the mean

P (0.28%) and K (2.60%) concentrations exceeded the reported critical levels for wheat, indicating no apparent nutritional deficiency in these elements.

The variation in Ca concentrations from 0.40% to 1.61% indicated considerable differences among the sampling sites in Ca uptake or accumulation within plant tissues. Nevertheless, all measured Ca concentrations exceeded the critical level reported for wheat. Magnesium concentrations varied within a narrower range and averaged 0.18%. Because even the lowest Mg concentration (0.14%) was above the critical level, no evident Mg deficiency was identified in the wheat plants (Jones et al., 1991; Reuter & Robinson, 1997; Plank & Donohue, 2000).

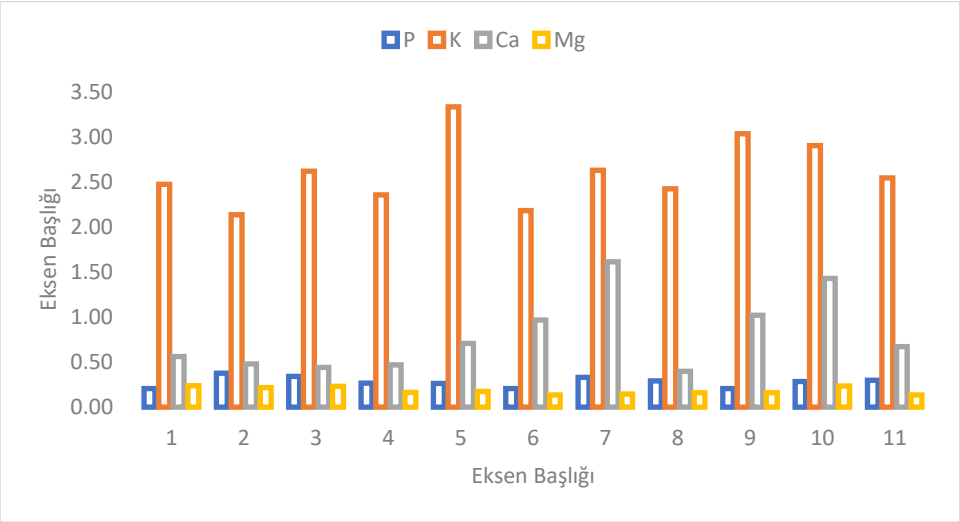

Figure 4. Foliar concentrations of macronutrients in wheat

Micronutrient Status of Wheat Flag Leaves

Micronutrient concentrations in wheat flag leaves varied among the sampling sites. Iron concentrations ranged from 69.00 to 156.75 mg kg^{-1}, with a mean of 97.93 mg kg^{-1}. Zinc concentrations varied between 17.50 and 30.00 mg kg^{-1}, averaging 21.84 mg kg^{-1}. Copper concentrations ranged from 4.50 to 8.75 mg kg^{-1}, with a mean of 6.75 mg kg^{-1}, whereas Mn concentrations varied between 16.00 and 54.25 mg kg^{-1}, averaging 40.41 mg kg^{-1} (Figure 6).

Based on the critical concentrations and sufficiency ranges reported for wheat, Fe, Zn, and Mn concentrations were generally considered adequate (Jones et al., 1991; Reuter & Robinson, 1997; Plank & Donohue, 2000). Iron concentrations of at least 69.00 mg kg^{-1} at all sampling sites indicated no evident Fe deficiency. Similarly, the observed Zn concentrations indicated that the wheat plants generally had an adequate Zn nutritional status.

Although the mean Cu concentration was within the sufficient range, the lowest value of 4.50 mg kg^{-1}, recorded at sampling site 2, was close to the critical level of approximately 5 mg kg^{-1} reported for wheat. Therefore, Cu nutrition was generally adequate, although a marginal Cu status may have occurred at this sampling site (Jones et al., 1991; Reuter & Robinson, 1997). Manganese concentrations indicated adequate nutrition at most sampling sites; however, the minimum concentration recorded at sampling site 11 was close to the lower limit of the sufficiency range.

Overall, wheat grown in the study area was adequately supplied with Fe, Zn, Cu, and Mn, although Cu and Mn concentrations approached the lower sufficiency limits at some sampling sites. Because tissue micronutrient concentrations may be influenced by soil pH, $CaCO_3$ and

organic matter contents, nutrient availability, and interactions among elements, the combined interpretation of soil and plant analyses provides a more reliable assessment of wheat nutritional status (Reuter & Robinson, 1997).

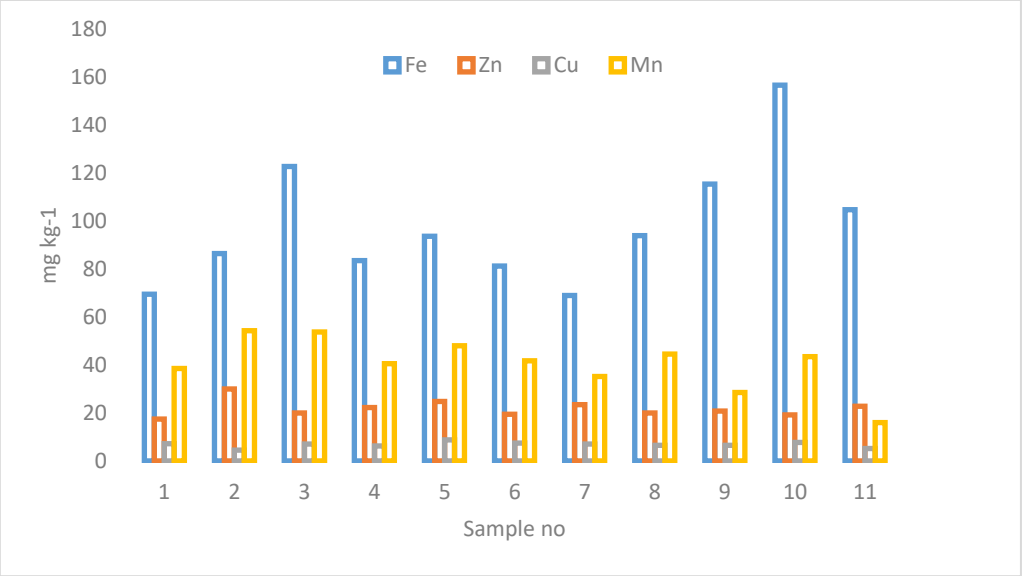

Figure 5. Foliar micronutrient concentrations in wheat

Relationships between soil lime and plant nutrients

No statistically significant correlations were detected between soil $CaCO_3$ content and P, K, Ca, Mg, Fe, Zn, Cu, or Mn concentrations in wheat flag leaves ($p > 0.05$; Table 2). Correlation coefficients ranged from −0.268 to 0.228, indicating no apparent linear relationship between soil $CaCO_3$ content and the macro- or micronutrient concentrations of wheat across the sampled fields. These findings suggest that variation in wheat nutritional status cannot be explained solely by soil $CaCO_3$ content and may also be influenced by soil nutrient reserves, fertilization practices, other soil properties, and plant-related factors. Nevertheless, because of the limited sample size ($n = 11$), the results should be interpreted within the context of the study area and sampling conditions (Table 2).

Table 2 Pearson correlation coefficients between soil lime and nutrient concentrations in wheat flag leaves

Plant nutrient	Pearson's r	p value	Significance
P	0,033	0,923	ns
K	−0,137	0,688	ns
Ca	−0,268	0,425	ns
Mg	0,228	0,500	ns
Fe	−0,028	0,934	ns
Zn	0,005	0,987	ns
Cu	−0,227	0,503	ns

Mn	0,001	0,998	ns

Note: Pearson correlation coefficients were calculated using 11 paired soil and flag-leaf samples (n = 11). ns: not significant ($p > 0.05$; two-tailed).

CONCLUSION

Wheat grown in the calcareous agricultural soils of the Narlı Plain was generally adequately supplied with P, K, Ca, Mg, Fe, Zn, Cu, and Mn. Available P and exchangeable K, Ca, and Mg concentrations in the soils were predominantly sufficient or high, while no clear deficiency of Fe, Cu, or Mn was identified. However, Zn concentrations were below the critical threshold in 45.5% of the soil samples, indicating a potential risk of Zn deficiency in some production fields. Plant analysis revealed no evident nutrient deficiencies, although Cu and Mn concentrations approached the lower limits of the sufficiency ranges at certain sampling sites. The absence of significant relationships between soil $CaCO_3$ content and nutrient concentrations in wheat flag leaves ($p > 0.05$) indicated that variation in plant nutritional status could not be explained solely by soil $CaCO_3$ content. Consequently, the combined interpretation of soil and plant analyses is recommended for a reliable assessment of wheat nutritional status in the Narlı Plain, with particular attention to the regular monitoring of Zn, Cu, and Mn.

ABSTRACT

The identification of drought-tolerant wheat germplasm is essential for developing climate-resilient cultivars. This study evaluated drought tolerance in 96 genotypes representing eight *Triticum* groups, including durum landraces, durum breeding lines, Polish wheat, Khorasan wheat, bread wheat landraces, Indian dwarf wheat, and tetraploid and hexaploid check cultivars. Drought responses were assessed using unmanned aerial vehicle (UAV)-derived thermal retention, membrane damage, and complementary drought stress indices. Thermal images acquired at the tillering and heading stages were processed using Pix4D, and the resulting thermal index values were used to calculate thermal retention (TE retention), while membrane damage was determined using the electrolyte leakage method. Grain yield under irrigated and water-deficit conditions was used to calculate the Relative Efficiency Index (REI), Stress Non-Stress Production Index (SNPI), Modified Stress Tolerance Index 1 (K1STI), and Modified Stress Tolerance Index 2 (K2STI). Principal component analysis (PCA) was performed separately for tetraploid and hexaploid materials to investigate relationships among physiological traits and drought indices. Substantial variation was observed among and within wheat groups for all evaluated traits. Membrane damage and TE Retention showed considerable genotypic variation, while drought indices revealed contrasting response patterns among genotypes. Durum breeding lines exhibited relatively higher SNPI values and broader variation than the other tetraploid groups, while bread wheat landraces showed substantial variability for the modified stress tolerance indices. PCA discriminated genotypes according to membrane damage, TE retention, and drought index profiles, identifying several durum breeding lines and Khorasan wheat genotypes with favorable drought-response characteristics. The integration of UAV-derived thermal traits, membrane damage, and complementary drought indices effectively characterized drought responses across genetically diverse wheat materials and provides a practical approach for identifying promising germplasm for wheat improvement programs.

Keywords: drought tolerance, UAV thermal imaging, membrane stability, stress indices, *Triticum* spp.

INTRODUCTION

Drought is one of the most severe abiotic stresses limiting wheat (*Triticum* spp.) production worldwide and is expected to intensify under changing climatic conditions. As one of the world's principal staple crops, wheat supplies nearly 20% of the calories and protein consumed by the global population, making the development of drought-resilient cultivars essential for sustaining future food security (Ashfaq et al., 2022). Water deficit adversely affects plant growth, photosynthesis, assimilate partitioning, and grain filling, ultimately reducing grain yield. However, the magnitude of yield loss largely depends on drought severity, duration, and the developmental stage at which stress occurs, making drought tolerance one of the most complex traits targeted in wheat breeding (Ashfaq et al., 2022; Ghanem & Al-Farouk, 2024).

The genus *Triticum* encompasses a broad range of cultivated species differing in ploidy level, evolutionary origin, genetic constitution, and adaptation to diverse agroecological environments. Ancient wheats and traditional landraces have recently attracted renewed interest because they represent valuable reservoirs of genetic diversity that may contain adaptive alleles lost during modern breeding (Lopes et al., 2015). Comparative evaluation of genetically diverse wheat groups therefore provides an opportunity to identify novel sources of drought tolerance and broaden the genetic basis of future breeding programs. Nevertheless, information describing the comparative physiological responses of diverse *Triticum* groups under water-deficit conditions remains limited, particularly when evaluated using integrated phenotyping approaches.

Conventional drought screening has primarily relied on grain yield measured under irrigated and stress conditions. Although yield remains the ultimate breeding target, it is strongly influenced by environmental variation and genotype × environment interactions, frequently limiting its effectiveness as the sole selection criterion (Ahmad et al., 2022). Consequently, physiological traits and complementary drought tolerance indices have become increasingly important for improving selection efficiency. Among physiological traits, membrane damage estimated by electrolyte leakage has been widely accepted as a reliable indicator of cellular injury caused by drought stress. Water deficit promotes oxidative stress, leading to lipid peroxidation, disruption of membrane integrity, and increased electrolyte leakage; therefore, genotypes exhibiting lower membrane damage generally possess greater tolerance to drought (Shahid et al., 2022).

Recent advances in high-throughput phenotyping have substantially improved the evaluation of drought responses in breeding populations. In particular, unmanned aerial vehicle (UAV)-based thermal imaging enables rapid, non-destructive, and repeated assessment of crop performance under field conditions. Thermal information derived from UAV platforms has been successfully associated with canopy temperature, plant water status, transpiration, biomass production, and grain yield, allowing the early identification of drought-responsive genotypes while greatly increasing phenotyping efficiency compared with conventional field measurements (Ashfaq et al., 2022; Awais et al., 2023; Das et al., 2022; Mali et al., 2025). The integration of UAV-assisted thermal phenotyping with physiological measurements therefore provides a powerful approach for characterizing drought adaptation in genetically diverse germplasm.

To complement physiological measurements, numerous drought tolerance indices have been proposed to simultaneously evaluate genotype performance under stress and non-stress environments (Jalili et al., 2026). Classical indices, including Mean Productivity (MP),

Geometric Mean Productivity (GMP), Harmonic Mean (HM), and Stress Tolerance Index (STI), have been widely used for drought evaluation, whereas recently developed indices such as Relative Efficiency Index (REI), Stress Non-Stress Production Index (SNPI), and Modified Stress Tolerance Indices (K1STI and K2STI) provide improved discrimination of genotypes exhibiting both high productivity and stable performance across contrasting environments (Jalili et al., 2026). Furthermore, multivariate statistical techniques, particularly principal component analysis (PCA), facilitate the simultaneous interpretation of physiological traits and drought indices, enabling more reliable identification of drought-tolerant germplasm than the use of individual parameters alone (Al-Ashkar, 2024; Jalili et al., 2026).

Although UAV-derived thermal traits, membrane damage, and drought tolerance indices have individually been used to characterize drought responses in wheat, studies integrating these complementary approaches across genetically diverse *Triticum* groups remain scarce. Therefore, the present study aimed to comparatively evaluate drought tolerance in 96 genotypes representing eight wheat groups using UAV-derived thermal responses, membrane damage, and complementary drought indices (REI, SNPI, K1STI, and K2STI). In addition, principal component analysis was performed separately for tetraploid and hexaploid materials to investigate the relationships among physiological traits, drought indices, and genotypic responses under contrasting water regimes.

MATERIAL AND METHOD

Plant Materials and Experimental Design

A total of 96 wheat genotypes representing diverse *Triticum* species were used as plant material in this study. The germplasm consisted of 90 accessions obtained from the United States Department of Agriculture (USDA) National Plant Germplasm System (NPGS), including 45 tetraploid genotypes (11 *T. durum* landraces, 14 *T. durum* breeding lines, 5 *T. polonicum*, and 15 *T. turanicum*) and 45 hexaploid genotypes (34 *T. aestivum* landraces and 11 *T. sphaerococcum*). Detailed information on the evaluated genotypes is presented in Table 1.

Table 1. Information about the genotypes used in the study.

T. aestivum_checks	MFTBY	Registered Cultivar	Müfitbey	Türkiye
	REİS	Registered Cultivar	Reis	Türkiye
	ESPE	Registered Cultivar	Esperia	Türkiye

Six commercially grown wheat cultivars were included as check varieties. The tetraploid checks comprised the durum wheat cultivars Kızıltan, Eminbey, and Kümbet, whereas the hexaploid checks consisted of the bread wheat cultivars Müfitbey, Reis, and Esperia.

The experimental soil had a clay texture, with a salt content of 0.06%, lime content of 8.24%, organic matter content of 2.65%, and a pH of 7.73. The amounts of plant-available P_2O_5 and K_2O in the soil were 10.31 and 271.93 kg da^{-1}, respectively. Climatic conditions during the 2023–2024 growing season differed from the long-term averages (1991–2022). The mean temperature during the growing period was 11.2°C, compared with the long-term average of 8.9°C, while total precipitation was 249.2 mm, approximately 15% lower than the long-term average of 294.5 mm. The difference was particularly pronounced during the later stages of crop development. Precipitation in April, June, and July was only 11.8, 5.6, and 4.4 mm, respectively, compared with the corresponding long-term averages of 44.1, 24.2, and 15.0 mm. In addition, June and July were warmer than the long-term averages, with mean temperatures of 22.9 and 23.7°C, respectively. These conditions indicate that the crop experienced relatively warm and dry conditions, particularly during the later part of the growing season.

Field experiments were established on 26 October 2023 under two contrasting water regimes, irrigated (IR) and rainfed (RF), using an augmented experimental design. Each genotype was sown with a plot drill at a seeding density of 500 plants m^{-2} in four-row plots, each 4 m in length with 25 cm row spacing. Phosphorus fertilizer was applied at sowing at a rate of 8 kg P_2O_5 da^{-1},

whereas nitrogen fertilizer was applied according to soil analysis recommendations to provide a total of 14 kg N da^{-1}, split between sowing and the stem elongation stage.

Physiological evaluations were performed using leaf samples collected at the tillering (Zadoks 30) and heading (Zadoks 58) growth stages under both irrigated and rainfed conditions. The experimental plots were harvested on 19 July 2024 using a plot combine harvester, and grain yield was determined for each genotype under both water regimes.

UAV-Based Thermal Imaging and Thermal Retention Analysis

High-throughput thermal phenotyping was performed using a DJI Mavic 2 Enterprise Advanced unmanned aerial vehicle (UAV) equipped with an integrated thermal infrared (TIR) camera. The thermal sensor had a resolution of 640 × 512 pixels and operated within the 8–14 μm spectral range. Thermal image acquisition was conducted at the tillering (Zadoks 30) and heading (Zadoks 58) growth stages under both irrigated (IR) and rainfed (RF) conditions. To minimize the influence of environmental variation on thermal measurements, all UAV flights were conducted under clear-sky conditions between 10:00 and 12:00 h, with wind speeds below 12 m s^{-1}. Images were acquired at an altitude of 15 m above ground level (AGL), with approximately 80% forward overlap and 70% side overlap, ensuring sufficient image overlap for orthomosaic generation.

Thermal images, from which orthomosaic maps were created using Pix4Dmapper software (Pix4D SA, Lausanne, Switzerland), were processed using the zonal statistics tool in ArcGIS to obtain average thermal index values derived from the image at the plot level under irrigated and rain-fed conditions. The image-derived thermal index reflects relative variation in canopy thermal conditions but does not represent absolute canopy temperature. To characterize the relative thermal response of each genotype to water deficit, the thermal index obtained under rainfed conditions was normalized to the corresponding value under irrigated conditions. This stress-to-irrigated ratio was termed thermal retention (TE retention) in the present study and was calculated separately for the tillering and heading stages as follows:

TE Retention = Thermal Index (RF) / Thermal Index (IR)

where Thermal Index (RF) and Thermal Index (IR) represent the plot-level image-derived thermal index values obtained under rainfed and irrigated conditions, respectively. A TE Retention value of 1.0 indicates no relative change in the thermal index between the two water regimes, whereas values above or below 1.0 indicate proportionally higher or lower thermal index values under rainfed conditions, respectively.

Membrane Damage Determination

Membrane damage was determined using the electrolyte leakage method described by Sairam et al. (1997) with slight modifications. At both the tillering (Zadoks 30) and heading (Zadoks 58) growth stages, three leaf discs (2 cm in diameter) were collected from irrigated (control) and rainfed (drought-stressed) plants. The discs were rinsed thoroughly with distilled water, gently blotted dry, and transferred into test tubes containing 20 mL of distilled water. Samples were incubated on a rotary shaker at 250 rpm for 4 h at room temperature, after which the initial electrical conductivity (EC_1) was measured using a conductivity meter.

Subsequently, the samples were autoclaved at 121°C for 15 min to completely disrupt the cell membranes and release the remaining electrolytes. After cooling to room temperature, the final electrical conductivity (EC_2) was recorded. Electrolyte leakage (EL) was calculated according to the following equation (Sairam et al., 1997):

$EL\ (\%) = (EC_1 / EC_2) \times 100$

Membrane damage (%) was subsequently calculated using the electrolyte leakage values of drought-stressed and irrigated plants according to the following equation:

$$\text{Membrane damage (\%)} = [(EL_{stress} - EL_{control}) / (100 - EL_{control})] \times 100$$

where ELstress and ELcontrol represent the electrolyte leakage percentages measured under rainfed and irrigated conditions, respectively.

Drought Tolerance Indices

Grain yield obtained under irrigated (Yp) and rainfed (Ys) conditions was used to calculate four complementary drought tolerance indices. The relative efficiency index (REI) was calculated as: $REI = (Ys_i / \bar{Y}s) \times (Yp_i / \bar{Y}p)$ according to Hossain et al. (1990).

The modified stress tolerance index 1 (K1STI) and modified stress tolerance index 2 (K2STI) were calculated according to Farshadfar and Sutka (2002) using the following equations: $K1STI = (Yp^2 / \bar{Y}p^2) \times STI$ and $K2STI = (Ys^2 / \bar{Y}s^2) \times STI$

The stress non-stress production index (SNPI) was calculated according to Moosavi et al. (2008) as: SNPI = [(Yp + Ys) / (Yp − Ys)]^(1/3) × (Yp × Ys × Ys)^(1/3)

where Yp and Ys represent grain yield under irrigated and rainfed conditions, respectively, while $\bar{Y}p$ and $\bar{Y}s$ denote the corresponding mean yields of all genotypes under irrigated and rainfed conditions. These indices were selected because they simultaneously evaluate genotype productivity under favorable and water-deficit environments and provide complementary information on drought tolerance and yield stability.

Statistical Analysis

Descriptive statistics were calculated for all physiological traits and drought tolerance indices to summarize the variation among wheat groups. The distributions of membrane damage, TE retention, REI, SNPI, K1STI, and K2STI were visualized using boxplots.

To investigate the relationships among physiological traits and drought tolerance indices and to identify the major sources of variation, principal component analysis (PCA) was performed separately for tetraploid and hexaploid wheat materials. The analysis included membrane damage at tillering (MDTL) and heading (MDHD), TE retention at tillering (TERTL) and heading (TERHD), and the four drought tolerance indices (REI, SNPI, K1STI, and K2STI). Prior to PCA, all variables were standardized to zero mean and unit variance to eliminate differences in measurement scales.

PCA biplots were generated to visualize the distribution of genotypes and the relationships among the evaluated variables. Descriptive statistics, boxplots, principal component analysis, and graphical visualizations were performed using R software (version 4.5.2; R Core Team, Vienna, Austria) with the ggplot2, ggrepel, factoextra, and dplyr packages.

RESULTS AND DISCUSSION

Thermal Retention Responses under Drought Conditions

The TE retention parameter showed substantial variation among wheat groups at both the tillering (TL) and heading (HD) stages (Figure 1), indicating marked genotypic differences

in the relative thermal response between rainfed and irrigated conditions. As observed for membrane damage, within-group variation was generally pronounced, highlighting considerable genetic diversity in thermal responses to water deficit.

At the tillering stage (Figure 1A), the tetraploid checks (DWC) exhibited TE retention values relatively close to 1.0, with a comparatively narrow distribution across the three check cultivars. Likewise, the hexaploid checks (BWC) displayed a relatively narrow distribution. In contrast, Polish wheat (P) and durum lines (OR) showed much broader distributions, reflecting greater genotypic variability. Among individual genotypes, A159 exhibited a high TE retention value (1.52) within the bread wheat landrace group, whereas D115 showed the lowest value (0.56) among the durum landraces. Considerable variation was also observed within Indian dwarf wheat, where TE Retention ranged from 0.46 (S26) to 1.24 (S23).

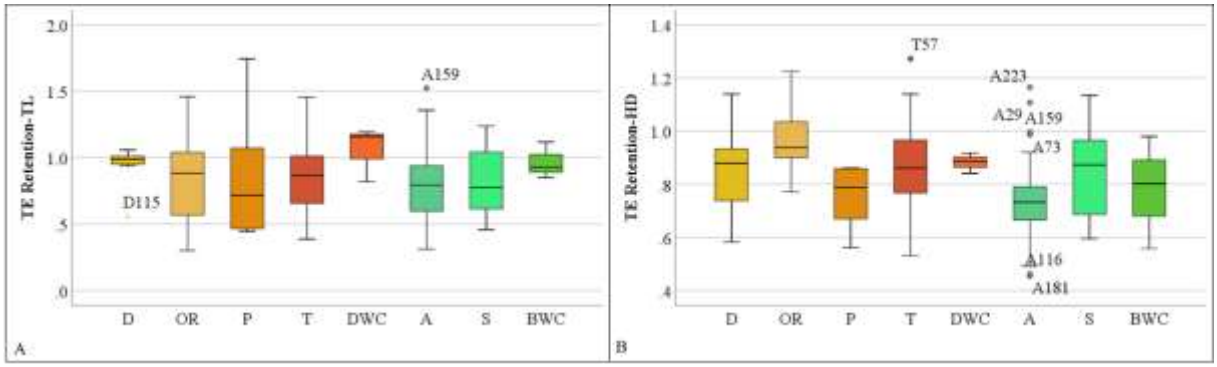

Figure 1. Thermal retention in the examined wheat genotypes under drought stress.

At the heading stage (Figure 1B), group differences became less pronounced, with most median values ranging approximately between 0.75 and 0.95. Nevertheless, several individual genotypes deviated markedly from their respective group distributions. Genotype T57 exhibited the highest TE retention value (1.27), while A223 (1.16), A29 (1.11), and A159 (1.00) showed relatively high values within the bread wheat landrace group. Conversely, A181 and A116 exhibited the lowest values (0.46), corresponding to substantially lower thermal index values under rainfed than under irrigated conditions.

The relatively narrow distributions observed for the tetraploid and hexaploid check cultivars indicate less genotypic variation in their relative thermal responses, whereas the broader distributions detected within several landrace and genetically diverse groups demonstrate substantial within-group variability. In particular, bread wheat landraces, durum lines, and Indian dwarf wheat contained genotypes with markedly contrasting TE retention values, providing useful variation for evaluating thermal responses to water deficit.

UAV-based thermal imaging has increasingly been used for high-throughput assessment of crop responses to water deficit because thermal characteristics can provide information related to plant water status and physiological responses to drought (Qin et al., 2022; Mali et al., 2025; Sharma et al., 2025; Cudjoe et al., 2026). As TE retention represents the ratio of the thermal index under rainfed to irrigated conditions (RF/IR), values close to 1.0 indicate a relatively small change between water regimes. Several genotypes remained close to unity, including D90 and D82 at tillering and A159, OR4, S3, and A73 at heading. However, pronounced stage-dependent responses were also observed. For example, P2 decreased from 1.74 at tillering to 0.79 at heading, OR32 from 1.46 to 0.91, whereas T37 increased from 0.43 to 1.14. These shifts indicate that genotypic thermal responses to water deficit were strongly influenced by developmental stage.

Thermal traits have been widely used to characterize wheat responses to water deficit because canopy thermal behavior is associated with plant water status, stomatal regulation, and transpirational cooling (Blum et al., 1989; Bhandari et al., 2021; Qin et al., 2022). In the present study, TE retention was used as a relative thermal-response parameter rather than as an independent measure of drought tolerance. Therefore, genotypes with values close to unity were considered to exhibit greater thermal stability between water regimes, while their overall drought performance was evaluated together with membrane damage and yield-based stress indices.

Membrane Damage Responses of Wheat Groups under Drought Stress

Membrane damage varied considerably among the evaluated wheat groups at both the tillering (TL) and heading (HD) growth stages (Figure 2), indicating substantial genetic variation in cellular responses to drought stress. However, variation within groups was generally greater than that among groups, demonstrating the broad diversity of drought adaptation mechanisms present within the evaluated Triticum germplasm.

At the tillering stage (Figure 2A), Indian dwarf wheat (S) exhibited the highest mean membrane damage (8.08%), followed by the hexaploid checks (BWC) (5.91%), bread wheat landraces (A) (5.05%), and tetraploid checks (DWC) (4.23%). In contrast, Khorasan wheat (T) (2.28%) and durum lines (OR) (2.31%) showed the lowest average membrane damage. The Indian dwarf wheat group also exhibited the greatest variability (SD = 7.49; CV = 92.66%), with membrane damage ranging from only 0.68% (S25) to 23.57% (S26). Similarly, bread wheat landraces displayed a broad range of responses, varying from 0.14% (A111) to 14.70% (A162), reflecting the large physiological diversity within this germplasm. In comparison, durum lines showed a narrower distribution despite a similar mean value, with OR32 (0.28%), OR25 (0.37%), and OR38 (0.47%) exhibiting the lowest membrane damage, whereas OR27 (6.12%) represented the most susceptible genotype within this group.

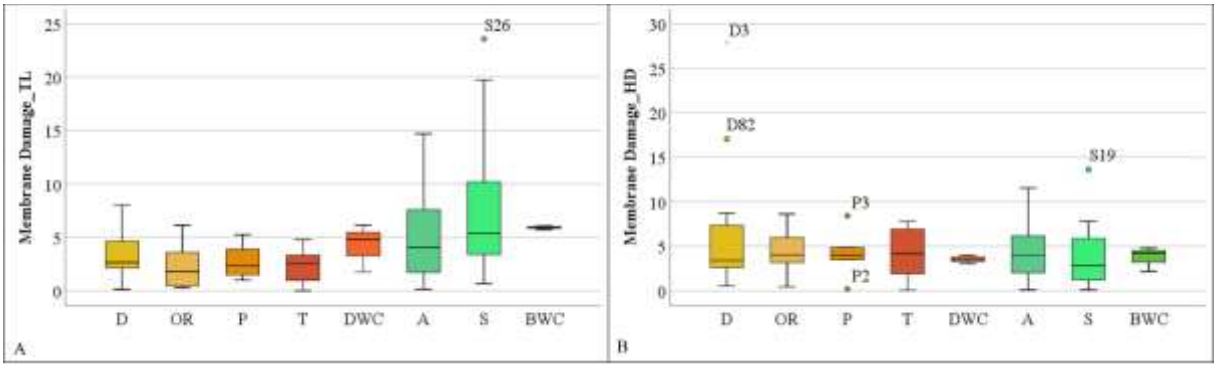

Figure 2. Membrane damage in the examined wheat genotypes under drought stress.

At the heading stage (Figure 2B), membrane damage became more uniform among wheat groups, with group means ranging from 3.54% (tetraploid checks) to 7.03% (durum landraces). However, several individual genotypes showed exceptionally high injury. Genotype D3 exhibited the greatest membrane damage (27.86%), followed by D82 (17.04%), resulting in the highest coefficient of variation for the durum landrace group (CV = 117.83%). Likewise, S19 (13.62%) represented a highly susceptible Indian dwarf wheat genotype, whereas P2 (0.20%), D45 (0.53%), S27 (0.09%), and T44 (0.31%) maintained remarkably low membrane damage, suggesting superior preservation of membrane integrity under drought conditions.

Maintenance of membrane integrity is considered one of the earliest physiological mechanisms associated with drought tolerance because drought-induced oxidative stress increases

membrane permeability and electrolyte leakage (Bajji et al., 2002). Consequently, genotypes exhibiting lower membrane damage are generally considered more capable of maintaining cellular function under water-deficit conditions. The broad within-group variation observed in the present study agrees with previous reports demonstrating that membrane damage is an effective physiological criterion for discriminating drought tolerance among wheat genotypes (Öztürk et al., 2016; Ghanem & Al-Farouk, 2024). Moreover, the large variability observed particularly within bread wheat landraces and Indian dwarf wheat suggests that these germplasm groups constitute valuable reservoirs of allelic diversity for future drought-tolerance breeding.

Drought Tolerance Indices

Considerable variation was observed among wheat groups and individual genotypes for all four drought tolerance indices (Figure 3), indicating marked differences in drought adaptation and yield stability under contrasting moisture conditions. Although the distribution patterns differed among indices, substantial within-group variation was consistently observed, reflecting the wide genetic diversity present in the evaluated *Triticum* germplasm.

The relative efficiency index (REI) showed relatively similar median values among most wheat groups, whereas the check cultivars displayed narrower distributions than the landrace groups (Figure 3A). The highest REI values were recorded for genotypes D115 (4.08), P1 (3.03), S20 (2.82) and A194 (2.64), indicating superior yield performance under rainfed conditions relative to irrigated conditions. In contrast, several genotypes, including D3 (0.04), A205 (0.11) and OR12 (0.23), exhibited considerably lower REI values, suggesting greater sensitivity to water deficit. The relatively broad distributions observed within bread wheat landraces and Indian dwarf wheat indicate substantial genetic diversity for drought adaptation within these groups. Group means for REI were relatively similar, ranging from 0.98 in the tetraploid checks to 1.23 in durum landraces, but within-group variability was much greater in the genetically diverse germplasm. Durum landraces and Polish wheat showed particularly high variation for REI, with CV values of 97.50 and 95.65%, respectively, whereas tetraploid checks were much more uniform (CV = 4.81%). Several individual accessions clearly exceeded their respective group distributions, emphasizing that genotype-level selection may be more informative than comparisons based only on group means. Because REI combines yield performance relative to the population means under both stress and non-stress conditions, the high values of these genotypes indicate comparatively favorable performance across the two environments rather than drought response based solely on yield under stress.

Greater differentiation among groups was evident for SNPI (Figure 3B). Mean SNPI was highest in the tetraploid checks (10.62), Khorasan wheat (9.87), and durum breeding lines (9.47), whereas Indian dwarf wheat had a markedly lower mean of 1.43. However, the high mean of the tetraploid checks was accompanied by relatively low variability (CV = 26.9%), while durum breeding lines displayed much greater variation (CV = 88.0%), largely reflecting the exceptionally high SNPI of OR32 (36.04). Other prominent genotypes included A10 (18.49), T13 (18.28), A4 (16.35), P1 (15.33), and OR21 (14.77). This pattern is particularly relevant because SNPI was specifically proposed to identify genotypes combining high and relatively stable yield under both irrigated and non-irrigated conditions. Moosavi et al. (2008), working with bread and durum wheat, reported positive relationships of SNPI with yield under both conditions and with several productivity-based indices and recommended it for identifying genotypes with desirable performance across stress and non-stress environments. The exceptionally high SNPI of OR32 therefore distinguishes this genotype from the broader durum

breeding-line population, although its overall drought response should be evaluated together with the other indices rather than on SNPI alone.

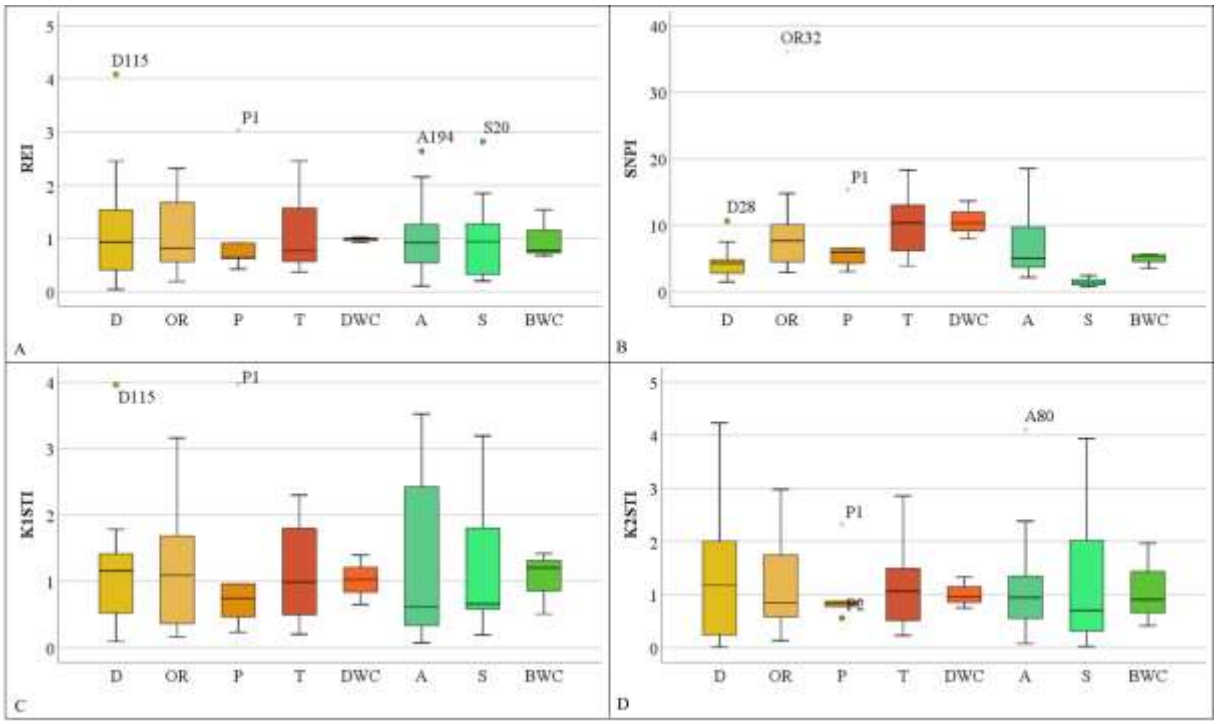

Figure 3. Drought tolerance indices in the examined wheat genotypes under drought stress.

The modified stress tolerance indices also revealed pronounced genotypic variation (Figures 3C and 3D). For K1STI, group means ranged from 1.02 in tetraploid checks to 1.28 in bread wheat landraces, but the magnitude of within-group variation was much greater than the differences among means. Polish wheat had the highest CV for K1STI (120.19%), followed by bread wheat landraces (93.59%) and durum landraces (89.11%). P1 (3.97), D115 (3.96), A194 (3.52), A7 (3.43), and S20 (3.19) occupied the upper end of the K1STI distribution. K2STI showed a similarly broad response, with D115 (4.23), A80 (4.10), S2 (3.94), S3 (3.61), D96 (3.39), and OR30 (2.98) among the highest-ranking genotypes. Particularly large variation for K2STI occurred in durum landraces and Indian dwarf wheat, both of which had CV values above 100%, whereas tetraploid checks were considerably more homogeneous (CV = 28.81%). Farshadfar and Sutka (2002) developed the modified stress tolerance index by applying correction coefficients to STI to improve discrimination among genotypes differing in performance under stress and non-stress environments. Their results also emphasized that genotype classification based on a single drought criterion can be contradictory and that modified indices can provide additional discrimination among contrasting response types.

Yield-based drought indices have long been recognized as effective tools for identifying superior genotypes because they simultaneously consider productivity under stress and non-stress conditions rather than evaluating yield in a single environment (Fernandez, 1992; Moosavi et al., 2008). Similarly, the modified stress tolerance indices proposed by Farshadfar and Sutka (2002) provide improved discrimination among genotypes differing in drought adaptation. The contrasting rankings obtained from REI, SNPI, K1STI, and K2STI are therefore biologically and statistically informative rather than inconsistent. Drought indices differ in the relative weight they assign to yield potential, yield under stress, and stability between environments. Fernandez (1992) emphasized that an effective selection criterion should

preferentially identify genotypes with high performance under both stress and non-stress conditions, while also demonstrating that different indices can favor different response groups. This explains why some genotypes were outstanding for a particular index but not consistently superior for all four indices. For example, OR32 was exceptional for SNPI (36.04) but showed more moderate REI (1.64) and K2STI (0.85), whereas D115 combined the highest REI (4.08) with very high K1STI (3.96) and K2STI (4.23). P1 similarly combined high REI (3.03), SNPI (15.33), and the highest K1STI (3.97). A194 also performed consistently well for REI (2.64) and K1STI (3.52), while T44 combined relatively high REI (2.46) and K2STI (2.86). Thus, D115 and P1 in particular exhibited favorable performance across several complementary yield-based criteria rather than superiority based on a single index.

Overall, the high coefficients of variation within several landrace and breeding groups demonstrate that drought-response diversity was often greater within taxonomic groups than suggested by their group means. This is particularly important for breeding because selection at the individual-genotype level can reveal useful accessions that would be obscured by group-level comparisons. Moosavi et al. (2008) emphasized the advantage of combining several indices and multivariate analysis rather than relying on a single drought criterion. This multi-index approach is also consistent with the recent declaration of Jalili et al. (2026), which incorporates REI, K1STI, K2STI, and SNPI among a broader set of complementary stress tolerance indices for comprehensive genotype evaluation in plant breeding. Khan (2025) also demonstrated that different drought indices provide complementary information and that the combined use of correlation analysis and PCA improves discrimination of genotypes with favorable yield performance across contrasting environments. Similarly, some wheat studies have emphasized that drought adaptation is better characterized through the integration of yield-based indices with physiological and agronomic responses rather than reliance on a single criterion (Ghanem and Al-Farouk, 2024). Accordingly, the consistent performance of D115 and P1 across several yield-based indices, together with the distinctive profiles of OR32, A194, T44, and other high-ranking genotypes, identifies a focused set of candidates for further evaluation. Their classification as drought-tolerant material, however, requires integration of these yield-based responses with membrane damage and Thermal Retention, which was subsequently achieved through PCA.

Principal Component Analysis

Principal component analysis (PCA) was performed separately for the tetraploid and hexaploid wheat materials to investigate the relationships among thermal retention, membrane damage, and drought tolerance indices and to visualize the distribution of genotypes according to their drought responses (Figure 4). The first two principal components explained 56.2% of the total variation in tetraploid wheat (PC1 = 37.5%, PC2 = 18.7%) and 50.1% in hexaploid wheat (PC1 = 31.0%, PC2 = 19.1%), revealing distinct multivariate response patterns within the two ploidy groups.

In the tetraploid materials (Figure 4A), REI and K1STI showed similar vector orientations, indicating that these indices represented relatively similar patterns of genotype differentiation. K2STI was also positioned in the upper-left region of the biplot, whereas SNPI was oriented toward the lower-left quadrant. The contrasting orientation of SNPI and membrane damage at tillering (MDTL) suggested that these variables represented different dimensions of the drought response. This differentiation among yield-based indices is consistent with Farshadfar et al. (2012), who showed through PCA that SNPI, K1STI, and K2STI differed in their relationships with grain yield under rainfed and irrigated conditions.

The thermal variables also showed stage-dependent patterns. TERTL and TERHD were oriented toward different regions of the biplot, indicating that the relative thermal response to water deficit differed between tillering and heading. Similarly, MDTL and MDHD showed contrasting orientations, suggesting that drought-induced membrane injury was also dependent on developmental stage. The separation of the thermal and membrane-damage vectors from several yield-based indices indicates that these physiological measurements contributed information that was not fully represented by yield-derived drought indices alone.

The distribution of tetraploid genotypes further illustrated this multivariate diversity. D115, T44, and D96 were separated from much of the population, reflecting distinctive combinations of drought-response traits, while OR32, T38, T17, and D3 also occupied relatively extreme positions in the ordination space. The tetraploid check cultivars KZLTN, EMNBY, and KMBT were located comparatively closer to the central region than several of the more widely dispersed landrace and breeding accessions. Notably, D115 was differentiated in the same multivariate analysis in which it had already exhibited the highest REI and high K1STI and K2STI values, strengthening its identification as a promising tetraploid candidate when multiple drought-response criteria are considered together.

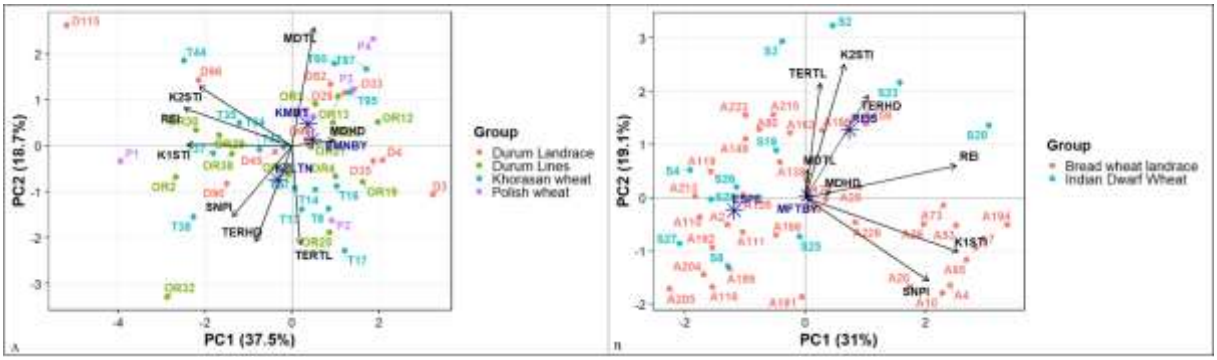

Figure 4. PCA biplot illustrating the multivariate relationships between wheat genotypes and drought stress indicators

For the hexaploid wheat materials (Figure 4B), REI, K1STI, and SNPI were projected predominantly toward the positive side of PC1, showing broadly similar orientations and contributing strongly to genotype differentiation along this axis. K2STI was more strongly oriented toward positive PC2, while the thermal retention variables were also represented primarily along the second component. Membrane damage variables showed shorter vectors than several drought tolerance indices, suggesting a comparatively smaller contribution to genotype differentiation represented by the first two components. Thus, as observed in the tetraploid material, the first two PCs represented different components of drought response rather than a single uniform tolerance axis.

Bread wheat landraces displayed broad dispersion across the biplot, demonstrating substantial within-group diversity. Several landraces, including A194, A95, A7, and A4, were positioned in the region associated with yield-based drought indices, whereas A205, A181, A116, and A204 occupied contrasting regions of the ordination space. Among Indian dwarf wheat genotypes, S2, S3, and S23 were positioned more closely to K2STI and the positive-PC2 region containing the thermal-response vectors, whereas S25, S27, and S8 showed contrasting multivariate positions. Among the bread wheat checks, MFTBY was located relatively close to the central region, whereas REIS and ESPE occupied different positions, indicating that the check cultivars did not exhibit a completely homogeneous multivariate response.

The joint use of REI, SNPI, K1STI, and K2STI is particularly relevant because these indices provide complementary rather than interchangeable information on genotype performance under contrasting water regimes. Jalili et al. (2026) classified REI as a stress-tolerance index, K1STI and K2STI as modified indices intended for environment-specific selection, and SNPI as a composite index useful when selection based on a single criterion is insufficient. The authors further demonstrated that a genotype ranking highly for an individual modified index may perform poorly according to other stress-related criteria, emphasizing that genotype selection should not rely on a single index. This interpretation agrees with the contrasting rankings observed in the present study, where D115 and P1 performed favorably across several indices, whereas OR32 was distinguished predominantly by its exceptionally high SNPI. Moosavi et al. (2008) and Farshadfar et al. (2012) similarly emphasized the value of combining complementary drought indices for genotype discrimination rather than relying on a single selection criterion.

Importantly, yield-based drought indices describe the agronomic outcome of stress but do not fully capture the physiological heterogeneity underlying that performance. The inclusion of thermal retention and membrane damage therefore added independent physiological dimensions to the yield-based assessment, allowing genotypes with similar agronomic performance to be distinguished according to differences in their canopy-level and cellular responses. This is particularly relevant for drought screening because comparable yield responses may result from different physiological strategies, which cannot be resolved through yield-derived indices alone. The use of thermal imaging together with conventional physiological traits has similarly improved the characterization of genotypic variation under water deficit in wheat (Ashfaq et al., 2022; Qin et al., 2022). Thus, the separation of thermal, membrane-damage, and yield-based variables observed in the present biplots supports their complementary value for multidimensional drought characterization.

The developmental-stage dependence observed for thermal retention in the present study is also physiologically relevant. Qin et al. (2022) reported that UAV-derived canopy thermal responses were associated with physiological traits related to plant water status and photosynthetic functioning under water deficit, while the strength of thermal discrimination varied with developmental stage and stress intensity. Thus, the contrasting orientations of TERTL and TERHD in the present PCA should not be regarded as inconsistent responses but rather as evidence that canopy thermal behavior under drought is dynamic across crop development. Repeated thermal phenotyping may therefore provide information that would be lost by measurements restricted to a single growth stage.

From a breeding perspective, thermal phenotyping is particularly attractive because drought-induced changes in stomatal regulation and transpiration can alter canopy thermal behavior before their consequences are fully expressed in final grain yield. UAV-based thermal imaging additionally provides rapid, non-destructive, and spatially extensive phenotyping of large numbers of breeding materials, offering potential as an intermediate physiological indicator of drought response (Qin et al., 2022; Das et al., 2022). However, thermal responses should not be considered stand-alone measures of drought tolerance because they are affected by developmental stage, stress intensity, and the physiological mechanisms regulating canopy cooling. Their interpretation together with membrane damage and final yield-based indices therefore provides a stronger basis for genotype evaluation than any of these components alone.

Overall, PCA demonstrated that thermal retention, membrane damage, and drought tolerance indices provided complementary information for differentiating drought responses among wheat genotypes. Their integration is biologically relevant because they represent different

levels of drought response: canopy-level thermal regulation, cellular membrane injury, and agronomic performance under contrasting water regimes. The broad dispersion observed particularly among landrace and breeding materials highlights substantial physiological and agronomic diversity within these germplasm groups. Accordingly, the combined approach allowed genotypes to be evaluated not merely for favorable yield-based index values, but for the extent to which these agronomic responses were accompanied by distinct thermal and membrane-level responses. Such multidimensional screening may provide a more robust basis for identifying promising drought-adapted germplasm for subsequent validation and use in wheat improvement programs.

An additional noteworthy finding of the present analysis was that the previously selected tolerant and sensitive genotypes could also be differentiated, to a considerable extent, using the independent set of variables evaluated here. The original tolerant (T) and sensitive (S) classification had been established from a broader set of traits using a PCA-based selection index, whereas the present analysis was based specifically on membrane damage, Thermal Retention, and complementary yield-based drought indices. Despite these methodological differences, most of the previously selected T/S pairs retained a broadly contrasting response pattern across the variables evaluated here, although the degree of separation varied among wheat groups (data not shown). This agreement suggests that the original classification captured drought-response differences that were also detectable through physiological and yield-based indicators not used in exactly the same combination during the initial selection.

The relevance of the multivariate discrimination obtained in the present study is further supported by the subsequent-season evaluation of 16 selected genotypes from the same germplasm. Based on the broader drought-response assessment conducted during the same screening season, contrasting tolerant and sensitive genotypes were selected from each wheat group and evaluated in the following growing season using UAV-derived canopy temperature, DREB expression, and a broader set of yield-based drought indices (Önal et al., 2026). Several of the original selections showed consistent responses across seasons. In particular, D115, which exhibited the highest REI and high K1STI and K2STI values in the present study, subsequently showed one of the most stable drought-response profiles, with the lowest TOL and among the lowest SDI and highest YSI and RSI values. MFTBY also maintained favorable performance across productivity and stability criteria, whereas previously selected sensitive genotypes such as T57 and A223 showed comparatively high drought sensitivity in the subsequent season. However, some genotypes showed less consistent classifications across years, emphasizing the influence of seasonal conditions and the importance of combining multiple physiological and agronomic criteria rather than assigning drought tolerance from a single season or index (Önal et al., 2026).

CONCLUSIONS

The present study demonstrated substantial variation in drought responses among diverse *Triticum* germplasm based on thermal retention, membrane damage, and complementary drought tolerance indices. The combined evaluation of physiological and yield-based responses revealed considerable within-group variation, particularly among landrace and breeding materials, emphasizing the importance of genotype-level evaluation rather than reliance on group means alone. D115 and P1 were particularly notable for their favorable performance across several yield-based drought indices, while other genotypes, including OR32, A194, and T44, exhibited distinctive response profiles that warrant further evaluation. PCA revealed that the evaluated traits represented distinct but complementary dimensions of drought response, enabling clearer differentiation among genotypes with contrasting physiological and agronomic

profiles. Notably, the present set of traits also broadly supported the tolerant and sensitive classifications previously established using a broader set of traits and a PCA-based selection index. Overall, the integration of UAV-derived thermal phenotyping, membrane damage, and complementary drought tolerance indices provides a practical multidimensional approach for high-throughput drought screening and the identification of promising germplasm for wheat improvement programs.

ABSTRACT

Evaluating soil nutrient availability together with plant nutrient concentrations provides a comprehensive understanding of crop nutritional status. Accordingly, this study aimed to assess the macro- and micronutrient status of wheat grown in the Narlı Plain of Kahramanmaraş, Türkiye. Soil samples were collected from a depth of 0–30 cm, and flag leaf samples were collected immediately before heading from 11 wheat-growing fields. Soil samples were analyzed for pH, calcium carbonate ($CaCO_3$) and organic matter contents, available phosphorus (Olsen-P), exchangeable potassium (K), calcium (Ca), and magnesium (Mg), and DTPA-extractable iron (Fe), zinc (Zn), copper (Cu), and manganese (Mn). Plant samples were analyzed for P, K, Ca, Mg, Fe, Zn, Cu, and Mn concentrations. The soils were slightly to moderately alkaline, with organic matter contents ranging from 2.13% to 4.50% and $CaCO_3$ contents ranging from 19.84% to 41.09%. Soil Olsen-P concentrations varied between 7.98 and 35.38 mg kg^{-1}, while the mean DTPA-extractable Fe, Zn, Cu, and Mn concentrations were 11.73, 1.05, 1.50, and 9.65 mg kg^{-1}, respectively. The mean exchangeable K, Ca, and Mg concentrations were 339.55, 3461, and 1145 mg kg^{-1}, respectively. The mean P, K, Ca, and Mg concentrations in wheat flag leaves were 0.28%, 2.60%, 0.80%, and 0.18%, respectively, whereas the mean Fe, Zn, Cu, and Mn concentrations were 97.93, 21.84, 6.75, and 40.41 mg kg^{-1}, respectively. The results showed that wheat grown in the Narlı Plain was generally adequately supplied with the macro- and micronutrients examined. However, the variation in soil and plant nutrient concentrations among the sampled fields suggests that wheat nutrient status may be influenced by differences in soil nutrient reserves, fertilizer management, and other soil properties. These findings highlight the importance of evaluating soil and plant analyses together when developing field-specific nutrient management strategies for wheat production in the region.

Keywords: Calcareous soil, flag leaf, mineral nutrition, wheat.

INTRODUCTION

Determining the mineral nutritional status of wheat grown in calcareous soils represents an important diagnostic challenge because soil nutrient reserves do not necessarily correspond to the availability of these nutrients to plants. High soil pH and $CaCO_3$ content may restrict nutrient uptake by roots by altering nutrient speciation in the soil solution, adsorption–desorption equilibria, and precipitation reactions. Therefore, the presence of an adequate reserve of a particular nutrient in the soil does not necessarily indicate that the nutrient can be taken up by plants in sufficient amounts (Hinsinger, 2001; Marschner, 2012; Xue et al., 2016). Recent studies conducted in calcareous soils have also demonstrated that these conditions may affect nutrient uptake and fertilizer-use efficiency in wheat (Martínez-Ríos et al., 2024; Zaheri Abdehvand et al., 2024; Demirkaya & Gülser, 2025).

In calcareous and alkaline soils, P may form sparingly soluble compounds with Ca or become immobilized through retention on $CaCO_3$ surfaces. Similarly, high pH and the presence of carbonate and bicarbonate ions may reduce the solubility and root availability of Fe, Zn, Mn, and Cu. Zinc availability, in particular, is strongly influenced by interactions among soil pH, carbonate content, P status, organic matter, and clay minerals (Chen et al., 2019; Martínez-Ríos et al., 2024). Consequently, wheat grown in calcareous soils may exhibit marginal or latent nutrient deficiencies even in the absence of visible deficiency symptoms. However, the relationship between soil $CaCO_3$ content and plant nutritional status is not straightforward. Nutrient availability in the root zone is governed by the combined effects of soil pH and $CaCO_3$ content, as well as texture, organic matter, cation exchange capacity, soil moisture, and rhizosphere processes. Plant nutrient uptake may also vary depending on genotype, root-system characteristics, growth stage, fertilization history, and interactions among nutrients (White & Brown, 2010; Marschner, 2012). Therefore, $CaCO_3$ content alone may not provide an adequate basis for assessing plant nutritional status in calcareous soils.

Soil analyses provide information on the potential availability of nutrients and the nutrient-supplying capacity of the soil, whereas plant tissue analyses reflect the integrated outcome of soil–root processes as expressed in plant nutrient uptake. However, because elemental concentrations in plant tissues vary with the sampled organ and growth stage, the results should be interpreted using appropriate sampling times and established sufficiency ranges (Jones et al., 1991; Reuter & Robinson, 1997; Lemaire et al., 2019). Flag leaves collected immediately before heading constitute suitable diagnostic material for assessing the nutrient status of wheat. Accordingly, the combined use of soil and plant analyses enables a more comprehensive assessment of nutrient deficiencies and limitations to nutrient uptake.

The Narlı Plain, located south of Kahramanmaraş, is an important agricultural production area characterized by soils developed from alluvial and colluvial parent materials. Variations in topographic position and soil-forming conditions have resulted in considerable heterogeneity in the physical and chemical properties of the plain's soils (Yakupoğlu et al., 2012; Yakupoğlu & Demirci, 2013). Previous studies conducted in the region have shown that this variability is also reflected in soil pH, $CaCO_3$ content, and nutrient concentrations (Saltalı et al., 2018). Total and active $CaCO_3$ contents have also been reported to be associated with the availability of certain metallic micronutrients in the soils of the plain (Kadifeci et al., 2024). Nevertheless, field-based information on the extent to which soil nutrient levels are reflected in the nutritional status of wheat remains limited. Accordingly, this study aimed to determine selected physical and chemical properties of calcareous agricultural soils under wheat cultivation in the Narlı Plain and to evaluate the macro- and micronutrient status of wheat through combined soil and flag-leaf analyses. The relationships between soil $CaCO_3$ content and P, K, Ca, Mg, Fe, Zn, Cu, and Mn concentrations in wheat flag leaves were also investigated.

MATERIAL AND METHOD

Study area

The study was conducted in wheat-growing areas of the Narlı Plain, located within the administrative boundaries of Pazarcık district, Kahramanmaraş Province, southern Türkiye. Situated approximately 30 km southeast of Kahramanmaraş city center, the plain covers an area of approximately 26,500 ha and lies within a transitional zone between Mediterranean and continental climatic conditions (Saltalı et al., 2018).

The soils of the Narlı Plain have developed predominantly from alluvial and colluvial parent materials transported from the surrounding uplands and deposited across the plain. Variations in depositional environments and topographic positions have resulted in pronounced spatial

variability in the physical and chemical properties of these soils (Yakupoğlu et al., 2012; Yakupoğlu & Demirci, 2013). The soils of the region have generally been characterized as neutral to slightly alkaline and as having varying $CaCO_3$ contents. Moreover, their total and active $CaCO_3$ contents may influence the availability of metallic micronutrients (Kadifeci et al., 2024).

The study area comprised fields under wheat cultivation within the Narlı Plain. Eleven wheat-growing fields were selected to represent the spatial variability in soil properties and plant nutritional status across the plain. The geographical coordinates of the soil and flag-leaf sampling points were recorded during fieldwork. The location of the study area within Türkiye and Kahramanmaraş Province, together with the distribution of the sampling points across the Narlı Plain, is presented in Figure 1.

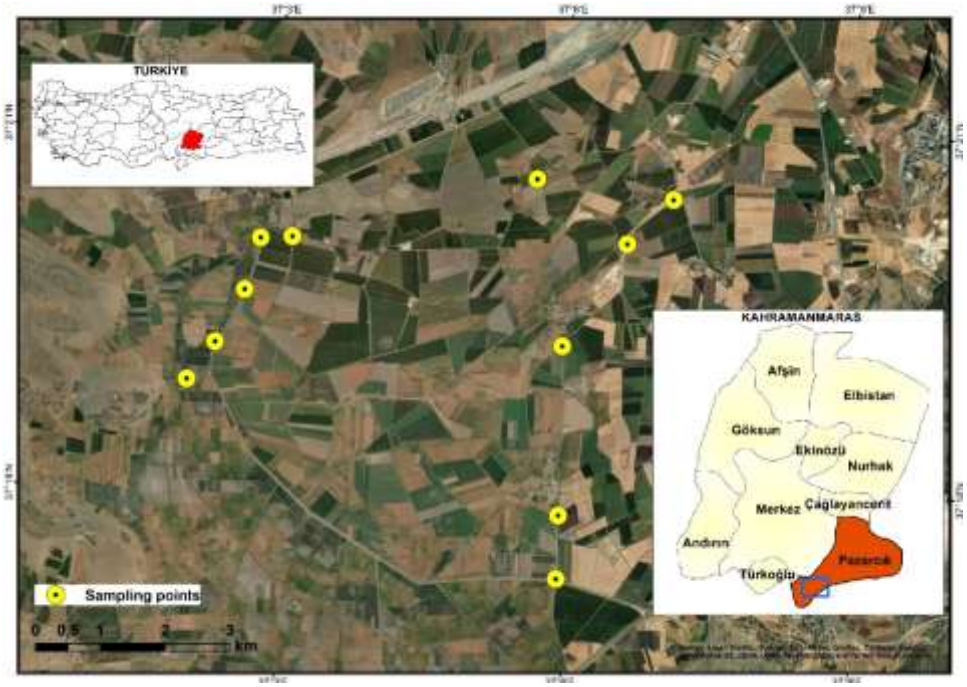

Figure 1. Location of the study area and distribution of soil and wheat flag-leaf sampling points in Narlı Plain

Soil and Plant Sampling and Preparation for Analysis

Soil samples were collected from a depth of 0–30 cm at 11 wheat-growing fields selected across the Narlı Plain, and the coordinates of the sampling points were recorded using a Global Positioning System (GPS). Composite soil samples representing each sampling point were transported to the laboratory, air-dried under ambient conditions, and passed through a 2-mm sieve. The prepared samples were labelled and stored in sealed plastic containers under cool and dry conditions until analysis (Richards, 1954).

Plant samples were collected simultaneously from the same fields where the soil samples were obtained. To assess the nutritional status of wheat, 25–30 representative flag leaves were collected from each field immediately before heading (Jones et al., 1991). The leaf samples were washed with distilled water to remove surface dust and other residues and subsequently oven-dried at 65 °C for 48 h. The dried plant material was ground and homogenized, transferred to labelled polyethylene bags, and stored under refrigerated conditions until chemical analysis (Jones & Case, 1990).

Soil and Plant Analyses

Soil pH and electrical conductivity (EC) were determined in saturated soil paste according to the methods described by Peech (1965) and Richards (1954), respectively. Total calcium carbonate ($CaCO_3$) content was measured using a Scheibler calcimeter (Loeppert & Suarez, 1996), whereas soil organic matter was determined using the Walkley–Black wet oxidation method (Nelson & Sommers, 1996). Available P was determined using the Olsen method based on extraction with 0.5 M $NaHCO_3$ at pH 8.5 (Olsen et al., 1954). Exchangeable K, Ca, and Mg were extracted with 1 N ammonium acetate (NH_4OAc) at pH 7.0 (Thomas, 1982). Plant-available Fe, Zn, Cu, and Mn were determined using the DTPA extraction method (Lindsay & Norvell, 1978). The concentrations of K, Ca, Mg, Fe, Zn, Cu, and Mn in the soil extracts were measured using an Agilent 240AA atomic absorption spectrophotometer (AAS).

A 0.50-g portion of each ground plant sample was wet-digested on a hot plate using a mixture of 5 mL HNO_3 and 4 mL $HClO_4$ until a clear solution was obtained (Jones & Case, 1990). Following digestion, the solutions were filtered and brought to a known volume with deionized water. Phosphorus concentration in the plant samples was determined spectrophotometrically using the vanadomolybdophosphoric yellow colour method. Potassium, Ca, Mg, Fe, Zn, Cu, and Mn concentrations were measured using an Agilent 240AA atomic absorption spectrophotometer.

Statistical Analyses

Minimum, maximum, and mean values for the soil and plant variables were calculated using Microsoft Office Excel. Relationships between soil $CaCO_3$ content and P, K, Ca, Mg, Fe, Zn, Cu, and Mn concentrations in wheat flag leaves were examined using two-tailed Pearson correlation analysis in IBM SPSS Statistics 23.0 (IBM Corp., Armonk, NY, USA). Statistical significance was accepted at $p < 0.05$, and graphical presentations of the results were prepared using Microsoft Office Excel.

RESULTS AND DISCUSSION

Characteristic Properties of the Study-Area Soils

Soil pH values ranged from 7.43 to 7.79, with a mean of 7.56. Electrical conductivity values varied between 303 and 501 µS cm^{-1}, averaging 349 µS cm^{-1}. Soil $CaCO_3$ contents ranged from 19.84% to 41.09%, with a mean of 27.95%, whereas organic matter contents varied between 2.13% and 4.50%, with a mean of 2.85%. Based on these results, the soils were generally characterized as slightly alkaline and non-saline, with high to very high $CaCO_3$ contents and moderate organic matter levels.

Table 1. Descriptive statistics of selected physicochemical properties of the study area soils

	pH	**EC**	**Lime**	**OM**
		(µS/cm)		%
Min	7,43	303	19,84	2,13
Max	7,79	501	41,09	4,50
Mean	7,56	349	27,95	2,85

Macronutrient Status of the Study-Area Soils

Evaluation of the macronutrient contents of soil samples collected from the Narlı Plain revealed different sufficiency levels among the nutrients examined. According to Cottenie (1980), available P concentrations of 8–25 mg kg^{-1} are classified as sufficient, whereas concentrations of 25–80 mg kg^{-1} are considered high (Figure 2). Based on these thresholds, the mean available P concentration (22.5 mg kg^{-1}) was within the sufficient range; 54.5% of the samples were classified as sufficient and 45.5% as high. However, because the minimum concentration was close to the lower limit of the sufficiency range, the mean value should be interpreted together with the variability among sampling sites.

The mean exchangeable K concentration (340 mg kg^{-1}) exceeded the ≥161 mg kg^{-1} threshold above which Kaiser and Piotrowski (2024) did not recommend K fertilization for wheat under Minnesota conditions. While 63.6% of the samples reached or exceeded this threshold, 36.4% had K concentrations within the range of 95–160 mg kg^{-1}. Therefore, the high mean K concentration should not be interpreted as indicating a uniform K status across all sampling sites. Because this threshold was developed for a different region, it should be used as a comparative benchmark rather than directly applied to fertilizer recommendations for the Narlı Plain.

Regarding exchangeable Ca, 45.5% of the samples were classified as sufficient (1150–3500 mg kg^{-1}), whereas 54.5% were classified as high (3500–10,000 mg kg^{-1}). The mean Ca concentration (3461 mg kg^{-1}) was close to the upper limit of the sufficient range. Accordingly, the results did not indicate Ca deficiency in the investigated soils under the classification system used. For exchangeable Mg, 72.7% of the samples were classified as high (480–1500 mg kg^{-1}) and 27.3% as very high (>1500 mg kg^{-1}). The mean Mg concentration (1145 mg kg^{-1}) was within the high range, and all samples exceeded the sufficiency range, indicating that the soils generally had high exchangeable Mg concentrations (Cottenie, 1980).

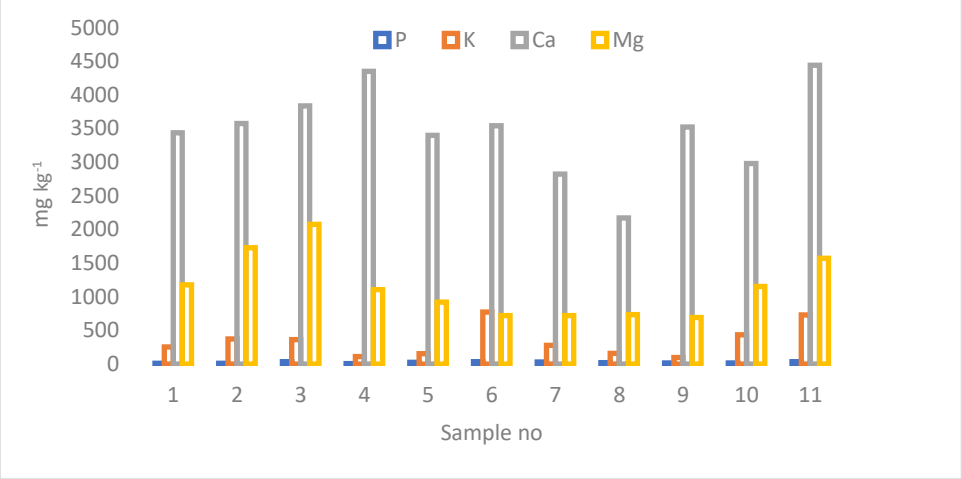

Figure 2. Distribution of available P and exchangeable cations

Micronutrient Status of the Study-Area Soils

The DTPA-extractable micronutrient concentrations of the soil samples collected from the Narlı Plain varied among the sampling sites (Figure 3). Iron (Fe) concentrations ranged from 8.88 to 23.52 mg kg^{-1}, with a mean of 11.73 mg kg^{-1}. Zinc (Zn) concentrations varied between 0.54

and 2.90 mg kg^{-1}, averaging 1.05 mg kg^{-1}. Copper (Cu) concentrations ranged from 1.08 to 2.20 mg kg^{-1}, with a mean of 1.50 mg kg^{-1}, whereas manganese (Mn) concentrations varied between 3.36 and 28.80 mg kg^{-1}, averaging 9.65 mg kg^{-1}. The mean concentrations of the micronutrients followed the order Fe > Mn > Cu > Zn.

Soil micronutrient status was evaluated using the critical levels reported for maize by Lindsay and Norvell (1978) as comparative benchmarks. In all samples, Fe, Cu, and Mn concentrations exceeded their respective critical levels of 4.5, 0.2, and 1.0 mg kg^{-1}. Thus, according to these thresholds, no indication of Fe, Cu, or Mn deficiency was identified in the investigated soils. However, the critical values reported for Mn and Cu were proposed tentatively and should therefore be interpreted with caution.

Based on the critical Zn level of 0.8 mg kg^{-1}, 45.5% of the samples were classified as deficient and 54.5% as sufficient. Although the mean Zn concentration (1.05 mg kg^{-1}) exceeded the critical threshold, the occurrence of concentrations below this value in 45.5% of the samples demonstrates that soil Zn status should not be evaluated solely on the basis of the mean. Zinc was the only micronutrient for which values below the critical level were detected, indicating a potential Zn deficiency at some sampling sites that warrants further investigation. Nevertheless, because the thresholds used were originally established for maize, definitive conclusions regarding wheat nutritional status should be supported by plant tissue analyses and crop-specific sufficiency criteria.

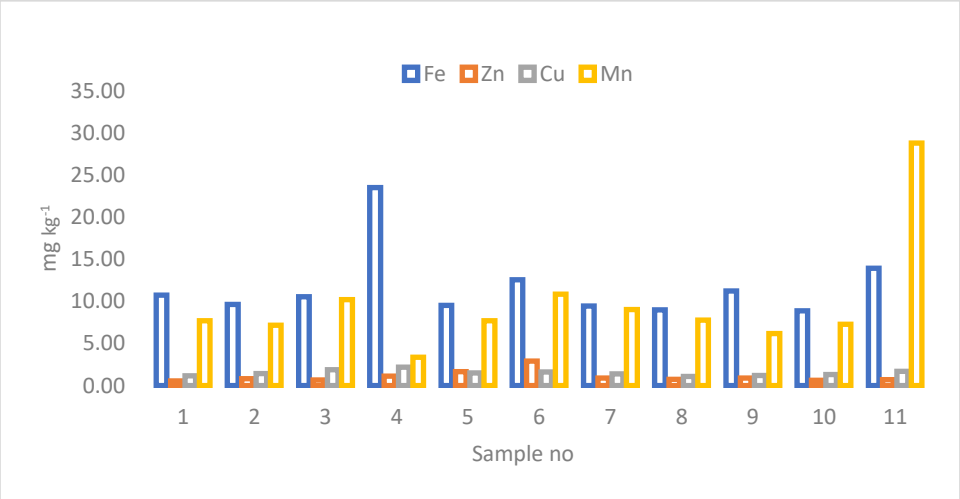

Figure 3. Distribution of DTPA-extractable Fe, Zn, Cu and Mn concentrations

Flag-Leaf Macronutrient Concentrations in Wheat

Macronutrient concentrations in wheat flag leaves varied among the sampling sites. Phosphorus concentrations ranged from 0.21% to 0.38%, with a mean of 0.28%. Potassium concentrations varied between 2.13% and 3.33%, averaging 2.60%. Calcium concentrations exhibited a relatively wide variation, ranging from 0.40% to 1.61%, with a mean of 0.80%. Magnesium concentrations ranged from 0.14% to 0.24%, with a mean of 0.18% (Figure 4). Among the macronutrients examined, K had the highest mean concentration, whereas Mg had the lowest.

The plant analysis results indicated that wheat grown in the study area generally had an adequate macronutrient status. When compared with the critical concentrations and sufficiency ranges reported for wheat, P and K concentrations were considered sufficient at all sampling sites (Jones et al., 1991; Reuter & Robinson, 1997; Plank & Donohue, 2000). In particular, the mean

P (0.28%) and K (2.60%) concentrations exceeded the reported critical levels for wheat, indicating no apparent nutritional deficiency in these elements.

The variation in Ca concentrations from 0.40% to 1.61% indicated considerable differences among the sampling sites in Ca uptake or accumulation within plant tissues. Nevertheless, all measured Ca concentrations exceeded the critical level reported for wheat. Magnesium concentrations varied within a narrower range and averaged 0.18%. Because even the lowest Mg concentration (0.14%) was above the critical level, no evident Mg deficiency was identified in the wheat plants (Jones et al., 1991; Reuter & Robinson, 1997; Plank & Donohue, 2000).

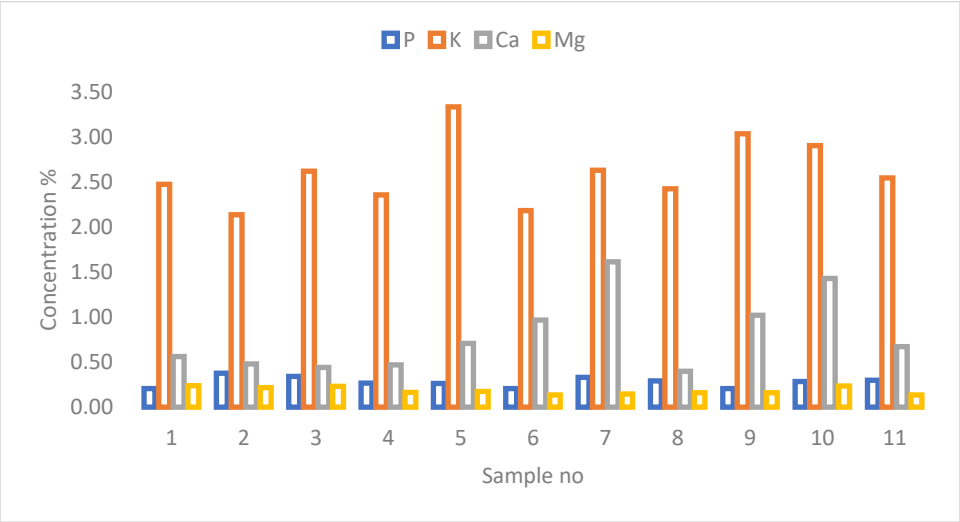

Figure 4. Foliar concentrations of macronutrients in wheat

Micronutrient Status of Wheat Flag Leaves

Micronutrient concentrations in wheat flag leaves varied among the sampling sites. Iron concentrations ranged from 69.00 to 156.75 mg kg^{-1}, with a mean of 97.93 mg kg^{-1}. Zinc concentrations varied between 17.50 and 30.00 mg kg^{-1}, averaging 21.84 mg kg^{-1}. Copper concentrations ranged from 4.50 to 8.75 mg kg^{-1}, with a mean of 6.75 mg kg^{-1}, whereas Mn concentrations varied between 16.00 and 54.25 mg kg^{-1}, averaging 40.41 mg kg^{-1} (Figure 5).

Based on the critical concentrations and sufficiency ranges reported for wheat, Fe, Zn, and Mn concentrations were generally considered adequate (Jones et al., 1991; Reuter & Robinson, 1997; Plank & Donohue, 2000). Iron concentrations of at least 69.00 mg kg^{-1} at all sampling sites indicated no evident Fe deficiency. Similarly, the observed Zn concentrations indicated that the wheat plants generally had an adequate Zn nutritional status.

Although the mean Cu concentration was within the sufficient range, the lowest value of 4.50 mg kg^{-1}, recorded at sampling site 2, was close to the critical level of approximately 5 mg kg^{-1} reported for wheat. Therefore, Cu nutrition was generally adequate, although a marginal Cu status may have occurred at this sampling site (Jones et al., 1991; Reuter & Robinson, 1997). Manganese concentrations indicated adequate nutrition at most sampling sites; however, the minimum concentration recorded at sampling site 11 was close to the lower limit of the sufficiency range.

Overall, wheat grown in the study area was adequately supplied with Fe, Zn, Cu, and Mn, although Cu and Mn concentrations approached the lower sufficiency limits at some sampling sites. Because tissue micronutrient concentrations may be influenced by soil pH, $CaCO_3$ and

organic matter contents, nutrient availability, and interactions among elements, the combined interpretation of soil and plant analyses provides a more reliable assessment of wheat nutritional status (Reuter & Robinson, 1997).

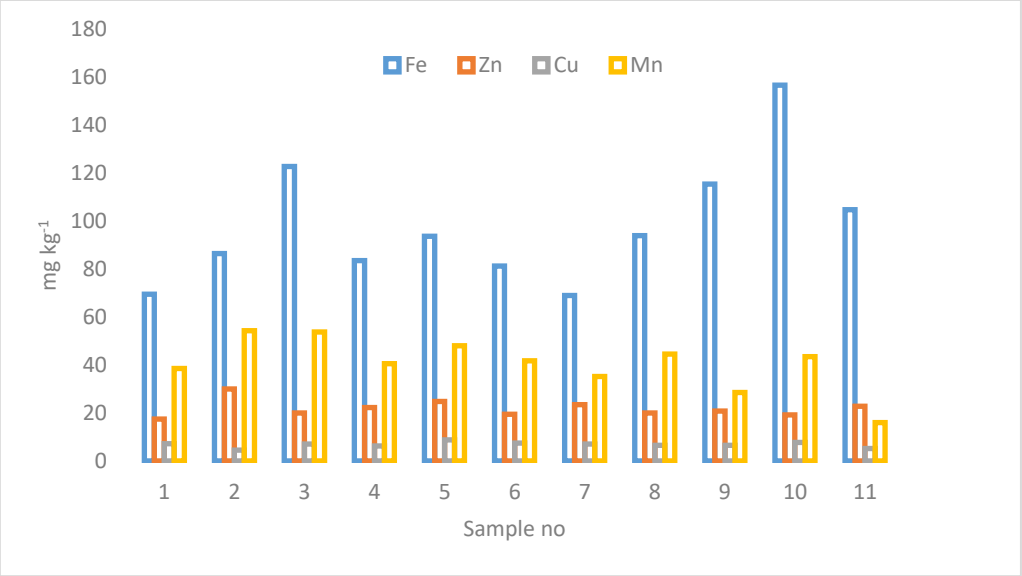

Figure 5. Foliar micronutrient concentrations in wheat

Relationships between soil lime and plant nutrients

No statistically significant correlations were detected between soil $CaCO_3$ content and P, K, Ca, Mg, Fe, Zn, Cu, or Mn concentrations in wheat flag leaves ($p > 0.05$; Table 2). Correlation coefficients ranged from −0.268 to 0.228, indicating no apparent linear relationship between soil $CaCO_3$ content and the macro- or micronutrient concentrations of wheat across the sampled fields. These findings suggest that variation in wheat nutritional status cannot be explained solely by soil $CaCO_3$ content and may also be influenced by soil nutrient reserves, fertilization practices, other soil properties, and plant-related factors. Nevertheless, because of the limited sample size ($n = 11$), the results should be interpreted within the context of the study area and sampling conditions (Table 2).

Table 2 Pearson correlation coefficients between soil lime and nutrient concentrations in wheat flag leaves

Plant nutrient	Pearson's r	p value	Significance
P	0,033	0,923	ns
K	−0,137	0,688	ns
Ca	−0,268	0,425	ns
Mg	0,228	0,500	ns
Fe	−0,028	0,934	ns
Zn	0,005	0,987	ns
Cu	−0,227	0,503	ns

Mn	0,001	0,998	ns

Note: Pearson correlation coefficients were calculated using 11 paired soil and flag-leaf samples (n = 11). ns: not significant ($p > 0.05$; two-tailed).

CONCLUSION

Wheat grown in the calcareous agricultural soils of the Narlı Plain was generally adequately supplied with P, K, Ca, Mg, Fe, Zn, Cu, and Mn. Available P and exchangeable K, Ca, and Mg concentrations in the soils were predominantly sufficient or high, while no clear deficiency of Fe, Cu, or Mn was identified. However, Zn concentrations were below the critical threshold in 45.5% of the soil samples, indicating a potential risk of Zn deficiency in some production fields. Plant analysis revealed no evident nutrient deficiencies, although Cu and Mn concentrations approached the lower limits of the sufficiency ranges at certain sampling sites. The absence of significant relationships between soil $CaCO_3$ content and nutrient concentrations in wheat flag leaves ($p > 0.05$) indicated that variation in plant nutritional status could not be explained solely by soil $CaCO_3$ content. Consequently, the combined interpretation of soil and plant analyses is recommended for a reliable assessment of wheat nutritional status in the Narlı Plain, with particular attention to the regular monitoring of Zn, Cu, and Mn.

ABSTRACT

Sulphites, Sulphates and phosphates play a significant role in microbiological stability, quality and safety of wines. This study aims to evaluate the impact of Sulphur dioxide (SO_2), sulphates SO_4^{2-} and Phosphate (PO_4^{3-}compounds on control of microbial growth and on key physicochemical properties of wine. Sulphites are widely used as preservatives due tu their antimicrobial and antioxidant activity, effectively inhibiting the growth of undersirable microorganisms such as wild yeasts, lactic acid bacteria and acetic acid bacteria. In contrast, phosphates contribute indirectly by supporting yeast metabolism during fermentation and stabilizing the chemical environment of the wine. Wine samples were analyzed for free and total SO_2, phosphate content, pH, acidity and microbial load using standard analytical and microbiological methods. The results demonstrate that appropriate level of sulphites significantly reduce microbial contamination and prevent spoilage, thereby enhancing shelf life and sensory quality. However, excessive sulphite concentrations may pose health concerns and negatively affect organoleptic properties. Phosphates were found to influence fermentation efficiency and microbial balance, although their direct antimicrobial effect is limited. In conclusion, the combined management of sulphites and phosphates is essential for maintaining wine stability, ensuring microbiological safety, and achieving high-quality products. Optimizing their concentrations in accordance with regulatory limits is crucial for balancing technological benefits and consumer health protection.

Keywords: *SO_4^{2-}, SO_2, PO_4^{3-}, Acetobacter spp., microbial load, assurance quality, food safety*

INTRODUCTION

Wine is a product produced by the fermentation of grape juice. It is produced from grapes of the species Vitis vinifera and a large number of varieties and cultivars.(Troja, R. 2005) The concentration of mineral salts in wine is regulated according to international standards and European Union legislation, to guarantee food safety and the quality of wines.(Troja, R. 2005) Wine contains the following elements and mineral salts:Sulfates SO_4^{2-}, phosphates PO_4^{3-}, potassium K^+, calcium Ca^{2+}, magnesium Mg^{2+} and in low concentrations sodium Na^+. (Bourgeois, C. M., & Larpent, J. P. 1989). Mineral salts in wine are inorganic compounds that come from grapes, soil, agricultural water (from irrigation) and technological practices during the winemaking process. They play an important role in biochemical reactions during fermentation, in the chemical quality, microbiological (stability of microorganisms) and organo-sensory characteristics of wine (body, taste). The origin of mineral salts in wine is from the vineyard soils, during the grape ripening phase, the use of mineral fertilizers (sulfates, phosphates) in the vineyards, agricultural water for irrigation and chemical and biological

additives during the fermentation and stabilization process of must for wine. The balance of mineral salts directly affects the resistance to microbiological diseases (spoiling) of wine. Sulphates in wine have a significant impact on the taste, chemical stability and microbial activity (yeast, lactic and acetic bacteria) of grape must and wine. At high concentrations they can inhibit and limit microbial activity. Their presence is related to natural and technological factors during wine production. Grapes absorb sulfates from the root (soil), especially in soils with high sulfur content. Sulfur is an important element for plants. Experimental measurements show that during the grape ripening period, a greater amount of sulfates accumulates and these pass into the final product (wine). Water used for irrigation increases the amount of sulfates. The use of phytosanitary components used to protect grapes from fungal diseases contributes to an increase in the concentration of sulfates (Formisano, M. 1990). Technological use of SO_2 during the sulfitation process. SO_2 is used as a preservative and antioxidant in wine. The oxidation of SO_2 converts them into sulfates, increasing their total concentration. [1] Phosphates in wine are natural compounds and additives that serve as an important source of phosphorus. Their levels range from 70 mg/L to 500 mg/L in white wines, and from 150 mg/L to 1000 mg/L in red wines. Their sources fall into three main categories: Soil and Grapes (Natural Source): Phosphorus is an essential nutrient for grapevines, which is naturally absorbed from the soil. (Jay, J. M. 1985). Most of the phosphate in wine originates from the grapes themselves and the crushing process. Fertilized Soil: To optimize soil chemistry and provide optimal nutrient levels to the vines, viticulturists use phosphate-based mineral fertilizers. Diammonium Phosphate (Added Additive): During the fermentation process, winemakers often add Diammonium Phosphate (DAP) as a nutritional supplement. This additive helps yeast (the fungi that carry out the fermentation) process sugar and produce alcohol more quickly. (Prifti, D. 2007)

MATERIAL AND METHOD

Physico-chemical analyses (Bindashi, H., & Frashëri, M. 1984)
Preparation of wine samples for physico-chemical analyses:(Frashëri, M., & Prifti, D. 1997)
Removal of carbon dioxide with an ultrasonic device
Method Reference ISO (International Organization for Standardization), ISO 6632
Preparation of wine sample for analysis.
Before determining the physico-chemical analyses, the wine must be decarbonated. For this, 300-400 ml of wine are poured into a large glass, heated, preferably to 20-250C, and placed in an ultrasonic device until the gas is removed (it is removed quickly). If the wine contains suspended matter, then after removing the carbon dioxide it is filtered through a dry filter paper. To determine reducing sugars, sulfates and phosphates in wine, the wines are decolorized with activated carbon or centrifugation, filtered and diluted before the chemical analysis of the determination.
Determination of free sulfuric acid
Method Reference ISO 6632
Ripper Method (Iodometry)
For red wines: In a 250 ml glass beaker, 10 ml of red wine, 1 ml of 1% starch solution, 1 ml of sulfuric acid (1:3) are added and titrated with a 0.01N iodine solution. The color change is determined by comparing it with a 250 ml glass beaker containing 10 ml of red wine, 1 ml of 1% starch solution, 1 ml of sulfuric acid (1:3), but without added iodine. The comparison is made with a white, well-lit surface. The number of ml of iodine solution consumed is indicated by N. The same determination is made on the desulphite sample by boiling with air cooling, during 45 min or by oxidation with two drops of 10 volumes of hydrogen peroxide (3%), the number of milliliters of iodine consumed is marked with N_1. For common analyses N_1=0.2 ml.

The content in free sulfuric acid in mg per liter is calculated using the following formula. (AOAC. 2005)

For white wines: For white wine the determination is simpler. Take 50 ml of wine with a pipette and pour it into a 200-300 ml Erlenmeyer flask, add 2 ml of starch solution and 1-2 ml of sulfuric acid solution (1:3) and immediately titrate with

0.02 N iodine solution, stirring continuously until with a single drop the liquid takes on a stable blue color for 10 seconds. In another Erlenmeyer flask, 50 ml of wine, 1 ml of starch, 1 ml of sulfuric acid and 0.5 ml of hydrogen peroxide are added to oxidize SO_2, stirring occasionally, and after 5 minutes, titration is performed as above.

Determination of total sulfuric acid

In common practice, an approximate and simplified process is used: In a 250-300 ml conical flask, 10 ml of 0.1 N sodium hydroxide solution and 25 ml of red or white wine are added, immersing the tip of the pipette in the alkaline solution. Stir and leave to stand for 5 minutes in the cold. Then, 5 ml of sulfuric acid solution (1:3), 1 ml of 1% starch solution are added and titrated with iodine solution at 4 g per liter. The total sulfuric acid content in mg/l is calculated using the following formula: Where: N-number of ml of iodine solution with 4 grams per liter consumed. Note: Due to the rapid oxidation sulfuric acid, the first analysis that is made to the wine after opening the bottles is free and total sulfuric gas.

Determination of Sulfates in Wine. Iris Spectrophotometer Apparatus (*AOAC. 2005)*

Wavelength 420 nm

The wine sample must be filtered and decolorized (with activated carbon) or with lead acetate. Decolorization with Chemical Reagents (Lead Acetate). A precipitate is formed with the compound (protein and phenols). We added a little lead acetate to the sample until a precipitate forms, then filtered. Activated carbon is the safest, simplest and most widely used method in wine analysis, only the filtration is carried out completely so that no particles remain. (Tini, V., & Ciudici, P. 2000)

Figure 2. Iris Spectrophotometer

We take 50-100 ml of wine, where we add 0.5-1 g of activated carbon. We mix it for 5-10 minutes. We let it stand for a while (or shake it lightly with a magnet). We filter it with filter paper (or membrane). The filtrate should be clear and without strong color. Phosphates (Wavelength) 700-880 nm according to the Spectrophotometric method (Iris Spectrophotometer). Standard norms for sulfates and phosphates in wine according to oenological practices and the International Organisation of Vine and Wine and the legislation of the European Union

Sulfates SO_4^{2-} in wine. Reference method ISO 9280. Spectrophotometric method at wavelength $\lambda = 420$ nm. Typical value: 200-600 mg/L → normal in most wines. It can reach up to 800 mg/L in some cases depending on the processing. 1000 mg /L It is considered high and can affect the taste (bitter/salty taste) and stability. Sulfates are actually related to the use of SO_2 and technological processing. Interpretation of sulfates should be done together with the parameters pH, SO2, mineralization.

Determination of Phosphates PO_4^{3-} in wines

Decolorization and filtration of red wine samples for sample preparation. Then we diluted the samples 2:10 to eliminate interferences during the determination of phosphates with the Spectrophotometer at wavelength $\lambda = 880$ nm

Reference method ISO 6878. Spectrophotometric method: Acceptable values 100-400 mg/L (as PO_4^{3-}) or 30-120 mg/L as P. High values: 500 mg/L may indicate contamination, high use of additives or special raw materials. Phosphates are important for: yeast nutrition during fermentation and biological stability.

Parameter Normal Value High Value

Sulphates 200-600 mg/L > 1000 mg/L

Phosphates 100-400 mg/L > 500 mg/L

A value of 600 mg/L phosphates in wines is above the norm and indicates the high use of phosphate fertilizers in vineyards, nutritional supplements for yeasts during fermentation or contamination from water, equipment, and higher concentration from the raw material. High phosphate values in wines affect chemical stability by causing turbidity and precipitation during the technological process and in the final product. This then requires stabilization, filtration and treatment of wines.

Microbiological Analysis of Wines of "ÇEÇI" Winery [7]

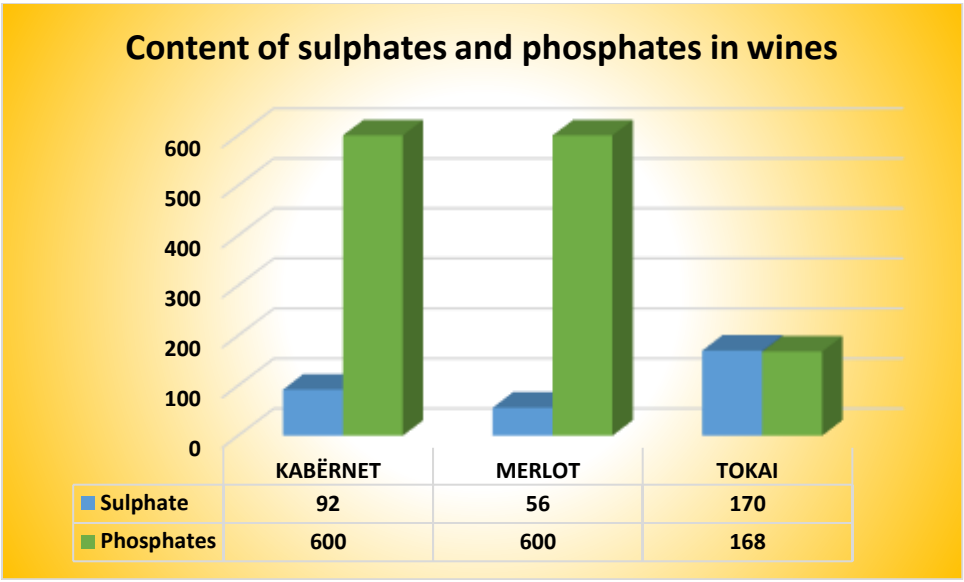
Determination and Identification of Acetic Bacteria (Acetobacter spp.) and Lactic Acid Bacteria in the Field Bromthymol Blue Agar.

Determination of mycorrhizal microflora on PDA (chloramphenicol) medium. Reference method ISO/CD 21527

Bromthymol blue agar medium is a selective medium for the identification of acetic and lactic acid bacteria. After incubation at 370C, the color changes from yellow to blue-green when acetic acid bacteria grow. (Shabani, L. 2003)

BROMTIMOL BLUE AGAR MEDIUM

Agar 1.5 g / 100 ml, Peptone 1 g / 100 ml, Yeast extract 0.5 g / 100 ml, NaCl 0.5 g / 100 ml, Bromtimol blue 2 mg / 100 ml



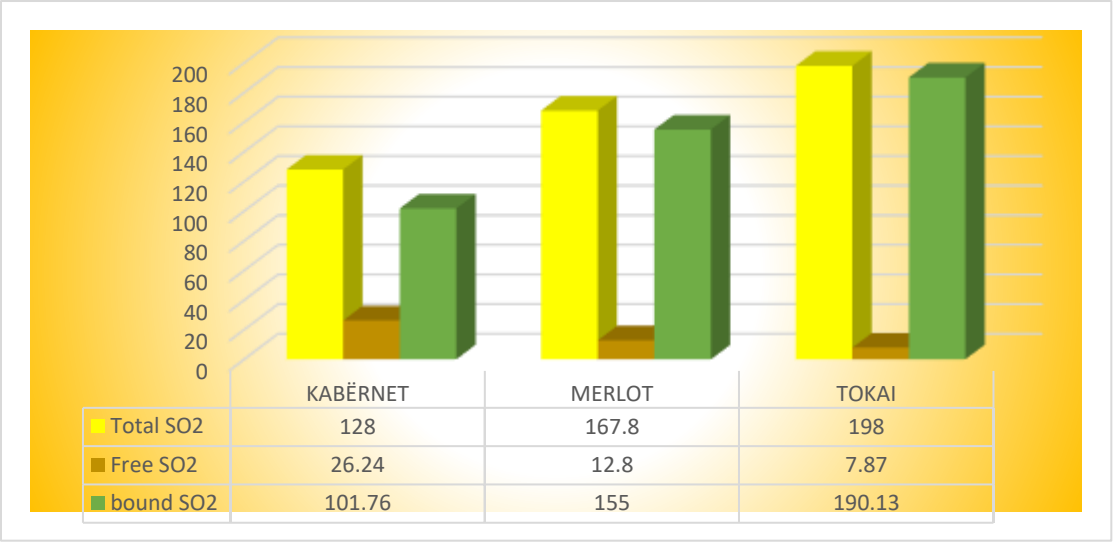
PDA MEDIUM (Potato Dextrose Agar) (For fungal load) (Gilliland, S. E. 1985) medium with a high polysaccharide content that favors the development of yeasts and molds, is a medium that favors the development of molds and yeasts and can be supplemented with other ingredients, e.g., acids and antibiotics to inhibit the development of bacterial loads. It is recommended for evaluating mold and yeast loads in food products as well as other foods and cosmetic products. It is sometimes used to grow fungal cultures in clinical trials. It is prepared with an infusion of dehydrated potatoes (200 ml of infusion containing 4 g of potato extract; 20 g of dextrose and 15 g of starch per 1 liter of medium. The pH of the medium is 5.6 +/- 0.2 at 25°C. Then, the count is made after 24 hours and after 48 hours for bacteria and after 7 days for yeasts and molds. Colonies with Bromthymol blue agar plates are counted after 48 hours, while those with Sabourand agar and PDA after 72 hours because molds develop more slowly (Frashëri, M., & Prifti, D. 1997). The counting of colonies is done by turning the plate upside down and placing it on a dark background (dark paper plate). The colonies appear in the form of dots of various sizes and shapes. The colonies that are counted are considered to be descendants of the cells of microorganisms; therefore, according to the number of colonies grown, the amount of microorganisms present can be determined in the air at the time of sowing (cultivation). Bromthymol blue agar media were used for acetic and lactic bacteria, Sabourand agar and PDA media for molds and yeasts. Two replicates for each sample and three decimal dilutions were used (Jay, J. M. 1985)

RESULTS AND DISCUSSION

Determination of sufates SO_4^{2-} and phosphates PO_4^{3-} in analyzed samples of bottled wines, with Spectrophotometer, after deggasing and decolorization.

Table. ***Content of sulphates SO_4^{2-} and phosphates PO_4^{3-} in analyzed samples of bottled wines***

Samples	SO_4^{2-} (sulphates) mg/L	PO_4^{3-} (phosphates) mg/L
"KABËRNET"Wine	92	600
"MERLOT"Wine	56	600
"TOKAI"Wine	170	168



Graph 1. ***Content of sulphates (SO_4^{2-}) and phosphates (PO_4^{3-}) in analyzed samples of bottled wines***

Content of total, free and bound SO_2 in the wines analyzed

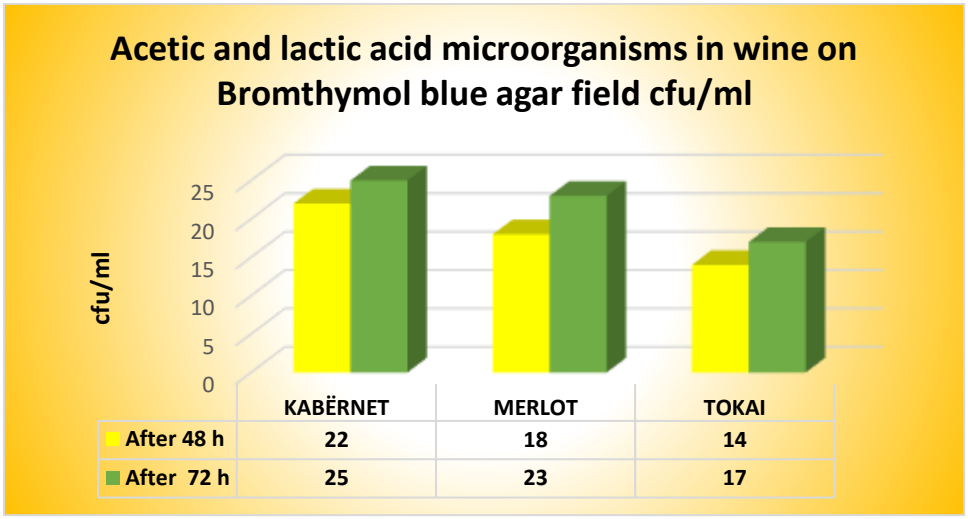
Table 1. Determination of total, free and bound SO_2 content in the analyzed wines

Samples	Total SO_2 (mg/L)	Free SO_2 (mg/L)	Bound SO_2 = Total SO_2- free SO_2 (mg/L)
"KABËRNET"wine	128	26,24	101,76
"MERLOT"wine	167,8	12,8	155
"TOKAI" wine	198	7,87	190,13

Graph 2. ***Content of mg/L*** **total, free and bound** ***SO₂*** **in the wines analyzed**

From the graphic presentation it is clear that:

Total SO_2 ranges from 128 mg/L in Cabernet wine to 198 mg/L in Tokai wine. According to the standard, it should not be more than 220 mg/l. This results in the total sulfur gas being within the parameters required to protect the wine from oxidation and bacterial diseases.



Free SO_2 It ranges from 7.87 mg/L in Tokai wine to 26.24 in Cabernet wine. According to the Standard, it should not be > 30 mg/L.

CONCLUSIONS

At the end of this study to determine the physical and chemical analyses of all types of "Winery Wines, Çeçi", we can draw some conclusions and recommendations.
Cabernet: The total extract is excellent (38.49 g/L) which promises a full-bodied wine. Monitoring only for the stability of phosphates so that it does not create a bottom after 6 months in the bottle.
Merlot: It has balanced parameters (pH 3.38, good total acidity, low volatile acidity 0.38 g/L). It is a stable wine.

Tokai: Requires care. It should be sold/consumed quickly on the market and stored in a cold chain. High Phosphate Management (Cabernet and Merlot Wines)
Problem discovered: The value of 600 mg/L of phosphates in both red wines is above the normal oenological limit (100–400 mg/L). This may come from excessive use of yeast nutrients (DAP - Diammonium Phosphate) during fermentation or from treatments in the vineyard.
Risk: High phosphates in the final product cause phosphate turbidity after bottling.
Recommendation: Adjustment of yeast nutrients: Reduce the dose of DAP during alcoholic fermentation in subsequent years and prefer organic nutrients (based on yeast autolysate), which do not increase inorganic phosphate residues. Reduce the use of chemical fertilizers containing phosphorus in the vineyard.
Microbiological Analysis. Gram-stained preparations for colonies grown on Bromthymol blue agar were short Gram-positive bacilli, while on PDA medium, colonies of beige, yellow and orange yeasts grew. The orange colonies, when identified under the microscope, resulted in elliptical clusters of *Rhodotorula spp*. On Sabourand medium, black molds grew, which after being identified under the microscope at x40, x100 magnification were of the genus *Aspergillus spp.* In the three analyzed wines, the mold load was within the limit values.
The number of colonies on the media used for the analyzed wines was within the allowed norms (<200cfu/ml) (State standards. 1982)
From the experiments performed, all three analyzed samples resulted qualitative from a physico-chemical and microbiological point of view.

IDENTIFICATION OF CANDIDATE GENES AND BIOLOGICAL PATHWAYS ASSOCIATED WITH GENETIC SHEEP RESISTOME TO GASTROINTESTINAL NEMATODES IN SHEEP: AN INTEGRATED MICROARRAY DATA MINING APPROACH

Arash Javanmard

[1] *Department of Animal Science, Faculty of Agriculture, University of Tabriz, Tabriz, Iran*

Corresponding author e-mail: a.javanmard@tabrizu.ac.ir

ABSTRACT

Gastrointestinal nematode (GIN) infections impose a substantial health and economic burden on sheep production worldwide, and although anthelmintics have traditionally served as the primary control measure, escalating drug resistance and growing consumer demand for chemical-free animal products have intensified efforts to breed sheep with innate genetic resistance—an endeavor complicated by the trait's polygenic architecture and modest heritability (h^2 = 0.22–0.63). In this integrated bioinformatic study, we analyzed 45 high-quality microarray samples across three platforms following rigorous quality control and identified 1,247 differentially expressed genes (DEGs) between resistant and susceptible animals, of which 689 were upregulated—including IFNG (log_2FC = 2.34), IL4 (2.21), TLR4 (1.98), TNF (1.87), Ovar-DRB1 (1.76), and NRAMP1 (1.45)—and 558 were downregulated, notably the mucin genes MUC7 (−1.45) and MUC15 (−1.05). Functional enrichment analyses (GO, KEGG, and GSEA) consistently highlighted immune and inflammatory responses, chemotaxis, cytokine-mediated signaling, and a pronounced Th2-skewed profile in resistant animals, with significant enrichment in Th1/Th2 differentiation, chemokine, and Toll-like receptor signaling pathways. Protein-protein interaction network analysis using the Maximal Clique Centrality (MCC) algorithm pinpointed ten hub genes—IFNG, TNF, TLR4, IL4, Ovar-DRB1, CCL5, IL6, STAT6, IL13, and NRAMP1—which coalesced into three core functional modules governing Th2 polarization, MHC class II-mediated antigen presentation, and inflammatory regulation. Collectively, these results provide a robust molecular signature for GIN resistance, positioning the identified hub genes, especially those linked to Th2 immunity and antigen presentation, as compelling targets for marker-assisted selection and genomic breeding programs. Furthermore, the observed downregulation of mucin genes in resistant animals implies that rapid parasite expulsion occurs without pathological mucus hypersecretion, challenging conventional views and offering a mechanistic foundation for designing sustainable breeding strategies aimed at reducing anthelmintic dependence and improving long-term flock health..

INTRODUCTION

Gastrointestinal nematode (GIN) infections impose a severe economic toll on sheep production, costing Australia and India hundreds of millions of dollars annually (Waller and Chandrawathani, 2005; Stear et al., 2005). Because grazing guarantees constant larval exposure, parasitic gastroenteritis remains a persistent threat. Although anthelmintics have been the

conventional control strategy, widespread resistance to all major drug classes (Wolstenholme et al., 2004), together with rising consumer demand for chemical-free meat and the lack of a commercial vaccine, has made genetic selection an increasingly attractive alternative.
Breed-specific genetic variation in resistance has been documented (Gosling et al., 2014), yet the trait exhibits low phenotypic variation and moderate heritability (0.22–0.63) (Riggio et al., 2013), which makes traditional selection based on fecal egg counts exceedingly slow. While candidate genes such as the MHC class II locus *Ovar-DRB1* (Sayers et al., 2005) and several quantitative trait loci on chromosomes 1, 3, 6, and 20 (Coltman et al., 2001) have been linked to resistance, existing studies have largely relied on sparse marker panels and have not provided a comprehensive, systems-level view of the underlying transcriptional mechanisms.
High-throughput transcriptomic technologies, such as microarrays, now offer an unbiased means of dissecting the molecular architecture of complex traits, though they are increasingly complemented by RNA-sequencing due to standardization and cost-effectiveness for large sample numbers (Ritchie et al., 2015). Nevertheless, publicly archived microarray data remain an underutilized resource. In this study, we therefore reanalyzed multiple independent ovine microarray datasets to systematically identify the genes, biological pathways, and regulatory networks that distinguish resistant from susceptible sheep following GIN infection
.

MATERIAL AND METHOD

To identify relevant data, we searched NCBI GEO using terms including "sheep", "Ovis aries", "nematode", and "microarray", applying strict inclusion criteria (clear phenotype distinction based on fecal egg count or related measures, ≥3 biological replicates per group, and valid probe-to-gene annotation). Three datasets—GSE36990, GSE36991, and GSE36992—spanning platforms GPL4077, GPL4076, and GPL4072, were selected (48 raw samples total). Preprocessing in R/oligo comprised norm-exp background correction, quantile normalization (Bolstad et al. 2003), and $\log_2$ transformation. After filtering probes with >20% missing values or lacking annotation and imputing remaining missing values via k-nearest neighbors (k=10), we obtained a final matrix of 32,847 probes representing 21,456 unique genes. Multi-step quality control—boxplots, MA-plots, hierarchical clustering, PCA, and kernel density estimation—removed low-quality arrays, leaving 45 high-quality samples..

ifferential expression was performed using limma with a linear model incorporating phenotype, batch, and their interaction; empirical Bayes moderation was applied, and genes with FDR < 0.05 and $|\log_2 FC| \geq 1.0$ were deemed significant. Functional annotation leveraged DAVID, clusterProfiler (with the ovine genome annotation database), REVIGO for redundancy reduction, and pathview for KEGG visualization. Separately, gene set enrichment analysis (GSEA) ranked all genes by signal-to-noise ratio and tested KEGG, REACTOME, and GO collections using 1,000 phenotype permutations, with significance defined as |NES| > 1.5 and FDR < 0.25 (Subramanian et al., 2005).

Protein-protein interaction (PPI) networks were constructed via STRING v11.5 (confidence ≥ 0.400, ≤ 50 interactors per query) and visualized in Cytoscape 3.9.1, where topology metrics and hub genes were identified using the MCC algorithm (cytoHubba). Finally, post-hoc power analysis confirmed adequate statistical power (0.92) for our sample size, while variance component analysis attributed 28.4% of expression variance to phenotype, 12.1% to batch, and 59.5% to residual error.

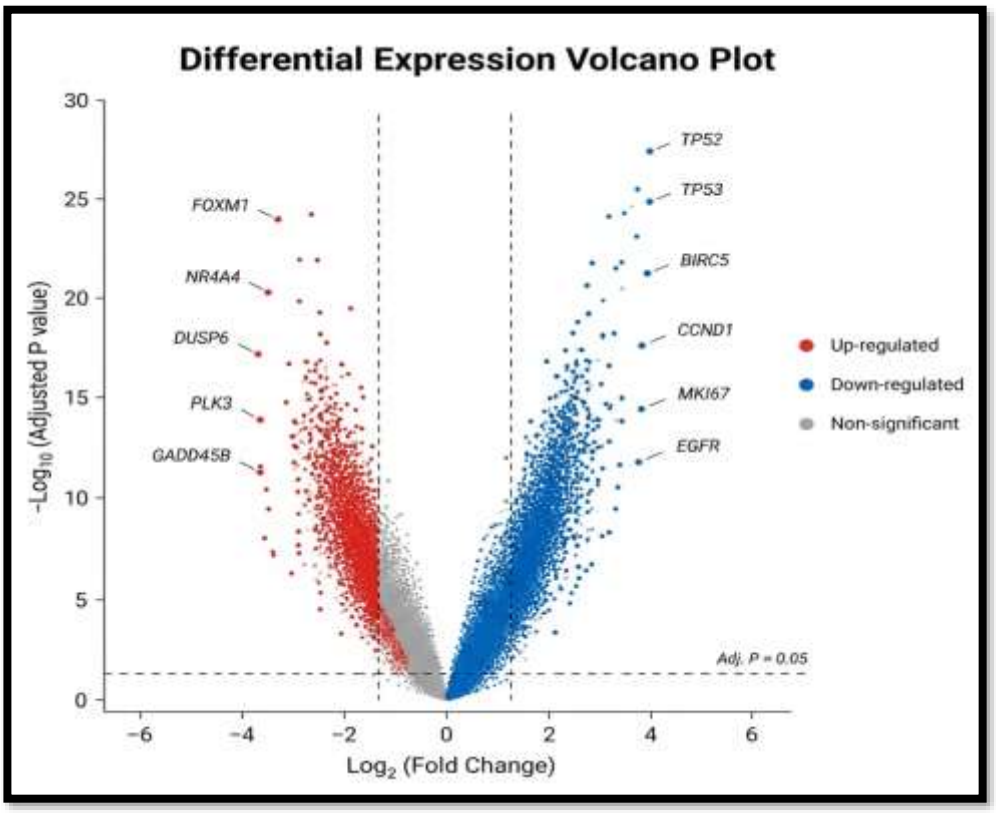

Figure 3. Differential expression volcano plot for microarray analysis

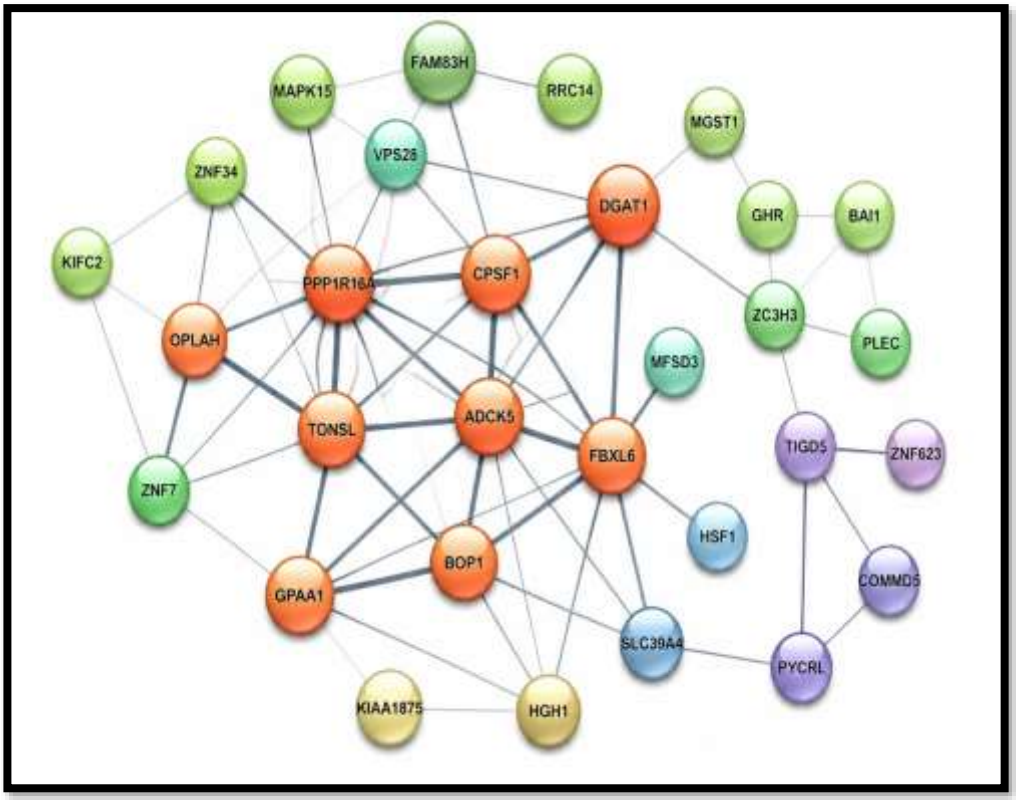

Figure 4. Gene networking and candidate key and hub gene resistance to nematode

RESULTS AND DISCUSSION

Following stringent quality control, three low-quality arrays were excluded, leaving 45 high-quality samples for downstream analysis. Of the 21,423 annotated genes interrogated, 1,247 (5.8%) were significantly differentially expressed between resistant and susceptible animals—689 upregulated and 558 downregulated in the resistant phenotype, with fold changes ranging from 2.0 to 12.1. The most prominently upregulated genes in resistant animals included key immune mediators such as IFNG (log_2FC = 2.34), IL4 (2.21), TLR4 (1.98), TNF (1.87), Ovar-DRB1 (1.76), and NRAMP1 (1.45). Conversely, mucin genes MUC7 (−1.45) and MUC15 (−1.05), along with the pepsinogen gene PGA5 (−1.18), were significantly downregulated..

Gene Ontology enrichment revealed a robust and consistent overrepresentation of immune-related terms across all domains: Biological Processes prominently featured immune and inflammatory responses, chemotaxis, cytokine-mediated signaling, lymphocyte activation, phagocytosis, and defense against parasites; Cellular Components highlighted the plasma membrane, extracellular region, cell surface, MHC class II protein complex, and the immunological synapse; while Molecular Functions were enriched for cytokine and chemokine activity, MHC class II receptor activity, signaling receptor binding, and pattern recognition receptor activity. KEGG pathway analysis identified 24 significantly enriched pathways, with the Th1/Th2 cell differentiation pathway showing the strongest enrichment (FDR = 1.2×10^{-9}), followed by chemokine, Toll-like receptor, Th17, T-cell receptor, and antigen processing and presentation pathways—all of which collectively point to a coordinated adaptive immune response with prominent Th2 polarization and efficient antigen presentation.

Gene set enrichment analysis (GSEA) corroborated these threshold-based findings, confirming strong enrichment for Th2-differentiation and cytokine-cytokine receptor interaction gene sets in resistant animals, alongside negative enrichment for mucus production and pepsinogen activity sets, consistent with the downregulation of *MUC7*, *MUC15*, and *PGA5*. Finally, the protein-protein interaction (PPI) network, comprising 847 nodes and 3,246 edges, exhibited scale-free topology and yielded ten hub genes via the MCC algorithm—*IFNG*, *TNF*, *TLR4*, *IL4*, *Ovar-DRB1*, *CCL5*, *IL6*, *STAT6*, *IL13*, and *NRAMP1*. These hubs coalesced into three interconnected functional modules: a Th2-polarization module centered on IL4, IL13, and STAT6; an antigen-presentation module anchored by Ovar-DRB1; and an inflammatory-signaling module coordinated by TLR4, TNF, and IFNG.

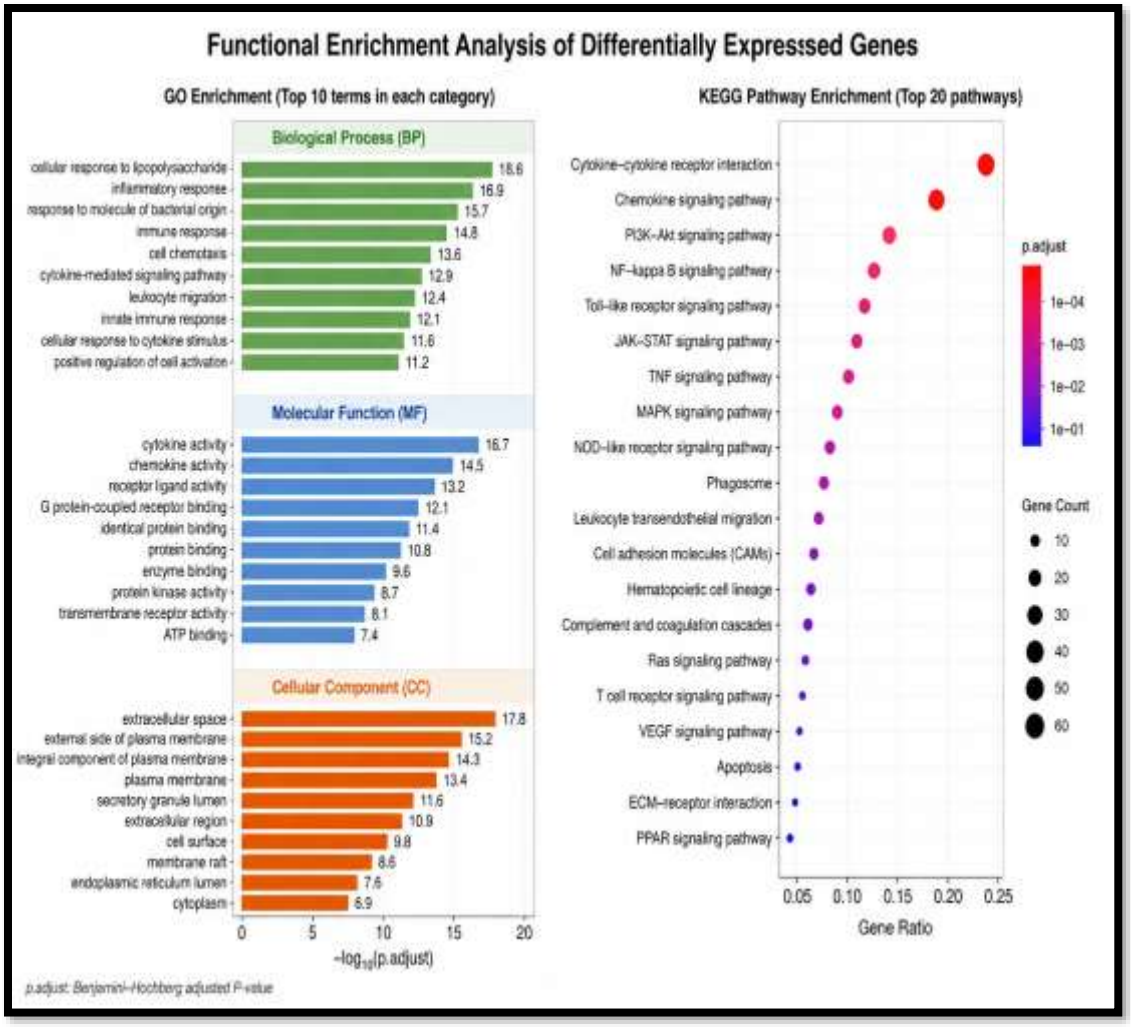

Figure 5. Gene ontology and system biology of discovered candidate gene

CONCLUSIONS

This reanalysis of publicly available microarray datasets has produced a thorough molecular description of genetic resistance to gastrointestinal nematode infection in sheep. The resistance phenotype is defined by a coordinated upregulation of Th2 cytokines (IL-4 and IL-13), the transcription factor STAT6, MHC class II molecules, TLR4, the iron transporter NRAMP1, and several inflammatory mediators, while resistant animals showed reduced expression of mucin genes and pepsinogen, presumably reflecting the absence of chronic mucosal pathology. Ten hub genes (IFNG, TNF, TLR4, IL4, Ovar-DRB1, CCL5, IL6, STAT6, IL13, and NRAMP1) were identified as the central nodes in the PPI network, which serve as the core molecular machinery of resistance. This information contributes to a fundamental knowledge of host-parasite interactions and provides a rational basis for marker-assisted selection programmes for genetic resistance improvement.

ABSTRACT

The present study aimed to evaluate the gastroprotective activity of hydromethanolic bark extract of Pinus halepensis (PHE) using both in vivo and in silico approaches. Gastric ulcers were induced in albino Wistar rats using an HCl/Ethanol model. PHE was administered at 250, 500, and 1000 mg/kg, with omeprazole (20 mg/kg) as the reference drug. Molecular docking of twelve LC-MS/MS-identified compounds was conducted against the gastric proton pump (H^+/K^+-ATPase). 3D structures of the ligands were sourced from PubChem, and the crystallographic structure of the gastric proton pump was obtained from the Protein Data Bank (PDB ID: 5YLU). Docking simulations were conducted using FlexX software. A clear dose-dependent effect was observed, with inhibition rates reaching 33.91 ± 1.02%, 51.08 ± 4.73%, and 62.04 ± 2.73% for the 250, 500, and 1000 mg/kg doses, respectively. The UI decreased from 70.37 ± 4.2 in the control group to 46.46 ± 0.72 (250 mg/kg), 34.55 ± 3.33 (500 mg/kg), and 26.73 ± 1.92 (1000 mg/kg). At the highest dose (1000 mg/kg). Macroscopic examination of the gastric mucosa demonstrated that pretreatment with PHE at the highest dose (1000 mg/kg) resulted in near-complete restoration of mucosal integrity compared to the untreated control group. Docking simulations of identified compounds against H^+/K^+-ATPase highlighted quercetin (−26.74 KJ/mol) and catechin (−25.95 KJ/mol) as the most promising candidates, both surpassing omeprazole (−18.49 KJ/mol) in binding affinity. Molecular interaction analysis revealed that the best compounds established multiple stabilizing contacts within the active site of H^+/K^+-ATPase. These findings suggest that *Pinus halepensis* bark extract possesses potent gastroprotective properties, likely mediated by the antisecretory activity of its flavonoid constituents, highlighting PHE as a promising candidate for future anti-ulcer therapeutic development.

Keywords: *Pinus halepensis*, gastroprotective effect, ulcer index, molecular docking, gastric proton pump.

INTRODUCTION

Gastric ulcers remain a major global health concern, resulting from an imbalance between aggressive factors and gastric mucosal defenses. Although conventional treatments are available, their side effects and increasing drug resistance highlight the need for safer alternatives (Chitapanarux et al., 2023). Medicinal plants are promising sources of bioactive compounds with antioxidant, anti-inflammatory, and gastroprotective properties (Aman et al.,

2025). *Pinus halepensis* is traditionally recognized for its biological activities related to oxidative stress and tissue protection, suggesting potential gastroprotective effects. Therefore, this study aimed to evaluate the gastroprotective activity of *P. halepensis* extract and investigate its possible mechanisms using complementary *in vivo* and *in silico* approaches.

MATERIAL AND METHOD

Plant material

The plant material was collected in June 2023 from Djbel El Ouahch forest, Constantine, eastern Algeria, identified, and dried under appropriate conditions prior to extraction.

Extraction

The hydroalcoholic extract of *Pinus halepensis* (PHE) was obtained by maceration using a methanol/water mixture (70/30, *v/v*) (Boudebbaz et al., 2025).

In vivo anti-ulcer activity

Healthy *Wistar* rats were fasted for 48 h, and acute gastric ulcers were induced using HCl/ethanol (80/20) (Zeghad et al., 2026). Animals received *Pinus halepensis* extract (0.25–1.00 g/kg) or omeprazole (0.02 g/kg). Gastric lesions were assessed using ImageJ, and the ulcer index and gastroprotection were calculated (Kim et al., 2020).

In silico molecular docking against the gastric proton pump

Molecular docking was performed to evaluate the interactions of LC-MS/MS-identified *Pinus halepensis* phytoconstituents with gastric H^+/K^+-ATPase (PDB ID: 5YLU). Ligand structures were obtained from PubChem, and omeprazole was used as the reference compound. Docking simulations were performed using LeadIT v2.1.8, and binding affinities were expressed as ΔG (kJ/mol) (Hioual et al., 2014).

RESULTS AND DISCUSSION

In Vivo Anti-Ulcer Activity

The results of the anti-ulcer activity summarized in Table 1, demonstrate a clear dose-dependent gastroprotective effect of PHE across the three tested doses (0.25, 0.50, and 1.00 g/kg body weight), and surpassing the reference drug at both 0.50 g/kg and 1.00 g/kg. The gastric mucosal protective effect of PHE may be primarily attributed to its phenolic compounds, which are known for their significant anti-ulcerogenic activity and ability to protect the gastric mucosa (Boudebbaz et al., 2025; Bakry et al., 2023).

Table 1. Effects of *Pinus halepensis* bark extract on ulcer index, ulcer inhibition in HCl/ethanol-induced gastric ulcerated rats.

Animal's group	Ulcer index	Inhibition (%)
Normal group	-	-
Control group	70.37 ± 4.2^{d}	0.00^{a}
Standard (Omeprazol 0.02 g/kg)	43.35 ± 2.16^{c}	38.57 ± 3.18^{b}
PHE 0.25 g/kg	46.46 ± 0.72^{a}	33.91 ± 1.02^{a}
PHE 0.50 g/kg	34.55 ± 3.33^{a}	51.08 ± 4.73^{a}
PHE 1.00 g/kg	26.73 ± 1.92^{a}	62.04 ± 2.73^{a}

PHE: *Pinus halepensis* extract. Values are expressed as Mean ± SD (n=6). Analysis of variance (ANOVA one-factor and Tukey Tests) revealed statistical difference ($P<0.05$). Different superscripts (a, b, c...) for values in the same columns are statistically different.

In silico molecular docking against the gastric proton pump

Molecular docking was performed to investigate the interaction of Catechin, Quercetin, Naringenin, and Luteolin with gastric H^+/K^+-ATPase (PDB ID: 5YLU), using omeprazole as the reference inhibitor. Binding affinities are presented in Table 2.

Table 2. Scoring functions of the phytoconstituents from *P. halepensis* docked to the gastric proton pump

Compounds	Gastric Proton Pump (5YLU)
	Scoring Function (KJ/mol)
Omeprazol	-18.4919
Catechin	-25.9543
Quercetin	-26.7423
Naringenin	-22.8859
Luteolin	-23.1306

Quercetin (−26.7423 KJ/mol) showed the strongest binding affinity, followed by Catechin (−25.9543 KJ/mol), with both displaying more favorable scores than Omeprazole (−18.4919 KJ/mol). Luteolin and Naringenin (−23.1306 KJ/mol and −22.8859 KJ/mol, respectively) also showed favorable interactions with H^+/K^+-ATPase. These affinities may be related to their hydroxyl groups and aromatic rings, which promote hydrogen-bonding and hydrophobic interactions (Shahidi & Dissanayaka, 2023; Lešnik et al., 2025). Overall, the findings support the potential contribution of these polyphenols to gastroprotection through proton pump inhibition.

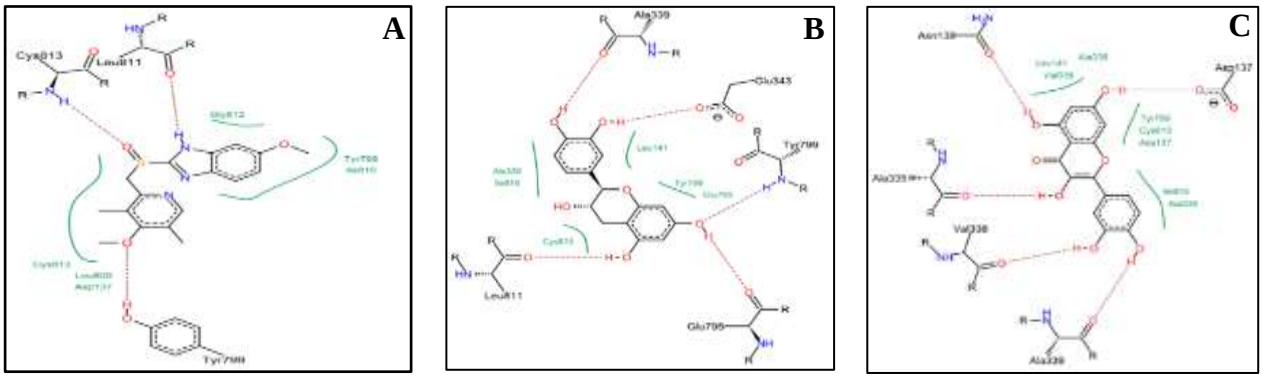

Figure 1. Binding interactions of omeprazole (A), catechin (B), and quercetin (C) within the gastric H^+/K^+-ATPase active site. Hydrogen bonds are represented by purple dashed lines, and hydrophobic interactions are highlighted in green.

CONCLUSIONS

Pinus halepensis shows promising gastroprotective potential due to its bioactive compounds with antisecretory properties. Combining *in vivo* experiments and *in silico* analyses

suggests that this plant may help protect the gastric mucosa and act on key molecular targets involved in ulcer formation. These findings support further studies to validate its use as a natural anti-ulcer agent.

COMPARATIVE EFFECTS OF EDTA AND DTPA ON THE STABILITY OF ASCORBIC ACID DURING CAPILLARY ELECTROPHORETIC DETERMINATION IN LEMON JUICE

Ahmet Dursun[1]

ABSTRACT

The oxidation of ascorbic acid especially in presence of metal catalysts can occur during sample preparation, resulting in an inaccurate measurement of its capillary electrophoretic determination. This study was performed in order to compare the effect of ethylenediaminetetraacetic acid (EDTA) and diethylenetriaminepentaacetic acid (DTPA) on the stability of ascorbic acid in lemon juice. Lemon juice was prepared freshly and then mixed (1:1 v/v) with EDTA or DTPA at concentrations of 0 (untreated), 0.5, 1.0 and 2.0 mM and measured either immediately or after 6 h waiting at room temperature. The external calibration curve ranged from 1.56125 to 100 µg/mL and had a higher linearity (R^2=0.99985), with limits of detection and quantification of 1.57 and 4.77 µg/mL, respectively. The recovery of this method was 95% which revealed a satisfactory analytical accuracy. The concentration of chelator had a significant effect on the initial ascorbic acid concentration measurement ($P < 0.001$). However, after waiting for 6 h, both the type ($P < 0.01$) and concentration ($P < 0.001$) of chelator significantly influenced ascorbic acid stability. The highest ascorbic acid concentration was found in samples treated with DTPA in comparison with EDTA-treated ones. These results showed that oxidation begins during sample preparation and suggested that adding approximately 1.0 mM of DTPA is an effective strategy to improve the reliability of capillary electrophoretic determination of ascorbic acid in food matrices.

Keywords: Oxidation, Ascorbic acid, Lemon juice, Metal-chelate complexes

INTRODUCTION

Ascorbic acid (Vitamin C) is one of the most important water-soluble antioxidants which is naturally present in fruits and vegetables and plays an important role in human nutrition due to its participation in collagen synthesis, iron absorption, immunity function, and oxidative stress protection (Yin et al., 2022). Additionally, ascorbic acid is commonly used in the food industry for retarding lipid oxidation, protecting color and flavor of foods, and improve product stability (Gérard et al., 2019). For this reason, the accurate determination of ascorbic acid is essential for quality control, nutritional labeling, and evaluation of food processing and storage conditions.

Different analytical techniques have been applied for the determination of ascorbic acid including titration, spectrophotometry, high-performance liquid chromatography (HPLC), and capillary electrophoresis (CE) (Suntornsuk et al., 2002; Uckoo et al., 2011). Among those, CE has received much attention due to its high separation efficiency, rapid analysis, low quantity of reagent, and minimal sample preparation (Maria Rizelio et al., 2012). Furthermore, CE could

be considered an eco-friendly analytical technique due to low solvents consumption (Topaloğlu & Dursun, 2026).

However, despite its advantages, the analysis of ascorbic acid by using CE has been found to be difficult due to the fact that it is very susceptible to oxidation during sample preparation and analysis. The oxidation of ascorbic acid into dehydroascorbic acid is greatly accelerated by oxygen, light, high temperatures, alkaline conditions, and especially by metal ions like Fe^{2+} and Cu^{2+} (Zinellu et al., 2006). This oxidation process not only reduces the amount of ascorbic acid but may also adversely affect electrophoretic performance through the alteration of peak area, migration time, peak symmetry, and theoretical plate number, thereby compromising analytical precision and accuracy.

In order to prevent oxidation catalyzed by metal ions, chelators are commonly added during the sample preparation stage. In particular, ethylenediaminetetraacetic acid (EDTA) has been widely used to maintain the stability of ascorbic acid through complexation with trace metal ions, and some studies have shown the positive impact of EDTA on maintaining ascorbic acid stability in fruit juices and biological samples (Cancalon, 2001; Zinellu et al., 2006). On the other hand, diethylenetriaminepentaacetic acid (DTPA), a chelator with a higher affinity for many transition metal ions compared to EDTA (Karak et al., 2016), has been successfully applied as a stabilizing agent in biological samples to minimize the oxidation of ascorbic acid. As reported by Collie et al. (2021), perchloric acid/DTPA-based stabilization effectively decreased the oxidation of ascorbic acid during sample storage; however, substantial oxidation occurred during sample preparation, which highlighted the importance of sample preparation stage in determining the ascorbic acid content. Despite the extensive use of EDTA in several CE analysis of ascorbic acid, there is no systematic study has been conducted on the effect of EDTA and DTPA in capillary electrophoretic determination of ascorbic acid in lemon juice.

Lemon juice constitutes an appropriate model matrix for the investigation of the stabilizing effect of chelator because it naturally contains relatively high concentrations of ascorbic acid, as well as trace metal ions that can oxidize this compound (Davey et al., 2000). Moreover, the evaluation of stabilization strategies particularly relevant for routine laboratory analysis, as sample handling and waiting at room temperature could increase the oxidative degradation.

Therefore, the aim of the present study was the investigation of the effect of EDTA and DTPA at various concentrations on the stability of ascorbic acid in the process of CE analysis of lemon juice. In order to simulate possible delays associated with sample processing in routine experiments, samples (with and without pretreatment) were kept at room temperature for up to 6 h prior to analysis. The impact of chelator was assessed according to the change in the content of ascorbic acid. The results of the present study can be used to improve the reliability and reproducibility of CE analysis of ascorbic acid in fruit juices.

MATERIAL AND METHOD

L-ascorbic acid, ethylenediaminetetraacetic acid (EDTA), diethylenetriaminepentaacetic acid (DTPA), boric acid and sodium hydroxide were purchased from Merck. Ultra-pure water was used throughout the study for the preparation of all solutions. Standard stock solution of L-ascorbic acid was freshly prepared on the day of analysis.

The fresh lemons were purchased from a local market (Hatay, Türkiye). Prior to analysis, the fruits were washed with tap water, and then by distilled water and dried. The peels were manually removed, and then the edible part was homogenized by using a laboratory homogenizer (HGB2WTG4, Waring Commercial, USA). Lemon juice was obtained by

filtering the homogenate through coarse filter paper and immediately used for subsequent analyses. The physicochemical characteristics of freshly prepared lemon juice were determined. The pH was measured at room temperature using a calibrated digital pH meter (HI2211, Hanna Instruments, Woonsocket, USA). The total soluble solids were determined using a digital refractometer (DR201-95, A. Krüss Optronic GmbH, Hamburg, Germany) and expressed as ^{o}Briks. The titratable acidity was determined by titration with standardized 0.1 N NaOH solution and expressed as g of citric acid per 100 mL of lemon juice. All the measurements were performed in triplicates.

In order to assess the impact of metal chelation on stability of ascorbic acid, freshly prepared lemon juice was divided into two experimental groups corresponding EDTA and DTPA. Each experimental group was further subdivided into 4 concentrations (0 (control), 0.5, 1.0, and 2.0 mM) of chelators. The concentrations of chelators were selected considering previous studies that used about 1 mM of EDTA to stabilize ascorbic acid (Spínola et al., 2012). Moreover, both low and high concentrations were used to determine the effect of concentration-dependent metal chelation and to identify the minimal concentration that stabilizes ascorbic acid adequately. Lemon juice was mixed with each chelator in equal volumes (1:1 v/v). In one group, the samples were analyzed immediately after preparation to represent the initial measured concentration (0 h). The other group of samples was kept for 6 h at room temperature to evaluate the effects of EDTA and DTPA on oxidation of ascorbic acid. Ascorbic acid concentration was calculated from the external standard technique.

Capillary electrophoresis-diode array detection (CE-DAD) method was used for ascorbic acid determination (7100, Agilent Technologies, Palo Alto, USA). The separations were carried out in an uncoated fused-silica capillary (50 µm i.d., 64.5 cm total length, G1600-61232, Agilent) using 30 mM borate buffer (pH 9.0) as background electrolyte. The detection wavelength was set at 270 nm. The samples and standards were injected to the capillary by hydrodynamically at 50 mbar 5 s (Cancalon, 2001). Prior to analysis, the CE system was conditioned according to the manufacturer's instructions.

Ascorbic acid measured from initial (0 h) and after waiting for 6 h samples were analyzed separately using a two-way ANOVA with chelator (EDTA and DTPA) and concentration (0, 0.5, 1, and 2 mM) as fixed factor in a completely randomized design. Duncan's multiple range test was applied for post-hoc comparison of means determined as significant at $P < 0.05$. Statistical analysis was performed using SPSS statistical software (Version 26, IBM, USA).

RESULTS AND DISCUSSION

The pH, total soluble solids (TSS), and titratable acidity determined in lemon juice were 2.65, 5.85 (^{o}Briks) and 4.55 g citric acid/100 mL, respectively. The measured pH is in accordance with the higher acidic nature of lemon juice and agrees well with the previous findings reported by Uçan et al. (2014). However, the authors reported higher TSS and titratable acidity compared to those obtained in the present study. These differences could be attributed to the type of lemon used, fruit maturity, cultivation and management conditions (Sun et al., 2019; Di Vaio et al., 2023).

The main analytical characteristics of the CE method were summarized in Table 1. A seven-point calibration curve was constructured within the concentration range of 1.56125-100 µg/mL. The calibration curve exhibited good linearity between the analyte concentration and peak area with a coefficient of determination (R^2=0.99985). The obtained linearity was higher than that of Dresler & Maksymiec (2013) who reported a R^2 of 0.988 for ascorbic acid using CE in plants. The response factor was determined as 2.35, which indicates a stable analytical response of the CE method within the calibration range. The low variation in response factor

(CV <5%) confirmed repeatability of the CE method. The limit of detection (LOD) and quantification (LOQ) were 1.57 µg/mL and 4.77 µg/mL, respectively. These values indicated that the CE method provides good sensitivity, necessary to detect natural concentrations of ascorbic acid in lemon juice. The LOD obtained from the present study were comparable to those reported for CE methods used borate electrolytes and UV detection (Dresler & Maksymiec, 2013). A higher LOD (10 mg/mL) of ascorbic acid had been previously reported for beverages analyzed by CE (Liu et al., 2014). Method accuracy was evaluated by recovery experiments (Table 1). The representative electropherograms of the native and ascorbic acid-spiked samples of lemon juice were shown in Fig 1. The mean recovery of 95% demonstrated a satisfactory analytical accuracy and negligible matrix interference. The confidence interval of 95% (81.2-109%) confirmed the reliability of the analytical method as well (Table 1). According to internationally analytical validation guidelines (ICH, 1996), recovery values of 80-110% are generally considered acceptable for food analysis. Similarly, Liao et al. (2001) obtained the recovery rates of 95-105% for ascorbic acid in fruit juices, including lemon.

Table 1. Analytical calibration characteristics and validation parameters of the applied capillary electrophoresis method for the determination of ascorbic acid in lemon juice.

Calibration characteristics	
Concentration range (µg/mL)	1.56125-100

CI 95% (lower-upper)	81.2-109

CV: Coefficient of variation. CI: Confidence interval. The data were expressed as mean±standard error (n=3).

The influence of EDTA and DTPA at different concentrations on the stability of ascorbic acid in lemon juice was presented in Table 2. The concentration dependents effects of both chelators were illustrated in Fig 2. The ascorbic acid concentration after the preparation of samples ranged between 334 and 445 µg/mL, depending on the concentration of chelators. The ascorbic acid concentration in the present study was consistent with the findings reported by (Uçan et al., 2014), who showed a significant reduction in ascorbic acid level from 420 µg/mL to 345 µg/mL during the processing. Similarly, it has been reported that the ascorbic acid concentrations in lemon juice decreased steadily during ripening from 31.4 to 23.7 mg/100 g (Di Matteo et al., 2021). The chelator concentration had a significant effect on the ascorbic acid content initially measured ($P < 0.001$). The samples with 1.0 and 2.0 mM chelator concentration showed higher concentrations of ascorbic acid in comparison to other treatments, regardless of the type of chelator used (Table 2, Fig 2).

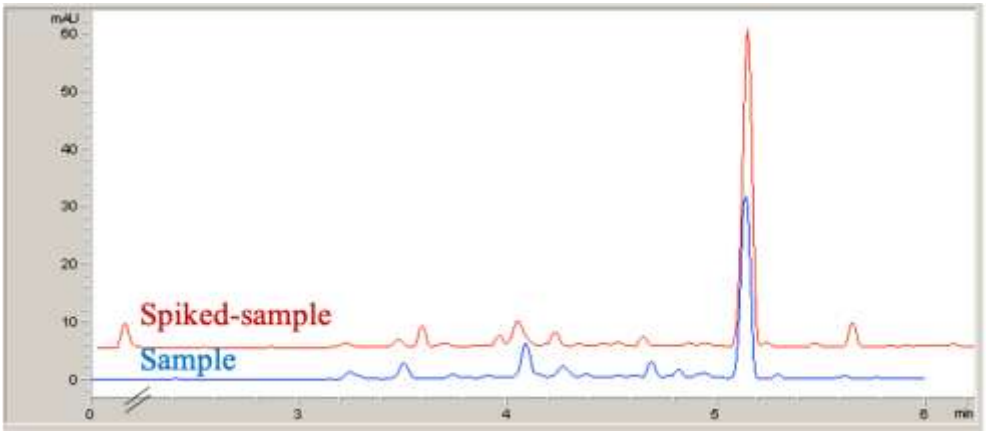

Figure 1. Capillary electropherograms of native and ascorbic acid-spiked lemon juice samples.

Table 2. Effects of DTPA and EDTA concentration on the measured ascorbic acid concentration in lemon juice analyzed immediately and after 6 h waiting at room temperature.

Chelator	Concentration (mM)	Ascorbic acid (µg/mL)	
		Initial	After 6 h
DTPA	0 (Control)	336±17.6	244±2.19
	0.5	334±9.39	327±8.88
	1.0	410±15.5	333±10.3
	2.0	445±25.0	353±6.00
EDTA	0 (Control)	336±25.2	239±10.1
	0.5	386±18.4	308±13.1
	1.0	409±13.9	309±4.10
	2.0	406±12.3	306±11.0
Chelator (A)			
DTPA		381±16.3	315±12.9
EDTA		384±11.8	291±9.96
P value		*0.831*	*0.002*
Concentration (B)			
0 mM (Control)		336^{b}±13.8	242^{b}±4.76
0.5 mM		360^{b}±14.7	318^{a}±8.26
1.0 mM		410^{a}±9.30	321^{a}±7.43
2.0 mM		425^{a}±15.2	330^{a}±11.9
P value		*<0.001*	*<0.001*
Interaction (A x B)		*0.135*	0.172

The data were expressed mean±standard error (n=3). $^{a-b}$Different lowercase letters within the same column indicate significant differences among chelator concentration ($P < 0.05$).

The initial ascorbic acid concentration obtained in the samples treated with chelators indicate that oxidative degradation of ascorbic acid begins immediately after tissue disruption and juice extraction before analysis. Mechanical homogenization leads to damage to cellular compartments, resulting in the interaction of ascorbic acid with endogenous metal ions and oxidative enzymes in the presence of oxygen (Spínola et al., 2012). That means oxidation of ascorbic acid may even in the stage of sample handling before the beginning of instrumental analysis when metal-catalyzed reactions are not appropriately controlled. Moreover, it has been

reported that significant loss of ascorbic acid happens immediately after the extraction of juice and in the next stages of processing (Davey et al., 2000; Uçan et al., 2014). Although the low pH (2.6) of lemon juice may be considered to keep ascorbic acid stable, acidic matrix alone is not enough to inhibit oxidation process. Previous studies have shown that metal ions like Fe^{3+} and Cu^{+2} still have the ability to oxidize of ascorbic acid even in acidic matrix by metal mediated electron transfer reaction (Bradshaw et al., 2011; Pullar et al., 2018).

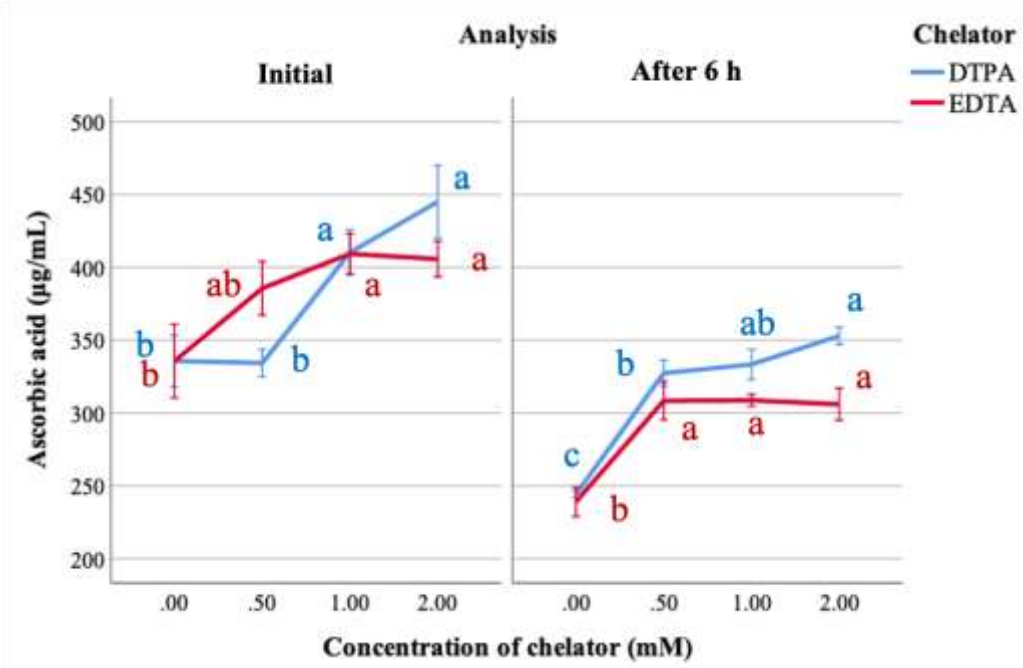

Figure 2. Effects of DTPA and EDTA concentrations on the measured ascorbic acid concentration (µg/mL) in lemon juice analyzed initial and after 6 h at room temperature. Error bar represents standard error (n=3). [a-c]Different lowercase letters indicate significant differences among chelator concentration within each chelator treatment ($P < 0.05$).

Upon waiting for 6 h after preparation of the samples, the concentration of ascorbic acid was decreased in all samples (Table 2, Fig 2). However, the addition of chelator minimized the amount of oxidation compared to the untreated control. Significant effects of both chelator concentration ($P < 0.001$) and chelator type ($P < 0.01$) were noted upon waiting for 6 h after preparation of the samples. In general, samples treated with DTPA had more amounts of ascorbic acid concentration (315 µg/mL) than those treated with EDTA (291 µg/mL). It should be stated that DTPA provided more effective protection against oxidation during prolonged sample handling. Pullar et al. (2018) demonstrated that ascorbic acid oxidation occurred rapidly in the process of sample preparation and processing, and the catalysts of this process was the transition metal ions. Addition of DTPA inhibited metal-catalyzed oxidation of the substance, while EDTA act less effectively because complexes between EDTA and metal ions retained redox activity at physiological pH. These results were shown in consistence well with those of the present study. Calculated losses also show the protective effects of both chelators. Without any chelator, about 28% of initial ascorbic acid were lost during 6 h period. On the contrary, losses from samples treated EDTA were about 24%, while losses from DTPA treated samples were about 17% (Fig 3). This higher efficiency of DTPA is expected because of the stronger complex formation ability of DTPA for metal ions compared with EDTA. Namely, DTPA molecule has an additional amino-carboxylate group, which provides it with larger stability

constants with Fe^{3+} and some other metal ions. Indeed, comparative studies have demonstrated that DTPA forms more stable complexes with iron than EDTA (Zhou et al., 2010).

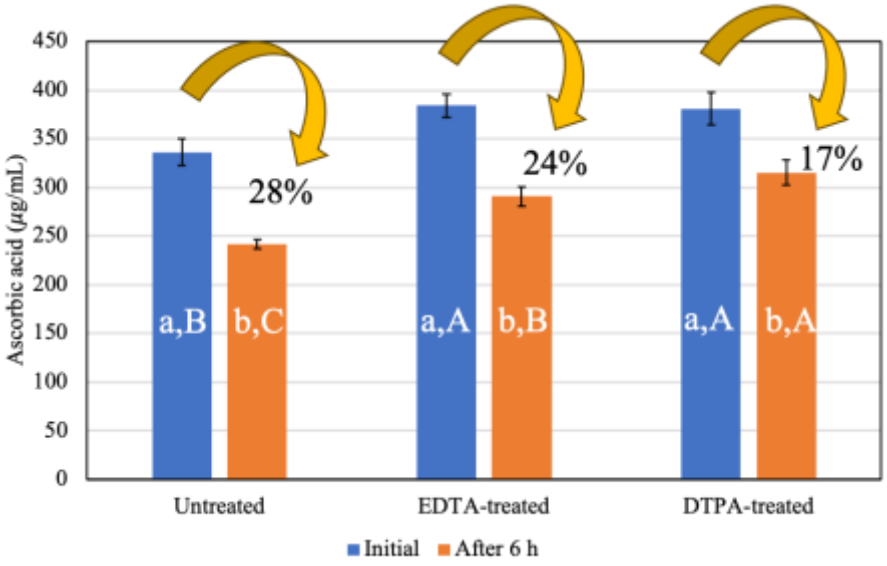

Figure 3. Changes in ascorbic acid concentration in untreated, EDTA- and DTPA-treated lemon juice after 6 h of waiting at room temperature. Arrows indicate the percentage loss of ascorbic acid. Error bar represents standard error (n=3). [a,b]Different lowercase letters indicate significant differences among analysis time within each treatment ($P < 0.05$). [A-C]Different uppercase letters indicate significant differences among treatments at the same analysis time ($P < 0.05$).

The concentration dependent effects observed in the present study further confirm that practicality of 1.0 mM as an adequate concentration for routine CE determination of ascorbic acid. While the samples which were treated with 2.0 mM chelator had numerically higher amounts of ascorbic acid than samples which were treated with 1.0 mM chelator, the difference did not statistically significant (Fig 2). In this case, it should be suggested that the majority of catalytically active metal ions can probably already be efficiently complexed at approximately 1.0 mM concentration under the experimental conditions of lemon juice analysis. Hence, increase in the chelator concentration to a value above 1.0 mM cannot appear to provide any analytical advantages but will result in more reagent usage. Moreover, previous studies have noted the susceptibility of ascorbic acid to its oxidation in the course of sample preparation. Collie et al. (2021) showed that the stabilization with perchloric acid/DTPA successfully prevented the oxidation of plasma ascorbate during frozen storage; however, considerable oxidation could take place during sample processing. Similarly, the present findings confirm this statement to a food matrix by noting the crucial influence of sample preparation rather than storage alone constitutes on the ascorbic acid quantification. Therefore, the incorporation of an appropriate chelating agent immediately after extraction appears to be essential for minimizing metal-catalyzed oxidation.

CONCLUSIONS

From an analytical perspective, based on the results obtained from the present study, the addition of about 1.0 mM EDTA or DTPA seem to be sufficient to improve the immediate determination of ascorbic acid through CE. However, when analysis is not performed directly and waiting for a while at room temperature becomes necessary, DTPA would be more

appropriate due to the higher capability of protecting native ascorbic acid. These results offer a practical guidance for routine capillary electrophoretic determination of vitamin C in citrus matrices and potentially any other food which is sensitive to metal-mediated oxidation. Moreover, the present investigation was limited to only one matrix, as well as a short time interval (6 h) under room temperature conditions. Further research should investigate the efficacy of EDTA and DTPA in different matrices with varying metal content along with different time periods and temperatures.

ABSTRACT

The increasing demand for environmentally sustainable agricultural practices has accelerated the development and application of organic fertilizers as alternatives to conventional mineral fertilizers. Organic fertilizers not only supply essential nutrients for plant growth but also improve soil structure, enhance microbial activity, increase organic matter content, and contribute to long-term soil fertility. This review summarizes recent advances in the application of organic fertilizers, with particular emphasis on vermicompost and innovative biocapsulated fertilizer technologies. The paper discusses the classification of organic fertilizers, their agronomic and environmental benefits, and their role in improving nutrient use efficiency while reducing nutrient losses and environmental pollution. Particular attention is given to biodegradable vermicompost-based biocapsulated fertilizers, which enable the controlled release of nutrients and support sustainable nutrient management. A conceptual model of a vermicompost-based biocapsulated fertilizer is presented to illustrate its potential as an environmentally friendly solution for enhancing soil fertility and crop productivity. The findings indicate that integrating organic fertilizers with controlled-release technologies represents a promising strategy for achieving sustainable agriculture and supporting the transition toward circular bioeconomy principles.

Keywords: organic fertilizers, sustainable agriculture, vermicompost, soil fertility, nutrient cycling, organic waste

INTRODUCTION

Agricultural intensification has substantially increased global food production over recent decades. However, the excessive use of mineral fertilizers has resulted in numerous environmental problems, including soil degradation, nutrient imbalance, water pollution, greenhouse gas emissions, and loss of soil biodiversity. Consequently, sustainable agricultural practices have become increasingly important for ensuring long-term food security while protecting natural ecosystems. Organic fertilizers represent one of the most promising approaches to sustainable crop production. Produced from plant residues, animal manure, compost, vermicompost, and other organic wastes, these materials recycle nutrients back into agricultural soils and contribute to the circular economy. Unlike synthetic fertilizers, organic fertilizers improve both the physical and biological properties of soil while gradually releasing essential nutrients. Among various organic fertilizers, vermicompost has attracted particular attention because of its high nutrient content, beneficial microorganisms, humic substances, and plant growth regulators. Numerous studies have demonstrated that vermicompost enhances seed germination, root development, nutrient uptake, and crop yield.

The aim of this review is to summarize recent advances in the application of organic fertilizers for sustainable agriculture, with particular emphasis on vermicompost and its contribution to improving soil fertility and crop productivity.

Types of Organic Fertilizers

Organic fertilizers originate from naturally occurring biological materials and vary considerably in their chemical composition and agronomic performance. Figure 1 illustrates the major types of organic fertilizers commonly used in agriculture, including farmyard manure, compost, vermicompost, green manure, poultry manure, and bio-organic fertilizers enriched with beneficial microorganisms.

Figure 4. Composition of the substrates used for vermicomposting (cattle manure, organic food waste, CaO_2, paper waste, and fallen leaves), %.

Chemical characterization of the samples was carried out to determine the content of organic matter (humus), total nitrogen (N), total phosphorus (P), and total potassium (K) in the vermicompost. The results of the chemical analysis are summarized in Table 2.

Table 2. Chemical composition of vermicompost samples.

Sample	Humus, %	Total nitrogen (N), mg kg^{-1}	Available phosphorus (P_2O_5), mg kg^{-1}	Available potassium (K_2O), mg kg^{-1}
1	34.7	66.75 ± 0.05	322 ± 0.01	1865 ± 0.8
2	33.0	236.75 ± 0.01	462 ± 0.06	1415 ± 0.5
3	41.5	393.25 ± 0.03	442 ± 0.03	2045 ± 0.9
4	23.1	1145.75 ± 0.60	407 ± 0.02	2760 ± 0.7
5	10.9	16.375 ± 0.03	422 ± 0.05	4375 ± 0.8
6	11.8	133.0 ± 0.02	417 ± 0.09	3170 ± 0.6
7	1.9	4.6 ± 0.04	32 ± 0.02	620 ± 0.07

Based on the results of the chemical analysis presented above, the vermicompost samples can be ranked according to decreasing humus content as follows: III > I > II > IV > VI > V. The difference in humus content between samples I and II was insignificant, indicating similar levels of organic matter. The highest humus content was observed in Sample III. Fallen leaves are rich in organic matter, and under favorable conditions red Californian earthworms (*Eisenia fetida*) are capable of converting up to 30% of this material into vermicompost during a single composting cycle. In contrast, the control sample exhibited considerably lower concentrations of humus and essential biogenic nutrients. These findings indicate that the activity of red Californian earthworms, together with their associated beneficial microorganisms, effectively accelerates the decomposition of organic residues and enhances the accumulation of humus as well as plant-essential nutrients in the resulting vermicompost.

CONCLUSIONS

This study demonstrated the effectiveness of vermicomposting as a sustainable biotechnology for the recycling of organic waste into high-quality organic fertilizer. Seven different substrate formulations were evaluated to investigate the influence of substrate composition on the physicochemical properties of the resulting vermicompost. The vermicomposting process, carried out over a period of 90 days using Eisenia fetida, resulted in the efficient decomposition and stabilization of organic matter under controlled environmental conditions.

The chemical analyses revealed considerable differences among the experimental treatments. Vermicompost produced from substrates containing cattle manure and plant-derived organic materials exhibited higher humus content and improved concentrations of essential nutrients, including nitrogen, phosphorus, and potassium. Spectroscopic analysis of humic and fulvic acids further indicated an increased degree of humification and structural complexity in the vermicompost compared with the initial substrate, confirming the formation of stable humic substances during the vermicomposting process. The obtained results demonstrate that substrate composition plays a crucial role in determining vermicompost quality and nutrient availability. The synergistic interaction between Eisenia fetida and associated microorganisms accelerated the transformation of organic residues into a biologically active and nutrient-rich fertilizer.

Overall, the findings confirm that vermicomposting is an environmentally friendly and economically viable approach for organic waste management. The produced vermicompost has considerable potential for improving soil fertility, enhancing nutrient cycling, and supporting sustainable agricultural production while simultaneously reducing the environmental burden associated with organic waste disposal. Future studies should focus on evaluating the long-term agronomic performance of vermicompost under field conditions and optimizing substrate formulations to maximize fertilizer quality and crop productivity.

Funding

This research was funded by the Young Scientist Project (2025-2027), grant No. AP25794509, titled «Development of biocapsulated fertilizers based on organic waste and their implementation in agriculture», supported by the Committee of Science of the Ministry of Science and Higher Education of the Republic of Kazakhstan.

INFLUENCE OF REMOVING THE OUTER SCALES OF THE CORM ON THE DEVELOPMENT AND PRODUCTIVITY OF GLADIOLI

Valentin Panchev

Agricultural University - Plovdiv, 12, Mendeleev Blvd.

e-mail: valentin_panchev@abv.bg

ABSTRACT

Gladiolus are one of the main flower crops used both for cut flowers. They are growing through corms. This also determined the scope of the study. The main goal of this article is to study the influence of removing the outer scales of the corm on the growth performance of different varieties of gladioli. The experiments were conducted with three varieties of gladiolus: Amsterdam, Oasis and Fado. The corms scales were removed immediately before planting. Whole unpeeled corms, planted at the same time and scheme, were used as controls. Planting was carried out during the period 25. 03. -5.04. 2023-2025 according to the 15 x 15 cm scheme. The phenological development of plants was observed - beginning and mass emergence, formation of the first leaves, appearance of the flower stalks, beginning and end of flowering. In the full flowering phase, biometric studies were carried out – flower stalk height, number of leaves, leaf length, fresh and dry weight of leaves, leaf area, number of flowers, length and diameter of the average flower. It was found that plants from peeled corms developed more dormant buds. These plants formed more leaves, with a larger area and weight. No changes in the height of the flower stalks were observed. Phenological development was close between the two methods of cultivation. Peeling of the corms in most plants caused the formation of a larger number of flower stalks, which led to a larger total number of flowers. The Fado variety emerged with the highest decorative value.

Key words: corm, gladiolus, vegetative mass, flower, phenology

INTRODUCTION

Flower production is a leading direction in industrial floriculture, with the genus Gladiolus (Gladiolus, family Iridaceae) ranking second among the main cut flower crops worldwide (Farhat T., 2004; Raj et al., 2009; Azim et al., 2019). The crop is widespread and is grown both in the field and in greenhouse conditions (Bai et al., 2009). Its high market value is determined by its valuable decorative qualities – spectacular inflorescences with rich color diversity, erect stems and great durability (Bose et al., 2003; Manning and Peter, 2008; Memon et al., 2013; Azim, 2019).

Most modern varieties (Gladiolus x grandiflora) are complex polyhybrids obtained through interspecific hybridization (Barnard, 1972; Huxley et al., 1992). In genetic terms, combinatorial selection (Denisa et al., 2012; Hort et al., 2012) and other methods, such as the application of RAPD markers (Pragya et al., 2010), are basic research tools for assessing genetic relationships and creating new adaptive genotypes.

In Bulgaria, the majority of planting material is of Dutch origin, but successful selection programs have also been carried out in our country, leading to the creation of highly competitive local varieties, such as the variety "Iva" (Ivanova et al., 2019).

In a biotechnological aspect, propagation is complemented by in vitro methods with stem explants under the influence of growth regulators (Meira et al., 1990).

However, the expression of genetic potential depends strongly on environmental factors and the applied agrotechnics. The light regime in the "4–6 leaf" phase is particularly critical, where the deficiency slows down morphogenesis (Shillo and Halevy, 1996). Studies in our country show that later planting dates accelerate development (Kaninski et al., 2012), with mid-April being the most favorable time for planting (Ivanova et al., 2016).

The application of gibberellic acid GA_3 also has a positive effect (Suman et al., 2012). Since different varieties react specifically, continuous variety testing and quality pre-sowing preparation of the planting material are mandatory. For example, the varieties Snow-Princes/Snow White and American Beauty are much earlier flowering than the Magic variety (Kamble et al., 2004).

A major factor in production is the low natural propagation coefficient, and obtaining high-quality new corms takes several growing seasons (Bose et al., 2003; Takatsu et al., 2005; Ramzan et al., 2010). To overcome this factor and improve germination, controlled temperature storage (Carpenter et al., 1991) and pre-sowing chemical treatment with potassium nitrate KNO_3 (Ramzan et al., 2010; Mushtaq et al., 2012; Memon et al., 2013) are used.

Along with chemical and physical methods (Aladjadjiyan, 2007), mechanical effects on the structure of the planting material also play an important role. The outer dry scales of the corm perform a protective function during storage, but after planting they can act as a physical and chemical barrier (through the inhibitors contained in them), limiting the access of moisture and oxygen to the dormant bud, which delays germination. The effects of removing these scales on the biometric indicators of the aboveground biomass and underground reproductive organs are not well studied and require detailed experimental clarification. In this regard, the main objective of the present study is to study the influence of removing the outer scales of the corm on the rate of germination and subsequent development, as well as to investigate a number of phenological characteristics of different gladiolus varieties grown in Bulgarian conditions.

MATERIAL AND METHODS

The research activity was carried out during the period 2023 – 2025. in the Experimental Field and the Scientific Laboratory at the Department of Horticulture of the Agricultural University – Plovdiv, Bulgaria. The object of the study is three modern gladiolus varieties Gladiolus x grandiflora, namely the variety "*Fado*", the variety "*Oasis*" and the variety "*Amsterdam*".

The main preparation of the area began in the fall with pre-plowing application of mineral fertilizers in doses of 15 $kg.da^{-1}$ phosphorus, in the form of triple superphosphate and 20 $kg.da^{-1}$ potassium, in the form of potassium sulfate. This was followed by deep plowing and the formation of evenly raised beds. Fine pre-sowing cultivation of the surface layer was carried out in the spring. Twenty days before planting, pre-sowing nitrogen fertilization with ammonium nitrate in a dose of 24 $kg.da^{-1}$ active substance nitrogen was applied.

The experiment was set up using a randomized method in three replications, with each experimental plot including 100 plants. Planting was carried out according to a 15 x 15 cm scheme in the period 5 - 10 April.

Two variants of planting material preparation were studied. The first variant was the experimental one, for which peeled corms were used. In them, the outer covering scales of the corms were removed mechanically immediately before planting in the soil. The second variant is the control one with unpeeled corms. In it, whole, structurally intact unpeeled corms were used, planted on the same day, under the same scheme and depth.

During the vegetation period, all standard and approved agrotechnical practices for the country (watering, weeding, plant protection) necessary for the normal growth and development of the plants were applied, according to the guidelines of the Institute of Ornamental and Medicinal Plants (Bistrichanov et al., 2008).

The indicators related to the phenological and vegetative development, as well as the decorative and productive qualities of the plants, were recorded during and after the vegetation. The measurements were made according to the methodology of Dimova et al. (2012), when exactly 10% of the plants in the respective plot enter the given phase. The measurements were carried out on 10 plants from each repetition, selected randomly. The obtained experimental data were subjected to mathematical and statistical processing by one-factor analysis of variance One-way ANOVA by the Fisher method, described by Fowel and Cohen (1992). The significance of the differences between the mean values was tested by the criterion for the least significant difference (LSD) at a critical significance level of p = 5.0%. Due to unidirectionality and high similarity in the trends in individual years, the final results presented in the study represent average values from the three-year experimental period.

RESULTS AND DISCUSSION

Immediately before planting, a biometric characterization of the corms was carried out, including measuring their diameter, height and weight. Table 1 shows the initial biometric indicators of the planting material. It is clear from it that the variety "*Amsterdam*" is characterized by the highest average values for all three measured indicators: corm height, diameter and weight, respectively 2.80cm, 4.10cm and 28.60g for the unpeeled controls and height 2.5cm, diameter 3.9cm and weight 27.73g for the peeled ones, and the variety "*Fado*" has the lowest values - for the unpeeled ones: height 2.2cm, diameter 2.8cm and weight 16.91g, and for the peeled ones height 1.9cm, diameter 2.7cm and weight 16.16g. After mechanical removal of the outer scales, a natural decrease in the parameters was observed in all three varieties.

Table 1. Morphological characteristics of a gladiolus corm.

Variety		**Unpeeled**			**Peeled**		
		Height (cm)	Diameter (cm)	Weight (g)	Height (cm)	Diameter (cm)	Weight (g)
1	*Fado*	2,6	3,6	26,14	2,4	3,5	25,84
2	*Oasis*	2,2	2,8	16,91	1,9	2,7	16,16
3	*Amsterdam*	2,8	4,1	28,60	2,5	3,9	27,73
LSD p=5.0%		0,28	0,48	2,02	0,33	0,33	1,06

The effect of peeling corms on the dynamics of germination and subsequent phenophases is presented in Table 2. One of the most significant results in the present study is the establishment of an accelerated germination rate in the variants with removed outer scales. In peeled corms, all phenophases occur on average 2-3 days earlier compared to the control. The earliest germinates the variety "*Fado*", followed by the varieties "*Oasis*" and "*Amsterdam*" respectively 25, 27 and 32 days for the control and 21, 25 and 28 days for peeled corms. This effect is due to the elimination of the mechanical barrier of the dry scales and the facilitation of the entry of moisture and oxygen to the corm. The trend is similar for the appearance of the first, third leaf and flowering stem.

Table 2. Phenological observation of different gladiolus varieties (days after sprouting).

Variety		*Fado*	*Oasis*	*Amsterdam*	LSD p=5.0%
Unpeeled	Sprouting*	25	27	32	2,0
	Appearance of First leaf	11	16	9	2,0
	Appearance of Third leaf	22	29	19	2,0
	Appearance of flower stalk	43	48	53	2,75
Peeled	Sprouting*	21	25	28	2,0
	Appearance of First leaf	9	14	7	2,0
	Appearance of Third leaf	21	26	18	2,0
	Appearance of flower stalk	41	46	50	2,0

*Days after planting

The accelerated vegetative start in the peeled variants also reflects directly on the generative development. The flowering start phase in the peeled bulbs is earlier, as can be seen from Table 3. The earliest of the peeled bulbs to start flowering is the '*Fado*' variety at 89 days after germination, followed by the '*Oasis*' variety - 94 days and the '*Amsterdam*' variety - 102 days, while in the unpeeled ones this happens at 91, 95 and 104 days respectively. Since all three tested varieties show a specific varietal reaction, the flowering duration is almost identical in both variants with a difference of only one day. The '*Fado*' variety has the shortest flowering, with the peeled ones lasting 61 days and the unpeeled ones - 62. The '*Oasis*' variety has a flowering duration of 63 and 64 days, respectively for unpeeled and peeled corms. Plants from peeled bulbs of the *Amsterdam* variety bloom the longest - 67 days. In the unpeeled variety, the variety retains its superiority with a flowering duration of 66 days. As a result of the faster start of flowering and the varietal specificity, the end of flowering phase also occurs earlier.

Table 3. Phenological observation of different gladiolus varieties (days after sprouting).

Variety		**Unpeeled**			**Peeled**		
		Begging of flowering	End of flowering	Flowering duration	Begging of flowering	End of flowering	Flowering duration
1	*Fado*	91	153	62	89	150	61
2	*Oasis*	95	158	63	94	158	64
3	*Amsterdam*	104	170	66	102	169	67
LSD p=5.0%		2,0	2,75	3,33	3,16	2,00	4,21

Removing the scales reduces the delay in the initial development of the plants, while at the same time increasing the number of developed dormant buds, and this is evident from Table 4. In all studied varieties, a tendency towards the formation of a larger number of flowering stalks is observed, with the control having average values of 1.2 for the "*Fado*" variety, 1.6 for the "*Oasis*" variety and 2.4 for the "*Amsterdam*" variety, while in the peeled varieties the values

for the varieties are 3.4, 3.6 and 3.9, respectively. In terms of height, diameter and mass of the flower stalk, the reported data show a negligible difference between the control and experimental variants, but we can still summarize that the values for these indicators for the flowering stems that emerged from unpeeled corms are higher than those of the unpeeled ones, with the exception of the "*Oasis*" variety with a stem height of 105.4 cm in the peeled ones and 104.6 in the control.

Table 4. Morphological characteristics of the flower stalk.

Variety		*Fado*	*Oasis*	*Amsterdam*	LSD p=5.0%
Unpeeled	Number of developed flower stalks	1,2	1,6	2,4	0,8
	Heigh of a flower stalk (cm)	97,1	104,6	127,7	1,9
	Diameter of a flower stalk (cm)	2,4	2,2	2,6	0,2
	Weight of a flower stalk (g)	37,8	40,6	46,3	1,74
Peeled	Number of developed flower stalks	3,4	3,6	3,9	1,42
	Heigh of a flower stalk (cm)	96,5	105,4	127,3	2,65
	Diameter of a flower stalk (cm)	2,3	2,1	2,5	0,2
	Weight of a flower stalk (g)	37,4	40,1	45,9	1,59

The data in Table 5 indicate that the removal of the scales has a strong stimulating effect on the number of leaves. In peeled bulbs, a greater number of leaves per plant is recorded compared to unpeeled ones, approximately three times more. In plants from the experimental variant of the "*Fado*" variety, their number is 24.8, unlike the control - only 8.3 pcs. In the "*Oasis*" variety, the readings are similar, and in the "*Amsterdam*" variety, the values are the highest - 11.3 pcs for the control and 33.6 pcs for the tested variant. A direct relationship is noted with the number of flower stalks formed. At the expense of the number of leaves, all other studied indicators, namely leaf area, length, width, fresh and dry mass, show smaller values in the variant with peeled corms, but the differences are insignificant.

Table 5. Morphological characteristics of the leaves.

Variety		*Fado*	*Oasis*	*Amsterdam*	LSD p=5.0%
Unpeeled	Number of leaves	8,3	9,0	11,3	1,44
	Weight of a leaf (g)	13,4	9,1	11,6	1,41
	Leaf area (cm^2)	210,1	112,6	157,3	1,9
	Leaf dry mass (g)	2,6	1,3	1,9	0,49
	Length of a leaf (cm)	76,5	60,2	68,5	9,15
	Width of a leaf (cm)	3,5	2,6	3,2	1,04
Peeled	Number of leaves	24,8	27,2	33,6	7,08
	Weight of a leaf (g)	13,2	7,7	9,8	0,86
	Leaf area (cm^2)	208,3	108,8	149,2	1,95

	Leaf dry mass (g)	2,4	1,1	1,5	0,54
	Length of a leaf (cm)	75,1	60,6	67,6	9,26
	Width of a leaf (cm)	3,4	2,3	2,9	1,12

The number of developed flowers in the spike inflorescence has been shown to decrease in plants grown from peeled bulbs. As can be seen in Table 6, in the control they are 12.3 pcs, 11.1 pcs and 16.2 pcs respectively for the varieties "*Fado*", "*Oasis*" and "*Amsterdam*", and in the experimental variant they are 11.8 pcs, 10.4 pcs and 14.6 pcs respectively. The length, diameter and mass of the single flower are affected in the same way. In the "*Fado*" variety, the length of the flower is 9.5 cm in the control variant and only 9.1 cm for the experimental variant. Similar data were recorded for the "*Oasis*" variety - the length is 10.2 cm in the control and only 9.8 cm in the experimental variant. The largest difference was recorded for the "*Amsterdam*" variety, where the data are 9.6 cm and 8.8 cm respectively. The data are similar for the other indicators.

Table 6. Morphological characteristics of the flowers.

Variety		*Fado*	*Oasis*	*Amsterdam*	LSD p=5.0%
Unpeeled	Number of flowers	12,3	11,1	16,2	0,82
	Length of a flower (cm)	9,5	10,2	9,6	0,86
	Diameter of a flower (cm)	10,1	11,4	10,7	0,85
	Weight of a flower (g)	7,4	6,1	6,8	0,86
Peeled	Number of flowers	11,8	10,4	14,6	0,79
	Length of a flower (cm)	9,1	9,8	8,8	0,63
	Diameter of a flower (cm)	9,7	11,1	9,9	1,52
	Weight of a flower (g)	7,1	5,7	6,2	1,03

CONCLUSIONS

Based on the three-year study conducted on the influence of pre-sowing removal of the covering scales in the gladiolus varieties "*Fado*", "*Oasis*" and "*Amsterdam*", the following important conclusions can be made:

1. Mechanical peeling of corms immediately before planting eliminates the protective barrier of dry scales, thus shortening the germination time and accelerating the entry into the various phenophases.

2. Removal of the scales stimulates the development of more dormant buds, which leads to a powerful increase in the total number of flowering stalks and in direct correlation with the increased number of leaves.

3. As a result of removing the outer scales of the corm, the total productivity increases at the expense of the single flower. Redistributed energy leads to a higher total number of flowers per plant, but is reflected in a slight, statistically insignificant decrease in the dimensions (length, diameter and mass) of the single leaves and flowers.

4. The three studied varieties respond specifically to the applied manipulation. The variety "*Amsterdam*" retains the highest absolute values in terms of total vegetative and generative biomass, while the variety "*Fado*" emerges as the earliest flowering variety with the highest decorative value.

ABSTRACT

The occurrence of mycotoxins in rye, barley, and wheat bran in Albania was investigated. Twenty-four mycotoxins—including aflatoxins (B1, B2, G1, and G2), deoxynivalenol (DON), 15-acetyl DON, 3-acetyl DON, mycophenolic acid, penicillic acid, zearalenone (ZEA), fumonisins (FB1, FB2), ochratoxin A (OTA), roquefortine C, HT-2, T-2, gliotoxin, neosolaniol, cyclopiazonic acid, diacetoxyscirpenol (DAS), tenuazonic acid, tentoxin, alternariol, and alternariol methyl ether—were analyzed using liquid chromatography-tandem mass spectrometry. Samples were collected from feed-producing facilities. At least one mycotoxin was detected in 75.0% of analyzed samples (9/12), with barley exhibiting the highest incidence (71.4%), followed by rye and wheat bran. Toxins produced by the Alternaria genus were most prevalent, while Fusarium toxins were less common; only DON was identified in one sample. Alternaria toxins—tenuazonic acid (75.0%), tentoxin (22.5%), alternariol (8.33%), and alternariol methyl ether (8.33%)—were the most abundant among analyzed mycotoxins. Deoxynivalenol (DON) was the only Fusarium toxins detected in wheat bran (33.3%), while mycotoxins from the genera Aspergillus and Penicillium were not detected. The occurrence of mycotoxins in feed ingredients was lower than previously reported for maize grown in Albania, with concentrations remaining below maximum levels where applicable. However, the presence of Alternaria toxins highlights the necessity for enhanced monitoring of raw materials, and preventive measures throughout the cereal supply chain.

Keywords: feed, rye, barley, wheat bran, mycotoxins, aflatoxin, deoxynivalenol, fumonisins, LC-MS/MS, Albania

INTRODUCTION

Mycotoxins are low-molecular-weight secondary metabolites produced by filamentous fungi (Costa et al., 2019; Gurikar *et al*., 2023). Fungal spoilage of agricultural commodities can contaminate food and feed (Stroka and Gonçalves, 2019). The main producing fungal genera

are Aspergillus, Penicillium, Fusarium, and Alternaria (Pinton et al., 2025), which grow in the field and during storage under inappropriate conditions (Kępińska-Pacelik & Biel, 2021).

Mycotoxin contamination is a global threat and will become more significant due to climate change and the globalization of the food and feed market (Altomare, Logrieco, Gallo, 2021). All over the world, more than 1000 mycotoxins have been identified, yet less than 20 are regulated (Pinton et al., 2025). Market globalization of agricultural commodities has increased awareness of mycotoxin contamination, with AFs being most distinguished for their public health implications and agro-economic significance (Altomare, Logrieco, Gallo, 2021).

European Commission has established maximum levels (ML) in food (European Commission, 2023; European Commission, 2024), where, for unprocessed cereals intended for human consumption or as an ingredient in foodstuffs other than maize, the ML is 2 µg/kg for AFB1 and 4 µg/kg for the sum of AFs, while in maize the ML is 5.0 µg/kg for AFB1 and 10.0 µg/kg for the sum of AFs. The ML of AFB1 is 0.02 mg/kg in feed, 0.01 mg/kg in complementary and complete feed, except feed for dairy animals, piglets and young poultry animals where ML is 0.005 mg/kg (European Commission, 2011).

Tabela 1. EU Maximum Levels in feed materials for main mycotoxins

Mycotoxin	Feed material (mg/kg)	Compound feed	Notes
Aflatoxin B1	0.02	(Cereal, oilseed, maize)	Strictet for dairy animals (carry over into milk)
Deoynivaleno (DON)	8-12	Cereal, maize, soybeans	Horses highly sensitive
Zearalenone	2-3	Maize, cereals	Pigs most sensitive
Ochratoxin A	0.25	Cereals, cereal products	Cats extremely sensitive
Fumonisins (B1 and B2)	60	Maize, maize products	Horses most sensitive
T-2 and HT-2- toxin	0.25-0.5	Cereals, cereal products	Cats excluded due to extreme sensitivity

Aflatoxins (AFs) are produced mainly by *A. flavus* and *A. parasiticus* (Cary et al., 2018; El-Sayed et al., 2022). The growth of aflatoxigenic-producing fungi depends on crop and soil types, as well as climate conditions (Sudan et al., 2026). Aflatoxin contamination of cereals is associated with poor storage conditions and field contamination. Post-harvest spoilage may occur due to inappropriate moisture content and storage temperatures. Natural aflatoxins include aflatoxin B1 (AFB1), aflatoxin B2 (AFB2), aflatoxin G1 (AFG1), aflatoxin G2 (AFG2) (CAST, 2003). AF contamination of foods and feedstuffs is global, but groundnuts, maize, and cottonseeds are reported to be at higher risk of contamination and, consequently, a major source of exposure (Akpoghelie et al., 2025).

Fusarium species are among the most well-known toxigenic fungi, particularly in temperate regions, and can cause severe reductions in crop yield through various plant diseases (Munkvold

et al., 2019). The most distinguished Fusarium mycotoxins are zearalenone (ZEA), fumonisins (FBs), T-2 toxin, HT-2 toxin, neosolaniol (NEO), diacetoxyscirpenol (DAS), deoxynivalenol (DON), and its 3-acetyl (3-AcDON) and 15-acetyl (15-AcDON) derivatives (Leite et al., 2021; El-Sayed et al., 2022).

Alternaria toxins naturally occur on food and feed that are contaminated with Alternaria species, and alternariol, alternariol monomethyl ether, tenuazonic acid, altertoxins, and tentoxin are the most present. Some of these mycotoxins are carcinogenic, toxic, and mutagenic. The limited evidence on toxigenic effects has dictated no established maximum levels for this group of mycotoxins (Nagda & Meena, 2024).

The fate of different mycotoxins during cereal treatment processes, such as sorting, cleaning, debranning, and thermal processing, can significantly reduce mycotoxin concentrations (Bullerman and Bianchini, 2007). In contrast, milling processes result in repartitioning of mycotoxins in different milling fractions (Tibola et al., 2015).

Exposure to these compounds is a major threat to human and animal health and is associated with different acute or chronic mycotoxicoses (Awuchi et al., 2022).

Mycotoxin occurrence in barley and rye

Among cereals, maize and wheat are the most important in terms of production quantity and are consequently the most studied for mycotoxin contamination. Occurrence of aflatoxins in barley was mainly reported from Europe and the Mediterranean region (Binder et al., 2007), Spain (Ibanez-Vea et al., 2012), Serbia (Kos et al., 2014) and Slovenia (Babič et al., 2021), occurrence of aflatoxins in rye was reported from Europe during the period 2007–2012 (EFSA, 2013), Serbia (Kos et al., 2014) and Poland (Kosicki et al., 2020)

This study aimed to provide insight into the presence of twenty-four mycotoxins produced by four fungal genera: Alternaria (tenuazonic acid, tentoxin, alternariol, alternariol methyl ether), Fusarium (DON, 3-acetyl-DON, 15-acetyl-DON, ZEA, FB1, FB2, T-2, HT-2, DAS, and NEO), Aspergillus (aflatoxins B1, B2, G1, and G2), and Penicillium (mycophenolic acid, cyclopiazonic acid, roquefortine C) in two main cereal commodities produced in Albania, maize and wheat, both used as food and feed. This study represents the first report on the presence of these mycotoxins in crop commodities from Albania.

MATERIALS AND METHODS

Sample characterization

Barley, rye, and wheat bran were sampled from local feed distributors in Albania. The sampling procedure was carried out in accordance with Commission Regulation (EC) No 401/2006 (European Commission, 2006) on sample collection.

Standards and Chemicals

Single standards of ZEA, FB1 and FB2 (Romer Labs, Tulln, Austria) mixed with trichothecene standard solution in acetonitrile (DON, 3-AcDON, 15-AcDON, T-2, HT-2, DAS and NEO) produced by Trilogy (Washington, MO, USA); both stock standard solutions and the mixed working standard solutions were prepared in acetonitrile and stored in amber glass vials at –20°C. Aflatoxin standards (AFB1, AFB2, AFG1 and AFG2) were purchased from Romer (Union, MO, USA). Stock standard solutions were prepared in acetonitrile, and the mixed working standard solution was prepared with acetonitrile, methanol, acetic acid (Sigma-Aldrich, Steinheim, Germany), and ammonium acetate (Merck, Darmstadt, Germany), all of p.a. or LC-MS grade purity. Deionized water was prepared using a Milli-Q system (Millipore, Bedford, MA, USA).

Deionized water was prepared using a Milli-Q system (Millipore, Bedford, MA, USA). The extraction solution was a mixture of acetonitrile and deionized water in an 84:16 (v/v) ratio. For the final sample solution, a mixture of deionized water and methanol in an 80:20 (v/v) ratio was used. Mobile phase components A and B were deionized water and methanol, both containing 0.2 g of ammonium acetate and 5 mL of acetic acid per liter.

Aflatoxin extraction

For simultaneous determination of aflatoxins (AFB1, AFB2, AFG1 and AFG2), a procedure consisting of the extraction of mycotoxins from ground cereal samples with the acetonitrile-deionized water mixture and liquid chromatography-tandem mass spectrometry (LC-MS/MS) was used. Sample preparation and mycotoxin determination were performed according to analytical procedures described elsewhere (Driehuis, Spanjer, Scholten, & Te Geffel, 2008; Lattanzio, Della Gatta, Suman, & Visconti, 2011; Rasmussen, Storm, Rasmussen, Smedsgaard, & Nielsen, 2010). 10 g of a sample was shaken with 100 mL of an acetonitrile-deionized water mixture (84+16) for 1 hour using a linear shaker IKA HS 501 digital (IKA Labortechnik, Staufen, Germany). 4 mL of the filtered extract was evaporated under vacuum to dryness using the system Syncore Polyvap (Büchi, Flawil, Switzerland). The dry residue was reconstituted with 0.5 mL of a methanol-deionized water mixture (80+20). 10 µl of the solution was injected into the LC-MS/MS system (Acquity UPLC H Class system coupled with a triple-quadrupole instrument, Waters).

Fusarium and Alternaria toxins extraction procedure

For the simultaneous determination of mycotoxins (DON, 3-AcDON, 15-AcDON, ZEA, FB1, FB2, T-2, HT-2, DAS, and NEO), a procedure described in detail by Topi et al. (60) was applied. The procedure consisted of extracting mycotoxins from ground cereal samples and determining them by LC-MS/MS. Specific MS/MS parameters related to the determined mycotoxins (retention times, ionization mode, and monitored transitions) are given in Table 7.

Table 1. Retention times of Fusarium toxins, ionization mode, and monitored transitions.

Analyte	Ionization mode	Retention time (min)	Precursor ion (m/z)	Quantifier ion (m/z)	Qualifier ion (m/z)

DON	ESI+	3.14	297.3	203.1	249.1
3-AcDON	ESI+	5.00	339.1	203.1	137.0
15-AcDON	ESI+	5.00	339.1	136.9	261.1
DAS	ESI+	7.06	384.3	307.2	247.2
HT-2	ESI+	8.91	442.4	215.1	263.2
T-2	ESI+	10.27	484.4	185.1	215.2
ZEA	ESI-	11.30	317.2	131.0	174.9
FB1	ESI+	10.20	722.4	334.2	352.2
FB2	ESI+	12.70	706.4	318.2	336.2

LC-MS/MS analysis

The chromatographic separation was performed on a Zorbax Eclipse Plus C18 Rapid Resolution HD column (2.1 x 100 mm, 1.8 µm; Agilent). The mobile phase consisted of two components mixed in gradient mode. Component A consisted of deionized water (995 ml), acetic acid (5 ml), and ammonium acetate (0.2 g), and component B consisted of methanol (995 ml), acetic acid (5 ml), and ammonium acetate (0.2 g). The initial eluent composition was 95% A and 5% B. The proportion of component B was linearly increased to 40% within 4 min and further to 70% within the next 8 min. The composition was held for 4 min, and then component B was increased to 90% in 1.5 min. The proportion of component B was held at 90% for 2.5 min, then returned to 5% over 1 min. The composition was held for 4 min. The mobile phase flow rate was 300 µL/min, and the chromatography column temperature was 40 °C. MS/MS analysis was carried out using electrospray ionization (ESI), and the triple-quadrupole mass spectrometer was operated in multiple reaction monitoring (MRM) mode. The capillary voltage was 3,4 kV, desolvation temperature 500 ºC, ion source temperature 150 ºC, and collision cell voltage 20 V. Other LC-MS/MS parameters as well as the limits of detection (LOD), limits of quantification (LOQ), and recoveries obtained within the validation process for single mycotoxins are given in Table 2. The Limit of detection (LOD) of single analytes was determined based on the signal-to-noise ratio of 3:1. As LOQ, a value of 2.5 times LOD was selected. LOD and LOQ were 0.20 µg/kg and 0.40 µg/kg, respectively, for every single aflatoxin.

Table 2. Retention times, the m/z precursor ion, the m/z monitored product ions, LOD, LOQ, and the recovery of aflatoxins (AFB1, AFB2, AFG1 and AFG2).

Analyte	Retention time (min)	Precursor ion (m/z)	Quantifier ion (m/z)	Qualifier ion (m/z)	LOD (µg/kg)	LOQ (µg/kg)

AFB1	5.25	313.2	213.2	241.1	0.6	2.0
AFB2	4.75	215.2	243.2	259.1	0.6	2.0
AFG1	2.92	329.1	214.8	199.9	0.6	2.0
AFG2	5.33	331.1	189.0	285.1	0.6	2.0

Method Validation

The Limit of detection (LOD) of single analytes was determined at a signal-to-noise ratio of 3:1. A value 3.3 times the LOD was selected as the Limit of quantification (LOQ). The recoveries and precision were tested using maize and wheat samples spiked with *Fusarium* toxins at the concentration levels of 50, 100 and 500 µg/kg.

The linearity of the method was tested in the concentration range 50–500 µg/kg using matrix-matched standard solutions analyzed in triplicate. Good linearity was demonstrated for all analytes, with correlation coefficients exceeding 0.997. The accepted LOD and LOQ for all single Fusarium toxins were 15 (g/kg) and 50 (g/kg), respectively. The mean recoveries of single toxins in maize at the tested concentration levels ranged from 90% to 117%. In wheat, recoveries ranged from 87% to 112%, except for DON, which was 124%. The reproducibility expressed as RSD_R was less than 16% for all *Fusarium* toxins in maize and ≤30% for all *Fusarium* toxins in wheat. The reproducibility and mean recoveries of the toxins were in line with the criteria set out in Commission Regulation (EC) No 401/2006 and its amendments, except for DON, which slightly exceeded the required value.

RESULTS AND DISCUSSIONS

Contamination of barley and rye

In the investigated barley samples, no aflatoxin contamination was detected (Table 3). Aflatoxin G2 was detected in one barley sample. Aflatoxin occurrence in barley has been reported mainly in European countries (Kow et al., 2025). AFB1 in barley from the Czech Republic was reported in 87% of samples, with mean and maximum values of 2.1 and 4.0 µg/kg, respectively (Sedmikova *et al*., 2001). The AFB1 incidence in barley samples from northern regions of Spain during 2007-2008 was found in 100%, and the mean value was 0.11 µg/kg, while the mean value of the sum of AFs was 0.12 µg/kg (Ibanez-Vea *et al*., 2012). In conclusion, our findings on AFB1 contamination are in accord with reports from Europe and the Mediterranean region (Pleadin *et al*., 2024).

Table 3: Occurrence of mycotoxin contamination in rye and barley samples

	Parameter	**Sum of AFs**	**AFB1**	**AFB2**	**AFG1**	**AFG2**
Barley	No. positive/Total samples	0/5	0/5	0/5	0/5	0/5

Rye	No. positive/Total samples	1/2	0/2	0/2	0/2	1/2
Rye	% of positive samples	50.0	0.0	0.0	0.0	50.0
Rye	Min-Max (□g/kg)	0.61	n.d	n.d	n.d	0.61
Rye	No. samples above 2 □g/kg		0			
Rye	No. samples above 4 □g/kg	0				

N.B. Results expressed for 12% moisture content.

Occurrence of aflatoxin G2 in one barley sample with an uncommon presence of 0.61 μg/kg. This situation was similar to that of wheat samples from the same region of Korça. Rye is cultivated and used in modest amounts in Albania compared to other cereal grains. Data on AFB1 Occurrence reported in rye samples come mainly from Europe. In the EFSA report, during the period 2007–2012 was not found AF contamination in a total of 57 analyzed samples (EFSA, 2013). Occurrence of aflatoxins in rye from the region indicates that they were not found in rye samples from Serbia (Kos *et al*., 2014), while they were found at elevated levels (4.56 μg/kg) in samples from Romania (Gagiu *et al*., 2018).

Results indicate the presence of four Alternaria toxins in barley samples: tenuazonic acid, tentoxin, alternariol and alternariol methyl ether, while in rye and wheat bran two toxins were detected: tenuazonic acid and tentoxin. The most prevalent was tenuazonic acid, with an incidence of 71.4% and a maximum value of 0.22 mg/kg.

The highest incidence (100%) was observed in wheat bran, while occurrence was the second-most-contaminated feed commodity, with a maximum of 0.088 mg/kg.

The rye commodity presented an incidence of 50%, and a maximum occurrence of 0.022 mg/kg. Based on the dataset for the Occurrence of Alternaria toxins in barley, rye, and wheat bran feed commodities, both the variability of contamination and the potential risk to animal exposure are evident.

Barley crop showed the highest contamination frequency, with 71.4% of samples positive for tenuazonic acid (TeA) and the same proportion positive for the sum of Alternaria toxins. The mean TeA concentration (0.1458 mg/kg) was notably higher than in rye and wheat bran, with values ranging from 0.0832 to 0.227 mg/kg. Tentoxin, alternariol, and alternariol methyl ether were each detected in only one sample (14.3%), but their presence indicates a broader spectrum of Alternaria metabolites. The relatively high median values suggest that barley is a significant contributor to Alternaria toxin exposure in feed.

Rye crop exhibited lower contamination levels, with only 50% of samples positive for TeA and tentoxin, and no alternariol or alternariol methyl ether detected. Concentrations were minimal (mean TeA 0.022 mg/kg; tentoxin 0.006 mg/kg), reflecting limited fungal activity or effective post-harvest handling. The absence of alternariol derivatives may indicate either lower fungal colonization or differences in substrate susceptibility compared to barley and wheat bran.

Wheat bran resulted contaminated with TeA, with all samples positive (100%). The mean concentration (0.061 mg/kg) was lower than in barley but higher than in rye. Tentoxin was detected in two-thirds of samples (66.7%), though alternariol and its methyl ether were absent.

The average sum of Alternaria toxins was 0.0693 mg/kg, with a maximum of 0.092 mg/kg. This suggests that wheat bran is a consistent carrier of TeA, possibly due to its high nutrient content and surface area that favor fungal growth.

Comparative Insights

Tenuazonic acid was the most prevalent toxin across all commodities, confirming its dominance among Alternaria metabolites in feed.

Barley seed showed the broadest toxin profile, with occasional detection of alternariol and alternariol methyl ether, while wheat bran was consistently contaminated but with a narrower spectrum. Rye appeared least affected, both in frequency and concentration, suggesting species-specific resistance or lower fungal colonization.

Implications

The findings emphasize the need for routine monitoring of Alternaria toxins in feed, particularly in barley and wheat bran, which demonstrated higher contamination rates. Although concentrations were relatively low compared to regulated mycotoxins (e.g., aflatoxins, DON), the co-occurrence of multiple Alternaria metabolites raises concerns about additive or synergistic toxic effects (Lin, Jia, Wu, 2023). Given the absence of EU maximum levels for Alternaria toxins in feed, these results contribute valuable baseline data for risk assessment and may support future regulatory considerations.

Table 4. Alternaria toxin occurrence in barley and rye grain.

The Occurrence of Fusarium toxins and other metabolites produced by Aspergillus and Penicillium species was also investigated in the analyzed feed samples. Target compounds included DON, 15-acetyl-DON, 3-acetyl-DON, mycophenolic acid, penicillic acid, zearalenone (ZEA), fumonisins (FB1, FB2), ochratoxin A (OTA), roquefortine C, HT-2, T-2, gliotoxin, neosolaniol, cyclopiazonic acid, and diacetoxyscirpenol (DAS). Among all these toxins, contamination was evidenced only in a single sample for DON, while the remaining analytes were not detected. This finding is in accordande with previous publication on mycotoxin occurrence (Topi et al., 2023).

CONCLUSİONS

This study provides new insights into the occurrence of twenty-four mycotoxins, analyzed by liquid chromatography coupled with tandem mass spectrometry, in selected feed commodities (barley, rye, and wheat bran) cultivated and used in Albania.

Alternaria toxins revealed the highest incidence, with tenuazonic acid (TeA) as the most prevalent metabolite, detected in all wheat bran samples and in the majority of barley samples, while rye showed lower contamination levels. These findings confirm that TeA is the dominant Alternaria toxin in feed, with barley and wheat bran representing consistent sources of contamination.

No aflatoxin B1 contamination was detected in the barley samples analyzed, although aflatoxin G2 was found in one barley sample at 0.61 μg/kg. This uncommon occurrence is consistent with sporadic findings reported in wheat from the same region. Rye samples analyzed in this study did not show aflatoxin contamination, in agreement with international reports.
Screening for Fusarium toxins (DON, 15-acetyl-DON, 3-acetyl-DON, zearalenone, fumonisins FB1 and FB2, HT-2, T-2) and for metabolites of Aspergillus and Penicillium (ochratoxin A, mycophenolic acid, penicillic acid, roquefortine C, gliotoxin, cyclopiazonic acid, diacetoxyscirpenol, neosolaniol) revealed contamination only in a single sample for DON. The low incidence of these regulated mycotoxins indicates that, under the conditions studied, Alternaria toxins are the primary concern for contamination.
Overall, the results highlight the importance of monitoring non-regulated mycotoxins such as Alternaria metabolites, which were consistently present in barley and wheat bran. Although aflatoxin contamination was limited in this dataset, its occurrence in barley confirms the need for vigilance, given the established risk in European contexts. The absence of significant Fusarium and Aspergillus toxins suggests that contamination pressure in the studied region is currently low. Nevertheless, continued surveillance is essential to ensure feed safety and to support future regulatory considerations for Alternaria toxins.

ABSTRACT

For many years, archaea were categorized alongside bacteria due to their structural similarities. However, the work of Carl R. Woese in the 1970s revealed their distinct molecular structures, establishing these organisms as one of the three domains of life (Bacteria, Archaea, and Eukaryota). While metabolic pathways are generally well-conserved in other domains, archaea have been found to possess variant pathways containing various novel enzymes with a different control mechanism. This difference, in particular, involves specific biochemical mechanisms involving deviations from central carbohydrate metabolism, classical glycolysis, and pentose phosphate pathways. Central carbohydrate metabolism is fundamental to energy production and biosynthetic activities in living organisms. Currently, research on glycolytic enzymes from various phylogenetic lineages has revealed a structure composed of canonical and novel enzymes in archaeal variants of the Embden-Meyerhof-Parnas (EMP) and Entner-Doudoroff (ED) pathways. These differences are known to be pronounced in species resistant to extreme conditions such as high temperatures, high salinity, extreme pH, and high pressure. Archaeal metabolic systems include kinases that utilize ADP instead of ATP, ferredoxin-dependent oxidoreductases, and phosphorylation-independent energy conversion mechanisms. These characteristics have demonstrated that archaeal enzymes hold significant potential for biotechnological applications. Furthermore, due to their high resilience, archaea are used as fundamental model organisms in astrobiology research. From a broad perspective, this study addresses the discovery process of archaea, their resistance mechanisms to extreme conditions, fundamental biochemical differences in central carbohydrate metabolism derived from molecular and genetic data, as well as the structure, function, enzymatic constituents, and regulation of archaeal glycolytic pathways. Additionally, current biotechnological application fields and their potential roles in space research are evaluated.

Keywords: Archaea, Carbohydrate metabolism, Embden-Meyerhof-Parnas pathway, Entner-Doudoroff pathway, ADP-dependent kinases.

INTRODUCTION

Until the last quarter of the 20th century, the phylogenetic and evolutionary classification of life was fundamentally understood within the framework of the prokaryote-eukaryote dichotomy. Due to their similar microscopic morphological characteristics and cellular dimensions, archaea were classified alongside prokaryotes/bacteria for many years. However, in the late 1970s, small subunit ribosomal RNA (16S/18S rRNA) sequence analyses conducted by Carl R. Woese and George E. Fox revealed that these organisms are distinct from both bacteria and eukaryotes at the molecular level. Today, building upon this evolutionary discovery, Woese et al. redefined the cellular organization of life, definitively demonstrating that living organisms consist of three primary domains at the cellular level: Bacteria, Archaea, and Eukaryota (Woese and Fox, 1977; Woese et al., 1990). While fundamental metabolic pathways and cellular processes are known to be highly conserved phylogenetically in bacteria and eukaryotes, archaea stand out due to the unique metabolic strategies they have developed throughout evolutionary history. In archaea, variant metabolic pathways containing numerous novel enzymes with distinct catalytic regulatory mechanisms have been identified. These unique differences become particularly pronounced in central carbohydrate metabolism, which is critically important for basic cellular energy production. Archaea possess specific biochemical mechanisms involving alternative intermediates and distinct enzymatic catalysts that show marked deviations from classical glycolysis and pentose phosphate pathways. Advancing technologies and recent research focusing on the glycolytic enzymes of phylogenetic lineages have unveiled a complex network composed of both canonical and non-canonical enzymes within the archaeal variants of the classical Embden-Meyerhof-Parnas (EMP) and Entner-Doudoroff (ED) pathways. It has become clear that these metabolic innovations are especially prominent in extremophilic species adapted to harsh environmental conditions that push the boundaries of life, such as extreme temperature (hyperthermophilia), high salinity (extreme halophilia), extreme pH values (extreme acidophilia/alkaliphilia), and high hydrostatic pressure (piezophilia). From a biochemical perspective, archaeal metabolic systems diverge significantly from conventional phosphorylation processes. For instance, specific kinases that utilize ADP instead of ATP in glycolytic steps, the use of ferredoxin-dependent oxidoreductases as reducing equivalents instead of NAD(P)+, and energy conversion mechanisms that bypass phosphorylation steps constitute key characteristic features of this group. These adaptations in archaea indicate a high potential for biotechnological, industrial, and pharmaceutical applications, owing to the resilience of archaeal enzymes under harsh industrial conditions. Furthermore, the robust resistance mechanisms exhibited by archaea in the Earth's most challenging ecosystems have made them essential model organisms in astrobiological research aimed at searching for life in extraterrestrial environments.

Although archaea were initially confused with bacteria due to their morphologically anucleate and organelle-lacking structures, they exhibit a profile close to eukaryotes in terms of genetic information processing mechanisms, while completely diverging from both groups in their unique membrane lipid chemistry (Woese et al., 1990; Siebers and Schönheit, 2005). While bacterial and eukaryotic membranes contain straight-chain fatty acids linked to a glycerol-3-phosphate (G3P) backbone via ester bonds, archaeal membranes feature isoprenoid (diphytanyl or phytanyl) chains attached to a glycerol-1-phosphate (G1P) backbone via ether linkages. These ether bonds and isoprenoid rings enable the cell membranes of hyperthermophilic archaea to maintain structural integrity and prevent proton leakage even under extreme temperature and extreme pH conditions (Koga and Morii, 2007). Furthermore, peptidoglycan (murein), the key structural component of the bacterial cell wall, is absent in archaea; instead, structures such as pseudomurein, S-layers (proteinaceous surface layers), or heteropolysaccharides are present.

From a metabolic perspective, archaea possess an exceptionally broad spectrum of life strategies, including chemosynthesis, fermentation, autotrophy, and heterotrophy. They constitute the dominant life forms in the most challenging ecosystems of the biosphere (Sato and Atomi, 2011). However, molecular ecology and metagenomic studies have proven that archaea are not restricted to extreme environments; they are also widespread in ocean surface waters, temperate soils, and even within the human microbiota (DeLong, 1992).

It was previously assumed that central carbohydrate metabolism, which is responsible for cellular energy production and the synthesis of structural building blocks in other domains of life, was strictly conserved throughout evolutionary history. However, biochemical and genomic investigations in archaea have demonstrated that these canonical pathways harbor numerous unusual modifications and entirely novel enzyme families (Verhees et al., 2003; Bräsen et al., 2014).

Molecular And Bıochemıcal Features Unıque To Archaea

To understand archaeal metabolism, it is essential to first comprehend the primary phylogenetic groups constituting this domain and their molecular adaptations. Currently, based on phylogenomic analyses and genomic data, archaea are classified within Euryarchaeota, the TACK supergroup (Thaumarchaeota, Aigarchaeota, Crenarchaeota, Korarchaeota), the Asgard supergroup (such as Lokiarchaeota) branching from TACK, and the cellularly/genomically reduced DPANN supergroup.

The majority of biochemical and metabolic studies have focused on the two initially discovered primary phyla, Euryarchaeota and Crenarchaeota. Euryarchaeota represents a metabolically highly heterogeneous group that encompasses extreme halophiles, methanogens, and certain hyperthermophiles. Species within this group frequently utilize modified mEMP and modified mED pathways for glucose catabolism, distinct from classical routes, and possess enzymatic mechanisms such as ADP-dependent glucokinase/phosphofructokinase or non-phosphorylating GAPDH. Crenarchaeota, on the other hand, predominantly consists of hyperthermophilic and acidophilic species; these organisms possess energy and carbon metabolisms adapted to harsh thermophilic conditions, such as sulfur oxidation/reduction or branched ED pathways. On the other hand, the discovery of novel phyla, particularly those included within the TACK and Asgard supergroups, has demonstrated that archaeal metabolism is not solely restricted to adaptation to extreme conditions. Eukaryotic Signature Proteins (ESPs), which form the foundation of eukaryotic cellular complexity, membrane remodeling, and vesicular mechanisms, have been identified within the genomes of these archaea. This finding proves that the ancestral molecular systems governing intracellular trafficking and organellar dynamics originally emerged in archaea (Spang et al., 2015).

From the perspective of biochemical adaptations, hydrophobic core packing, salt bridges, disulfide bonds, and oligomeric complexations, which confer protein stability in archaea exposed to extreme temperatures and pressures, are particularly noteworthy. To prevent intracellular metabolites from undergoing thermal degradation at elevated temperatures, such as the isomerization and degradation of triose-phosphates or 1,3-bisphosphoglycerate, archaea have evolved alternative pathway adaptations that bypass canonical glycolytic steps or incorporate high-affinity, stable enzymes (Verhees et al., 2003).

CENTRAL CARBOHYDRATE METABOLISM AND GLYCOLYTIC DEVIATIONS

The classical glycolytic pathway (EMP) serves as the fundamental catabolic route conserved across all bacterial and eukaryotic systems, generating a net yield of 2 moles of ATP and 2 moles of NADH during the conversion of 1 mole of glucose into 2 moles of pyruvate. In the canonical EMP pathway, hexoses are phosphorylated by hexokinase (HK) or glucokinase

(GLK), converted to fructose-6-phosphate (F6P) by phosphoglucose isomerase (PGI), and subsequently transformed into fructose-1,6-bisphosphate (F1,6BP) through phosphofructokinase (PFK). F1,6BP is then cleaved into dihydroxyacetone phosphate (DHAP) and glyceraldehyde-3-phosphate (GAP) by fructose-1,6-bisphosphate aldolase (FBPA) (Nelson and Cox, 2000). In archaea, however, this process follows biocatalytic steps that diverge markedly from classical paradigms (Verhees et al., 2003; Bräsen et al., 2014).

Modified Embden-Meyerhof-Parnas (EMP) Pathway

Glucose catabolism proceeds through a modified EMP pathway in model organisms, particularly the anaerobic hyperthermophilic euryarchaeota *Pyrococcus furiosus* and *Thermococcus kodakarensis*, alongside the microaerophilic crenarchaeote *Thermoproteus tenax* (Selig et al., 1997; Siebers and Schönheit, 2005; Verhees et al., 2003). The principal points of divergence in this modified pathway comprise the following steps:

Glucose Phosphorylation: ADP-Dependent Glucokinases and ROK Hexokinases

While classical glycolysis consumes ATP to phosphorylate glucose, most hyperthermophilic archaea utilize ADP-dependent glucokinase (ADP-GLK) as the phosphate donor instead of ATP. First identified in *Pyrococcus furiosus*, the ADP-GLK enzyme converts glucose into glucose-6-phosphate (G6P) while releasing AMP (Kengen et al., 1995).

ADP-GLK enzymes belong to the ribokinase superfamily. Crystal structure analyses revealed that these enzymes share no sequence or fold homology with ATP-dependent hexokinases (Ito et al., 2001). This preference for ADP allows glycolytic flux to continue uninterrupted even under severe stress conditions where the intracellular ATP/ADP ratio declines. Conversely, glucose phosphorylation remains ATP-dependent in crenarchaeal species such as *Aeropyrum pernix* and *Thermoproteus tenax*, though the reaction is catalyzed by broad-substrate-specificity hexokinases belonging to the ROK family (Hansen et al., 2002).

Isomerization and Phosphofructokinase Deviations (ADP-PFK, PP_i-PFK)

Beyond the classical bacterial and eukaryotic PGI enzymes, two novel isomerase classes involved in the conversion of G6P to F6P have been identified in archaea: bifunctional PGI/PMI (which also exhibits phosphomannose isomerase activity) and cupin-type PGI (cPGI), a metalloenzyme structure (Hansen et al., 2002; Hansen et al., 2005). The active center of cPGI enzymes contains Fe^{2+} or Ni^{2+} ions and displays no sequence similarity to classical PGIs.

The key regulatory step of glycolysis, the conversion of F6P to F1,6BP, proceeds irreversibly via ATP-dependent phosphofructokinase (PFK-A) in canonical systems. In archaea, two principal unconventional alternatives exist:

ADP-Dependent Phosphofructokinase (ADP-PFK): In Pyrococcus and Thermococcus species, F6P phosphorylation is likewise driven by ADP (F6P + ADP → F1,6BP + AMP) (Tuininga et al., 1999). The identification of ADP-PFK and ADP-GLK enzymes confirmed that the preparatory phase of glycolysis in hyperthermophilic Euryarchaeota relies entirely on ADP.

Pyrophosphate-Dependent Phosphofructokinase (PP_i-PFK): In *Thermoproteus tenax*, F6P is phosphorylated using inorganic pyrophosphate (PP_i). This reaction is reversible, functioning bidirectionally in both glycolysis and gluconeogenesis depending on the cellular energy charge (Siebers et al., 1998).

Glyceraldehyde-3-Phosphate Oxidation: Non-Phosphorylating GAPDH (GAPN) and GAPOR

The most radical biochemical deviation within the archaeal EMP pathway occurs during the oxidation of triose phosphates (GAP). In classical glycolysis, GAP is oxidized to 1,3-bisphosphoglycerate (1,3BPG) by GAPDH with the incorporation of inorganic phosphate (P_i), followed by substrate-level phosphorylation (SLP) catalyzed by PGK to generate ATP. In most hyperthermophilic archaea, the 1,3BPG intermediate exhibits extreme thermal instability, possessing a half-life of merely a few seconds at elevated temperatures. Consequently, archaea have evolved two distinct enzymatic mechanisms that completely bypass the formation of 1,3BPG (Bräsen et al., 2014):

-Non-Phosphorylating Glyceraldehyde-3-Phosphate Dehydrogenase (GAPN): Converts GAP directly and irreversibly into 3-phosphoglycerate (3PG). The reaction consumes no P_i and yields no ATP synthesis, instead reducing $NADP^+$ or NAD^+ to form NAD(P)H (Reher et al., 2007).

-GAP:Ferredoxin Oxidoreductase (GAPOR): Present in anaerobic hyperthermophiles such as *Pyrococcus furiosus*, this enzyme contains iron-sulfur (Fe-S) clusters and a tungsten-pterin center, coupling GAP oxidation directly to the reduction of ferredoxin (Fd) (Mukund and Adams, 1995). The operation of GAPN or GAPOR eliminates the 2 moles of ATP typically generated by the classical GAPDH/PGK enzymatic pair. This substitution reduces the net ATP yield of the modified EMP pathway to zero or negative values (Selig et al., 1997).

Modified Entner-Doudoroff (ED) Pathway Variants

In bacteria such as *Pseudomonas* species, the classical ED pathway relies on the oxidation of glucose to gluconate, its subsequent phosphorylation to form 2-keto-3-deoxy-6-phosphogluconate (KDPG), and the cleavage of KDPG into pyruvate and GAP via KDPG aldolase. In archaea, however, the ED pathway diverges into two principal modified variants (Ahmed et al., 2005; Siebers and Schönheit, 2005):

Semi-phosphorylated ED Pathway

Operating in organisms such as *Halobacterium salinarum*, *Haloferax volcanii*, and *Thermoplasma acidophilum*, this route begins with the oxidation of glucose to gluconate by glucose dehydrogenase (GDH), followed by dehydration to 2-keto-3-deoxygluconate (KDG) via gluconate dehydratase (GAD). At this stage, KDG undergoes phosphorylation by ATP-dependent KDG kinase (KDGK) to yield KDPG, which is subsequently cleaved into 1 mole of pyruvate and 1 mole of GAP by KDPG aldolase (KDPGA). The resulting GAP is then processed down to pyruvate through modified EMP pathway enzymes (Reher et al., 2007).

Non-phosphorylated ED Pathway

Identified in extreme thermoacidophilic crenarchaeotes such as *Sulfolobus solfataricus* and *Sulfolobus acidocaldarius*, this pathway involves no phosphorylated intermediates. Following the formation of KDG, KDG aldolase (KDGA) directly cleaves non-phosphorylated KDG into pyruvate and non-phosphorylated glyceraldehyde (GA). GA is subsequently oxidized to glycerate by glyceraldehyde dehydrogenase (DH), phosphorylated to 2-phosphoglycerate (2PG) by glycerate kinase, and ultimately converted to pyruvate via enolase and pyruvate kinase steps (Lamble et al., 2003). The net ATP yield of this non-phosphorylated pathway is zero.

Pentose Metabolism and Pentose Phosphate Pathway Deviations

The classical pentose phosphate pathway (PPP) represents the primary metabolic network supplying ribose-5-phosphate (R5P) for nucleotide synthesis and NADPH for biosynthetic reducing power. In most archaea, however, the oxidative phase of the classical PPP, involving glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, is entirely absent (Bräsen et al., 2014). Instead, archaea rely on reversed non-oxidative PPP steps or unique

alternative pathways, such as hexulose-6-phosphate synthase (HPS) and 3-hexulose-6-phosphate isomerase (PHI) replacing transaldolase, to synthesize pentoses (Soderberg, 2005). For pentose catabolism, they employ specialized dehydratase and dehydrogenase cascades operating through dicarboxylic acid intermediates, which diverge completely from bacterial systems.

Bıotechnologıcal Applıcatıons And Astrobıologıcal Potentıal Of Archaea

Enzymes exhibiting high stability obtained from archaea (extremozymes) offer significant operational advantages in industrial biotechnology (Özkan and Başbülbül, 2021). Archaeal amylases, glucoamylases, and pullulanases involved in carbohydrate metabolism retain their catalytic activity even under elevated temperatures (>90°C), extreme pH levels, and in the presence of organic solvents. For instance, amylolytic enzymes derived from Pyrococcus species eliminate cooling costs during industrial starch processing by simultaneously reducing viscosity and hydrolyzing starch into glucose at high temperatures (Vieille and Zeikus, 2001). Similarly, ADP-dependent glucokinases (ADP-GLK) exhibit prolonged shelf life and exceptional stability as enzymatic components in commercial biosensor kits used for blood glucose quantification and analytical measurement of clinical ATP/ADP ratios (Sakuraba et al., 2002). Furthermore, promiscuous archaeal isomerases and aldolases providing broad substrate specificity facilitate high selectivity and yield in the industrial-scale biosynthesis of high-value rare sugars from aldoses.

Astrobiology is an interdisciplinary field investigating the origin, evolution, and distribution limits of life in the universe. The remarkable resilience of archaea toward hostile environmental conditions, alongside their non-canonical metabolic pathways, renders them primary model organisms in extreme environment simulations (Rothschild and Mancinelli, 2001; DasSarma et al., 2020).

CONCLUSIONS

Research on central carbohydrate metabolism in archaea demonstrates that metabolic flexibility and evolutionary adaptability across life are far broader than previously recognized. The archaeal variants of classical EMP and ED pathways feature highly unique biocatalysts, including ADP-dependent kinases, cupin-type isomerases, GAPN, and GAPOR. These modifications enable the bypass of thermally unstable intermediates under extreme environmental conditions while optimizing cellular energy balance. As genome editing technologies become more broadly implemented in archaeal systems, future investigations will elucidate the functions of currently uncharacterized archaeal enzymes.

ABSTRACT

In recent years, bifunctional nanomaterials with magnetic and optical properties have gained considerable attention in nanomedicine, especially for nanoscience applications. Materials show different properties at the nanoscale than at bulk size. In addition, as size decreases, nanoparticles develop richer surface properties. For example, a higher surface-to-volume ratio provides a larger surface area, increasing functional efficiency. Therefore, quantum dots (QDs) and magnetic nanoparticles are commonly used for their unique properties. Conventional quantum dots often contain highly toxic heavy metals, such as cadmium, which restricts their clinical translation. Manganese-doped zinc sulfide (ZnS:Mn) quantum dots have been developed to overcome this drawback and are a biocompatible, cadmium-free substitute with stable luminescence. In this study, we synthesized core-shell $CoFe_2O_4$-ZnS:Mn QD nanocomposites through co-precipitation and then successfully developed a dual-modal imaging platform. SEM morphology showed that the composite structure consisted of ZnS:Mn quantum dots inside the cobalt ferrite magnetic nanoparticles. Also, the Fluorescence spectra showed a strong and characteristic orange-pink emission around 630-700 nm, which corresponds to the 4T1→6A1 transition of Mn2+ ions. The coexistence of a strong magnetic response and bright luminescence indicates that these cadmium-free core-shell nanostructures are promising for targeted drug delivery and concurrent optical/magnetic resonance imaging.

Keywords: Nanoscience, Quantum Dots, Magnetic Nanoparticles

INTRODUCTION

Currently, nanotechnology is a hot topic in science. These researchs have led to the development of goods and methods that improve the efficiency of everyday life. The development of nanoscience is being driven by a number of issues, including the need for renewable energy sources, the identification and treatment of novel illnesses, and the growing need for food due to population expansion. The basic building elements of the scientific method of product development are nanostructures. Nano-sized materials are very helpful in biological research due to their special characteristics(Ahmad et al., 2025; Dowling, 2004; Hughes et al., 2025) .

Magnetic nanoparticles (MNPs) are a rapidly expanding class of metal nanoparticles (NPs) that have sparked a revolution in materials science due to their unique combination of advantageous properties, including high surface-to-volume ratio, superparamagnetism, size-dependent properties, and quantum confinement effects, with conventional bulk material characteristics(Chand & Vasquez-Guardado, 2025) . The weak plasmonic optical properties of magnetic nanoparticles limit their use in applications such as imaging. The absence of plasmonic properties, meaning they do not emit fluorescence when exposed to light at a specific

wavelength, prevents their use as sensors. To overcome this limitation, composite structures were developed. Magnetic nanoparticles were combined with molecules or nanoparticles that have plasma or fluorescence emission properties, making them multifunctional(Corr et al., 2008). The aim was to perform both magnetic applications such as MRI, hyperthermia, and magnetic targeting, and optical applications such as SERS detection and fluorescence detection, simultaneously(Mir et al., 2025; Sirgedaite et al., 2023; Wolfbeis, 2015).

Quantum dots (QDs) are semiconductor particles with optical and electronic (optoelectronic) characteristics that vary with size and composition. QDs are very tiny, usually ranging in size from 1.5 to 10.0 nm. QD nanotechnology has recently made significant inroads into a number of biological and electrical areas. Because of their special qualities—such as excellent photostability, size-dependent optical characteristics, high brightness and extinction coefficient, and significant Stokes shift—QDs have been shown to be effective. Due to their limited ability to display all of these characteristics, organic dyes or fluorophore molecules are unsuitable for many imaging and biosensing applications. Furthermore, because of their enormous surface area, ultrasmall QDs may provide additional benefits over another type nanomareials for creating multimodal/multifunctional probes(Bera et al., 2010; Maxwell et al., 2020) . Quantum dots based on cadmium are generally used due to their high emission properties. However, because cadmium-containing quantum dots are not stable under UV light, there is a possibility of cadmium ions leaching into the environment. Since cadmium has high toxicity, its use for biomedical purposes is problematic. Therefore, Cd-based quantum dots are coated with Zn-derived quantum dots. Alternatively, for biomedical applications, Zn and Mn-based or carbon-based quantum dots with lower toxicity are used (Hardman, 2006; Lin & Chen, 2023).

In the literature, nanocomposites containing multifunctional magnetic particles and quantum dots have been produced for this purpose. Some of these include: Wang et al. Fe_2O_3 Beads−CdSe/ZnS Quantum Dots nanocomposite(Wang et al., 2004); Xu et al. Fe_3O_4/SiO_2 and water-soluble CdSe−ZnS quantum dots (QDs) nanocopmpsite. (Xu et al., 2010); Tadesse et al. nitrogen doped carbon quantum dots/magnetite nanocomposites (Tadesse et al., 2018), and Bunkoed et al. graphene quantum dots and magnetite nanoparticles embedded in molecularly imprinted polymer (GQDs@Fe_3O_4/MIP) nanocomposites(Bunkoed et al., 2020).

In this study, Cobalt ferrite magnetic nanoparticles were modified with ZnS:Mn quantum dots. Quantum dots provided fluorimetric properties to magnetic nanoparticles

METHOD

1.) $CoFe_2O_4$ nanoparticles (MNPs) were created via co-precipitation. A 1:2 mole solution of $CoCl_2$ and $FeCl_3$ salts was prepared in a flask and mixed with a NaOH solution at 80°C for an hour. The resulting black particles were gathered using a magnet, and a solution of water was used for three magnetic washing processes. After that, it was dissolved in 50 mL deionized water (Roy et al., 2024)

2.) 1.0 ml $CoFe_2O_4$ nanoparticle (MNP) solutions were added to 10.0 ml 0.025 M Zn(NO3)2 and Mn(NO3)2 mixed solution.After 1 hour of mixing, 0.1 M Na2S solution was added to the previous solution. After 12 hours of mixing in a dark room, a gray-brownish precipitate was obtained and washed with dı water three times using a magnet.Finally, nanoparticles were dispersed in water. Supernatant was disposed of.

3.) To demonstrate the effect of nanocomposite ratios in optimization studies, the experiment was performed twice separately by adding 1.0 and 2.0 ml of magnetic particle solution to equal amounts of Zn and Mn ion mix solutions.

RESULTS AND DISCUSSION

The adherence of quantum dots to the magnetic nanoparticle surface was checked using a UV lamp. First, it was observed that the prepared ZnS:Mn QDs composites gave an orange color under UV light at a wavelength of 365 nm (Figure 1a). Then, the prepared nanocomposite was visualized in daylight and under UV light at the same wavelength. The color, which was light gray-brown under daylight, appeared orange-pink under UV light (Figure 1b and 1c).

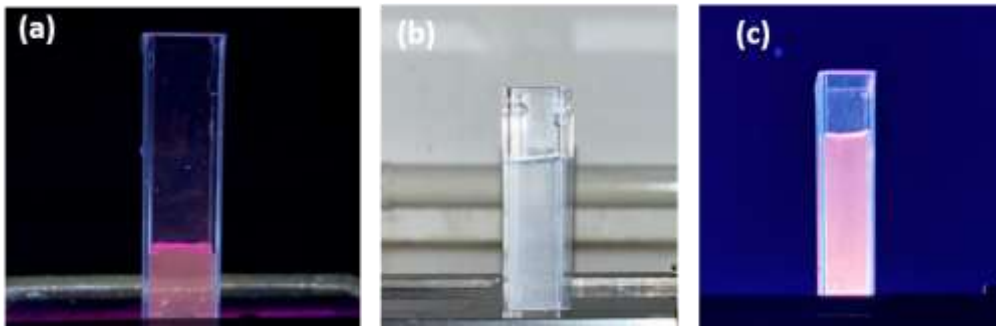

Figure 1. Image of a.) ZnS:Mn QDs under UV light, b.) Nanocomposite under solar light, c) nanocomposites under UV light.

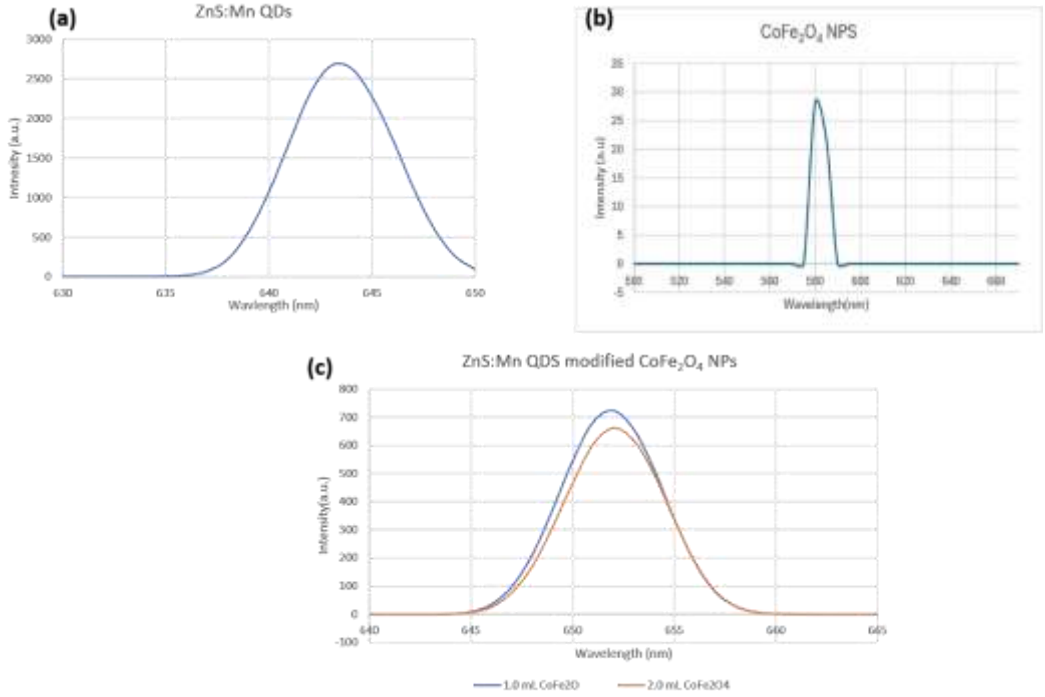

Figure 2. Emission spectrum of a.) ZnS:Mn quantum dots, b) $CoFe_2O_4$ NPs c.) ZnS:Mn quantum dots modified magnetic nanoparticles

Fluorescence Spectroscopy (FL) was used for emission measurements. For measurements, a quartz cell was used, and the device was adjusted to 320 nm excitation wavelength. ZnS:Mn quantum dots give emission at 642 nm(Figure 2a). These results are consistent with the literature (Patel et al., 2020). The fluorescence emission spectrum shown in Figure 2b corresponds to the prepared cobalt ferrite nanoparticles. It exhibits a peak at 580 nm that is either absent or negligibly weak. This wavelength does not coincide with the emission wavelength of ZnS:Mn quantum dots. ZnS:Mn quantum dots modified magnetic nanoparticles(nanocomposite) emitted at 652 nm. The wavelength shifted with agglomeration (Figure 2c). In addition, the emission intensity decreased significantly due to quenching caused

by agglomeration of the magnetic nanoparticles. For optimization, we used 1.0 mL (blue line) and 2.0 mL (orange line) magnetic nanoparticles during synthesis, separately. Figure 2c indicated that there is no significant difference. As a result, the ratio of components is not effective for this method.

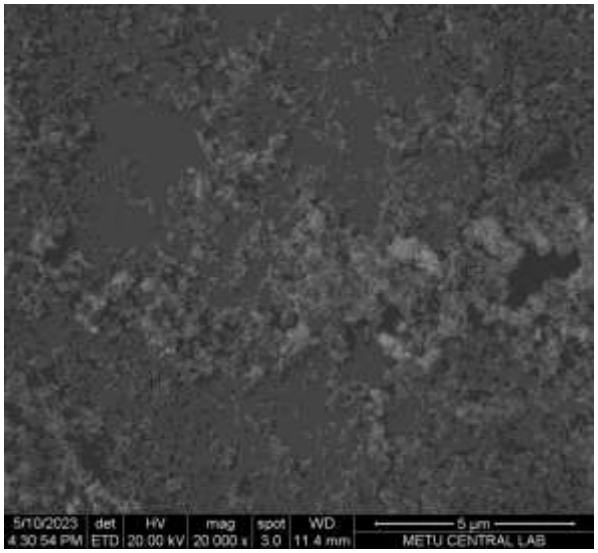

Figure 3. SEM images of ZnS:Mn quantum dots modified magnetic nanoparticles(Nanocomposites)

Figure 3 shows the SEM image of the prepared nanocomposite. In the image, the dark gray particles are magnetic nanoparticles, and the light gray particles are quantum dots attached to the magnetic particles.

CONCLUSIONS

This study aimed to produce a bifunctional nanomaterial by combining two different nanomaterials solely through adsorption, without the need for any interconnecting groups and an extra reaction step. The goal was to obtain a core-shell structure, but SEM images showed that the core-shell structure was not fully formed. Instead, a randomly distributed composite structure was formed. Fluorescence spectroscopy measurements and UV light beams showed that quantum dots in the structure adhered to the magnetic particle surface. In the future, other combination methods will be tried to produce more efficient emissions and a core-shell structure. Several techniques, including TEM, Zeta Potentiometer, VSM, and FTIR Spectroscopy, will improve characterization. The stability of the nanocomposite will also be tested. The produced particles will be used in imaging, biomedical applications,water splitting, and dye degradation as catalysts.

ABSTRACT

Background: Orthodontic treatment relies on controlled mechanical forces to modify tooth position and correct dental and skeletal malocclusions. Their clinical effects depend on force magnitude, direction, duration, point of application, force–moment relationships, anchorage, and biological tissue response. **Aim:** This narrative review examines the biomechanical forces generated by commonly used orthodontic appliances and their relationship with biological response and the management of dental and skeletal malocclusions. **Material and Method:** Peer-reviewed literature addressing orthodontic biomechanics, force–moment relationships, biological mechanisms of tooth movement, anchorage, and appliance-generated force systems was narratively reviewed. Evidence concerning fixed appliances, elastics and springs, temporary skeletal anchorage devices (TADs), and clear aligners was considered and synthesized according to biomechanical principles and clinical applications. **Results and Discussion:** Orthodontic force systems determine the pattern of tooth movement through interactions among force, moment, and the center of resistance. Mechanical loading induces biological responses involving the periodontal ligament and alveolar bone, including cellular activity, inflammatory signaling, bone resorption, and bone formation. Fixed appliances provide versatile three-dimensional control, while elastics and springs introduce additional force vectors. TADs enhance skeletal anchorage, whereas clear aligners generate forces and moments through appliance deformation and tooth–aligner interaction. Available evidence remains heterogeneous regarding optimal force magnitude and the predictability of newer appliance systems. **Conclusions:** Effective orthodontic treatment requires integration of malocclusion characteristics, desired tooth movement, force–moment relationships, anchorage requirements, appliance selection, and biological response. A biomechanically informed approach may facilitate controlled treatment, while further clinical research is needed to establish the predictability of emerging technologies.

Keywords: Orthodontic biomechanics; Orthodontic forces; Orthodontic appliances; Malocclusion; Orthodontic tooth movement; Anchorage; Clear aligners.

INTRODUCTION

Orthodontic treatment relies on the controlled application of mechanical forces to modify tooth position and correct dental and skeletal malocclusions. The clinical effect of an orthodontic force is determined by its magnitude, direction, point of application, and duration, together with

the moment generated around the tooth and the characteristics of the supporting tissues (Hocevar, 1981; Proffit et al., 2018).

Orthodontic biomechanics provides the mechanical basis for predicting and controlling tooth movement. A force applied to a tooth may produce translation, rotation, or a combination of these movements, depending on the relationship between its line of action and the center of resistance (Hocevar, 1981). Consequently, orthodontic tooth movement should not be considered simply as a response to force magnitude; rather, it reflects the complete force–moment system acting on the tooth and its supporting structures.

The biological response is equally important. Mechanical loading of the periodontal ligament produces cellular, vascular, inflammatory, and molecular responses that contribute to periodontal ligament adaptation and alveolar bone remodeling (Asiry, 2018; Li et al., 2018; Li et al., 2021). Tooth movement therefore represents a dynamic interaction between mechanical stimulation and biological tissue response.

Different orthodontic appliances are capable of generating different force systems. Fixed appliances allow interaction between brackets and archwires, while elastics, springs, temporary skeletal anchorage devices (TADs), and clear aligners provide additional or alternative mechanisms for force delivery (Proffit et al., 2018; Dalessandri et al., 2014; Park et al., 2021; Iliadi et al., 2019). The selection and activation of these systems should be related to the desired tooth movement and anchorage requirements.

The treatment of malocclusion further illustrates the importance of biomechanical planning. Sagittal, vertical, transverse, and space-related discrepancies may require different force vectors and anchorage strategies. Consequently, patients within the same broad malocclusion category may have substantially different biomechanical requirements.

The aim of this narrative review is to examine the biomechanical forces generated by commonly used orthodontic appliances and their relationship with biological tissue response and the clinical treatment of dental and skeletal malocclusions. The review specifically addresses fundamental force–moment relationships, biological mechanisms associated with orthodontic tooth movement, appliance-generated force systems, anchorage considerations, and the clinical implications of these principles for individualized orthodontic treatment planning.

MATERIALS AND METHODS

This work was conducted as a narrative review of peer-reviewed scientific literature addressing orthodontic biomechanics and the biological response to orthodontic forces.

The literature was considered according to four interconnected areas: fundamental biomechanical principles, biological mechanisms of orthodontic tooth movement, force systems generated by orthodontic appliances, and clinical application in the treatment of malocclusion.

Relevant literature concerning force magnitude and direction, force–moment relationships, periodontal and alveolar responses, fixed orthodontic appliances, elastics, springs, skeletal anchorage, and clear aligner systems was considered. Particular emphasis was placed on established biomechanical literature, systematic reviews, and clinically relevant studies

addressing the mechanical and biological mechanisms of orthodontic tooth movement (Hocevar, 1981; Theodorou et al., 2019; Dalessandri et al., 2014; Iliadi et al., 2019).

The evidence was synthesized narratively rather than quantitatively. Findings were interpreted in relation to the intended type of tooth movement, anchorage requirements, appliance characteristics, and biological response. No meta-analysis or pooled effect calculation was undertaken because the purpose of this review was to provide an integrated clinical overview rather than a quantitative estimate of treatment effects.

As a narrative review, the present work does not claim to represent an exhaustive systematic review of all available literature. Instead, it provides a focused synthesis of established biomechanical and biological concepts and contemporary evidence relevant to orthodontic force application and the treatment of malocclusion.

RESULTS AND DISCUSSION

Fundamental Biomechanical Principles

Orthodontic biomechanics describes the mechanical principles governing the application of forces to teeth and their supporting structures. Its clinical purpose is to establish a predictable relationship between an applied force system and the resulting tooth movement (Hocevar, 1981; Proffit et al., 2018).

A force applied to a tooth can produce translational and/or rotational effects depending on its magnitude, direction, and line of action. When the line of action does not pass through the center of resistance, a moment is generated. The combined control of force and moment is therefore fundamental to determining the resulting pattern of tooth movement (Hocevar, 1981).

The center of resistance represents a theoretical point within the tooth-supporting system at which application of a force can produce translational movement. Its position is influenced by the morphology of the tooth and the characteristics of its periodontal support. The center of rotation, in contrast, is determined by the applied force–moment system and changes according to the relationship between force and moment (Hocevar, 1981).

The moment-to-force (M/F) relationship is an important determinant of orthodontic tooth movement. Changes in this ratio alter the center of rotation and consequently influence whether movement is predominantly tipping, translation, or root movement (Hocevar, 1981; Proffit et al., 2018). This relationship is particularly relevant during space closure, torque expression, intrusion, extrusion, and movements requiring accurate root positioning.

Force Magnitude and Duration

The biological and mechanical effects of orthodontic force are influenced by both force magnitude and duration. Current evidence does not support a single universally optimal force magnitude for every type of orthodontic movement (Theodorou et al., 2019).

A systematic review concluded that forces between 50 and 100 cN may be appropriate for bodily orthodontic tooth movement, patient comfort, and potentially fewer side effects. However, the authors emphasized substantial methodological heterogeneity and weak-to-moderate evidence, indicating that these findings should not be interpreted as a universal force prescription (Theodorou et al., 2019).

Accordingly, force selection should be related to the intended movement, appliance characteristics, anchorage requirements, and biological response rather than to an isolated numerical value.

Anchorage

Anchorage refers to resistance to unwanted movement of teeth or other anatomical structures during orthodontic treatment. Because orthodontic force systems generate reciprocal reactions, control of these reactive forces is essential for achieving the intended treatment objective (Proffit et al., 2018).

Conventional anchorage relies primarily on teeth and their supporting structures. TADs provide an additional source of skeletal anchorage and have expanded the range of force systems available when conventional anchorage is insufficient (Dalessandri et al., 2014; Park et al., 2021).

Clinical success of TADs is influenced by patient-, device-, and management-related factors. Their use therefore remains dependent on appropriate biomechanical and clinical planning.

Biological Response to Orthodontic Forces

Orthodontic tooth movement results from a coordinated biological response to mechanical loading of the periodontal ligament and surrounding alveolar tissues. Application of an orthodontic force changes the mechanical environment of the periodontal ligament and initiates cellular, vascular, inflammatory, and molecular responses involved in tissue remodeling (Asiry, 2018; Li et al., 2018; Li et al., 2021).

Mechanical loading produces areas of compression and tension and modifies cellular activity, extracellular matrix organization, and local tissue signaling (Li et al., 2018; Li et al., 2021).

Orthodontic tooth movement depends on coordinated remodeling of the periodontal ligament and alveolar bone. Mechanical loading can initiate inflammatory and cellular responses that participate in bone resorption and formation (Asiry, 2018; Li et al., 2018; Li et al., 2021).

Osteoclast-mediated bone resorption contributes to tooth displacement in areas subjected to appropriate mechanical and biological stimuli, while osteoblast activity contributes to bone formation and adaptation (Li et al., 2018; Li et al., 2021).

The RANK/RANKL/OPG system has an important role in regulating osteoclast differentiation and activity during orthodontic tooth movement (Yamaguchi, 2009). Inflammatory and signaling mediators also participate in the tissue response to orthodontic loading (Asiry, 2018; Li et al., 2021).

The relationship between orthodontic force and biological response cannot be reduced to a simple linear relationship between force magnitude and rate of tooth movement. The response depends on the type of movement, force characteristics, tissue condition, and individual biological variability (Li et al., 2021; Theodorou et al., 2019).

Root resorption is one clinically relevant adverse outcome associated with orthodontic tooth movement, although its occurrence is multifactorial and cannot be attributed to force magnitude alone (Weltman et al., 2010).

Biomechanical Forces Generated by Orthodontic Appliances

Fixed Orthodontic Appliances

Fixed appliances provide a versatile system for controlling tooth movement through interactions between brackets, archwires, and auxiliary components. The resulting force and moment systems are influenced by archwire dimensions and material properties, bracket geometry, activation, and tooth position (Proffit et al., 2018).

During alignment, flexible archwires can generate forces for correction of displaced and rotated teeth. As treatment progresses, stiffer archwires and auxiliary mechanics may be used to improve three-dimensional control and facilitate torque expression and root positioning.

Elastics and Springs

Elastics and springs provide additional force vectors that can be incorporated into orthodontic mechanics. Interarch elastics may generate sagittal and vertical components, and their effects depend on attachment sites and direction of application. Because these systems generate reciprocal forces, appropriate anchorage control is essential (Proffit et al., 2018).

Elastomeric materials may undergo force degradation during clinical use. A systematic review demonstrated that orthodontic elastomeric power chains undergo force decay over time, which may influence their mechanical performance (Halimi et al., 2012).

Springs may be incorporated into fixed appliance systems for space opening, space closure, distalization, or other controlled movements. Their mechanical characteristics depend on material properties, activation, geometry, and deactivation behavior.

Temporary Anchorage Devices

TADs have expanded the biomechanical possibilities of orthodontic treatment by providing skeletal anchorage when conventional dental anchorage may be insufficient. Their use can facilitate movements such as intrusion, distalization, mesialization, and retraction while reducing reliance on reciprocal dental movement (Dalessandri et al., 2014; Park et al., 2021).

The biomechanical advantage of TADs depends on their position, stability, direction of force application, and relationship to the desired tooth movement. Clinical success is also influenced by patient-, device-, and treatment-related factors.

Skeletal anchorage therefore does not eliminate the need for biomechanical planning; instead, it provides an additional anchorage point from which force and moment systems can be designed.

Clear Aligner Systems

Clear aligners generate orthodontic forces through elastic deformation of the appliance and its interaction with individual teeth. The resulting forces and moments depend on aligner

geometry, material properties, tooth morphology, planned movement, and auxiliary features such as attachments.

A systematic review and meta-analysis evaluated the forces and moments generated by aligner-type appliances for different orthodontic tooth movements. The evidence was based on in-vitro laboratory studies, and the authors emphasized that the findings should be interpreted within the specific experimental conditions. Tipping and rotation were among the most frequently examined movements (Iliadi et al., 2019).

Recent evidence has also investigated the combined use of clear aligners and temporary skeletal anchorage devices for selected complex tooth movements, including intrusion, extrusion, and distalization. However, the evidence remains relatively limited. A 2025 systematic review identified 14 records for qualitative analysis and emphasized the need for further research to optimize clinical outcomes (Marinelli et al., 2025).

Application of Biomechanical Principles to Malocclusion

The clinical application of orthodontic biomechanics becomes particularly relevant when mechanical principles are translated into treatment strategies for specific malocclusion patterns. Conventional classifications provide a useful description of sagittal, vertical, and transverse discrepancies, but they do not independently determine the mechanical strategy required for correction.

Sagittal Malocclusions

Class II and Class III malocclusions represent common sagittal discrepancies, but their biomechanical management varies according to the relative contribution of dental and skeletal components.

In Class II treatment, interarch elastics can generate combinations of sagittal and vertical force components and may contribute to correction through reciprocal dental effects. Their use therefore requires appropriate anchorage control and consideration of the resultant force vector (Proffit et al., 2018).

Class III correction similarly depends on the underlying diagnosis. Dental Class III relationships may be addressed through controlled dentoalveolar compensation, whereas skeletal Class III discrepancies may require orthopedic or surgical approaches depending on growth status and severity.

Vertical Malocclusions

Vertical malocclusions require careful control of intrusive and extrusive force systems. Deep-bite correction may involve incisor intrusion, posterior extrusion, or a combination of movements depending on facial pattern, incisor position, and periodontal conditions.

Intrusion is particularly sensitive to the location and direction of the applied force. Skeletal anchorage has expanded the possibility of applying intrusive forces with reduced dependence on conventional dental anchorage (Dalessandri et al., 2014; Park et al., 2021).

Open-bite correction presents a different biomechanical challenge. Depending on the underlying etiology, treatment may involve anterior extrusion, posterior intrusion, dentoalveolar compensation, growth modification, or orthognathic intervention.

Transverse Malocclusions

Transverse discrepancies may involve dental, dentoalveolar, or skeletal components. This distinction is important because dental expansion primarily modifies tooth inclination and dentoalveolar relationships, whereas skeletal expansion aims to modify the transverse skeletal relationship.

The biomechanical response to expansion is influenced by age, skeletal maturity, appliance design, activation protocol, and periodontal anatomy. The choice of expansion mechanism should therefore consider the source and magnitude of the discrepancy.

Crowding and Space Management

Crowding may be managed through combinations of arch development, interproximal enamel reduction, distalization, space redistribution, or extraction, depending on severity and distribution.

Following extraction, space closure requires careful control of anchorage and incisor movement. The force–moment relationship influences the pattern of anterior tooth movement and the distribution of anchorage demands (Hocevar, 1981; Proffit et al., 2018).

For non-extraction treatment, expansion and distalization can provide additional space in selected patients, but periodontal and anatomical limits of dental movement must be respected.

Complex and Combined Malocclusions

Many patients present with combinations of sagittal, vertical, transverse, and dental discrepancies. In these cases, individual force systems may interact and produce secondary effects that influence other components of treatment.

For example, sagittal mechanics may generate vertical effects, while transverse expansion may modify dental inclination and periodontal loading. Similarly, space closure may influence incisor torque and anchorage requirements.

Complex treatment therefore requires consideration of combined mechanical effects rather than evaluation of each movement independently.

Individualized Biomechanical Treatment Planning

Traditional malocclusion classifications remain clinically useful, but classification alone does not define the complete biomechanical requirements of treatment. Patients within the same malocclusion category may differ in skeletal pattern, dental compensation, periodontal support, facial morphology, anchorage requirements, and treatment objectives.

Biomechanical diagnosis can therefore complement conventional classification by identifying the specific movements required and the mechanical conditions necessary to achieve them.

The first step in biomechanical treatment planning is identification of the discrepancy requiring correction. The mechanical objective should then be defined in terms of the desired movement, such as bodily movement, controlled tipping, root movement, intrusion, extrusion, rotation, distalization, or mesialization.

Different orthodontic appliances generate different combinations of forces and moments. Fixed appliances provide extensive control through bracket–archwire interactions, whereas elastics, springs, skeletal anchorage, and clear aligners provide additional or alternative mechanisms for force delivery (Proffit et al., 2018; Dalessandri et al., 2014; Park et al., 2021; Iliadi et al., 2019).

Anchorage control is central to individualized treatment planning because orthodontic force systems generate reciprocal reactions. Conventional dental anchorage may be sufficient in some cases, whereas skeletal anchorage may be advantageous when greater anchorage control is required (Dalessandri et al., 2014; Park et al., 2021).

Biomechanical planning must also account for the biological response of periodontal and alveolar tissues. Individual variability in periodontal support, root morphology, alveolar anatomy, and tissue response may influence the clinical expression of an otherwise similar mechanical system (Asiry, 2018; Li et al., 2018; Li et al., 2021).

Digital and Computational Biomechanics

Digital technologies have increasingly influenced orthodontic diagnosis and treatment planning. Three-dimensional imaging, digital models, virtual setups, and computational approaches can facilitate visualization of dental and skeletal relationships and may assist in planning complex movements.

Finite element analysis can provide information concerning stress and strain distributions associated with different force systems and has been increasingly used to investigate orthodontic tooth movement and appliance–periodontium interactions. However, computational predictions should be interpreted cautiously because model assumptions, material properties, boundary conditions, and biological simplifications can influence the results (Cattaneo and Cornelis, 2021).

Recent systematic evidence concerning finite element analysis of clear aligners has also highlighted substantial methodological heterogeneity and limited standardization in the assessment of aligner biomechanics (Cao et al., 2025).

A digitally planned tooth position should therefore not be considered equivalent to a guaranteed biological outcome. Clinical results remain dependent on the actual force system, appliance fit and activation, patient compliance when relevant, tissue remodeling, and treatment execution.

Limitations and Future Perspectives

The literature addressing orthodontic biomechanics encompasses experimental studies, clinical investigations, systematic reviews, and computational models with substantial variation in study design, appliance characteristics, force systems, outcome measures, and patient populations. This heterogeneity limits direct comparison between studies and prevents formulation of universally applicable biomechanical prescriptions.

The biological response to orthodontic force is also variable. Although established biomechanical principles provide a theoretical basis for predicting tooth movement, differences in periodontal anatomy, alveolar bone morphology, root characteristics, tissue response, and treatment conditions may influence clinical outcomes (Asiry, 2018; Li et al., 2018; Li et al., 2021).

Evidence concerning newer technologies, particularly clear aligners, skeletal anchorage-assisted mechanics, and computational modeling, continues to evolve. Evidence regarding their long-term clinical advantages and ability to consistently improve treatment predictability remains heterogeneous (Iliadi et al., 2019; Marinelli et al., 2025; Cao et al., 2025).

Future research should integrate biomechanical measurements with clinical and biological outcomes. Standardized reporting of force magnitude, direction, duration, anchorage conditions, appliance characteristics, and treatment outcomes would improve comparability between studies.

Three-dimensional imaging, digital models, intraoral scanning, and computational biomechanical analysis may provide additional opportunities for patient-specific treatment planning. However, future studies should determine whether computational predictions correspond sufficiently to actual clinical tooth movement (Cattaneo and Cornelis, 2021; Cao et al., 2025).

Technological sophistication should not replace established clinical diagnosis and biomechanical principles. The principal future challenge is to determine when and for whom a particular biomechanical strategy provides a clinically meaningful therapeutic advantage.

CONCLUSIONS

Orthodontic treatment is fundamentally based on the interaction between mechanical force systems and the biological response of dentoalveolar tissues. Correction of malocclusion therefore requires more than appliance selection or application of a predetermined force. It requires understanding the relationship between malocclusion characteristics, desired tooth movement, force–moment relationships, anchorage requirements, and tissue response.

Fixed appliances, elastics, springs, temporary skeletal anchorage devices, and clear aligner systems can generate different biomechanical environments and consequently provide different possibilities for controlling orthodontic tooth movement (Proffit et al., 2018; Dalessandri et al., 2014; Park et al., 2021; Iliadi et al., 2019). Their clinical application should be determined by the treatment objective and mechanical requirements of the individual case.

An integrated approach linking malocclusion diagnosis, desired tooth movement, force–moment requirements, anchorage control, appliance characteristics, and biological considerations provides a rational framework for individualized orthodontic treatment planning.

Digital and computational technologies may further support biomechanical planning, but their predictions should be interpreted within the limitations of current evidence and validated against clinical outcomes. Overall, orthodontic biomechanics provides a mechanistic bridge between diagnosis and treatment and may contribute to more controlled tooth movement,

rational appliance selection, and treatment strategies adapted to individual anatomical and biological conditions.

ABSTRACT

The olive tree is a typical Mediterranean climate plant characterized by dry and hot summers and capable of surviving with minimal water. However, if olive trees are irrigated, they exhibit increased bud formation and flowering, higher fruit production, larger fruit size, greater yield per tree, and a higher amount of olive oil. In recent years, renewable energy resources have been preferred in irrigation applications in order to both reduce fossil fuel-based energy consumption and irrigation costs. The use of solar energy as a renewable energy resource for agricultural irrigation has been steadily increasing. In this study, an off-grid solar-powered, soil moisture-controlled daytime drip irrigation system is implemented in an olive grove located in Ezine, Çanakkale. The mentioned irrigation system essentially includes a 12 Volt submersible pump, two photovoltaic panels (12 Volt, 340 Watt) and a control unit. The control unit determines the conditions under which the submersible pump operates and basically consists of a circuit breaker, a solar charge controller, a battery, a digital timer, and a soil moisture controller. The function of the battery in the control unit is to continuously provide energy needs of control circuits. Thus, control settings can remain constant at all times. In addition, since the battery is not used to power the submersible pump, a low-cost system can be designed using a low-capacity battery. Thanks to a digital timer, the solar drip irrigation system can operate at scheduled intervals during the daytime on a weekly basis. With the help of the soil moisture controller, efficient drip irrigation can be carried out based on the predetermined set value of soil moisture. In this design, the soil moisture controller continuously measures soil moisture with a sensor. If the level of soil moisture is below the set value and the time is between 9:00 and 18:00, the control unit allows irrigation. On the other hand, if the soil moisture level is above the set value or the time is outside the specified time range, irrigation is prevented. Owing to the drip irrigation system mentioned, water needs of olive trees are met during the daytime by controlling soil moisture. In this way, economical irrigation is achieved while agricultural productivity is enhanced. By preventing unnecessary irrigation, efficient use of water is possible. Additionally, this study can be used in any area where a sustainable irrigation system is required.

INTRODUCTION

In traditional irrigation systems, pumps powered either by electricity or fossil fuels are used. Electric pumps generally obtain the energy they need either from the power grid or from

generators that run on fossil fuels. In any case, the required energy relies on fossil fuels. As is well known, fossil fuels are not unlimited and their reserves are steadily decreasing. Moreover, the use of these fuels not only causes greenhouse gas (GHG) emissions but also releases pollutants such as benzene, carbon monoxide, sulfur oxides, and ammonia. Therefore, the transition to renewable energy resources (RES) in agricultural irrigation, where energy is essential, has become increasingly important (Mirahmad et al., 2026).

Nowadays, when people think of RESs, solar and wind energy are usually the first that come to mind. Solar energy is one of the most important RESs, as it is clean, free, and easily accessible, making it a key contributor to electricity generation worldwide. However, a country's geographical location directly determines how much it can benefit from solar energy. Türkiye has rich solar energy potential because it is located in a sunny region of the Earth, between the 36th - 42nd northern parallels and the 26th - 45th east meridians, which provides an advantage over most other countries (Kotcioğlu, 2011). Solar energy potential atlas of Türkiye is given in Figure 1. Solar energy potential is directly proportional to the duration of sunlight in specific regions, and Türkiye demonstrates considerable capacity for power generation from solar energy, as evidenced in Figure 1 (Kabalci et al., 2016).

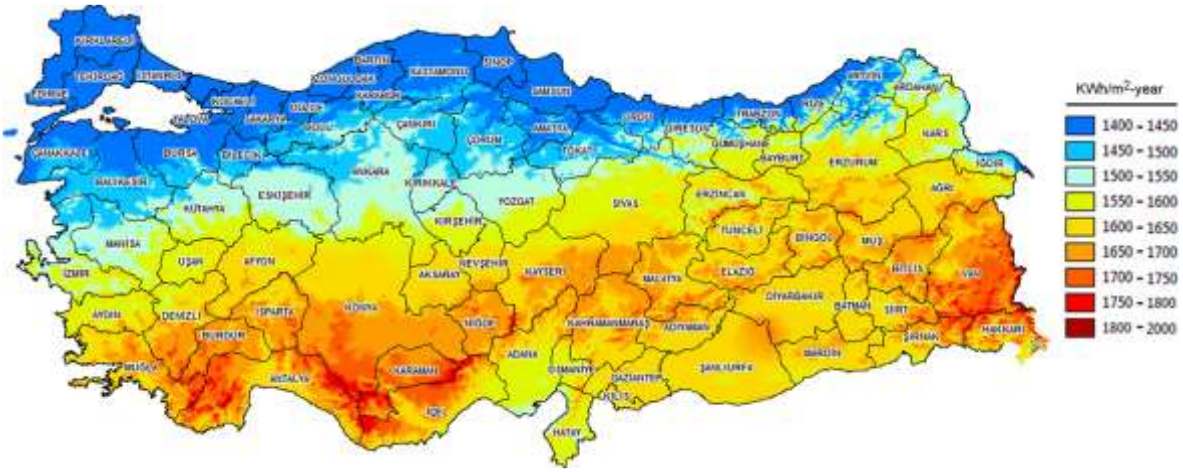

Figure 1. Solar energy potential atlas of Türkiye (Kabalci et al., 2016)

Solar-powered systems are consistently finding various application areas (Şen, 2024). One of them is a solar-powered agricultural irrigation (Şen, 2023). These systems reduce operational costs while supporting environmental sustainability. They can be used in regions with limited access to electricity, improve water efficiency, and lower GHG emissions. In addition, they ease labor and boost production. Being reliable, scalable, and integrable with a battery unit, they provide a sustainable solution for agricultural irrigation (Hossain et al., 2024).

With the integration of sensors suitable for agricultural irrigation systems, the concept of smart irrigation systems has emerged. For example, soil moisture sensors provide real-time measurements. Farmers can evaluate the relevant soil moisture data to accurately assess the water needs of trees or crops. Soil moisture data are used to determine at what intervals and how much water should be supplied to trees or crops. When irrigation is carried out based on soil moisture data, the soil moisture level is maintained at an optimum level, allowing trees or crops to access necessary nutrients and reducing the risk of water stress (Wanyama et al.,2023). Drip irrigation is a micro-irrigation technology that delivers controlled amounts of water and nutrients directly to the root zone of trees or crops through networks of pipes and drippers. Replacing inefficient irrigation methods with drip irrigation has been shown to reduce water losses during irrigation by 20% to 76% and to increase crop water productivity by 15%. Farmers

who adopt drip irrigation can achieve water savings while simultaneously improving crop yields (Grant et al., 2022).

Olive trees are among the most resilient traditional dryland fruit species under water stress conditions. Although olive trees are generally drought-tolerant, not all phenological stages exhibit the same level of resistance, and the combination of the duration and severity of water stress is critical. Flowering, fruit set, and oil accumulation phases are the most sensitive stages to water stress conditions (Molina-Moral et al., 2022).

In this study, the off-grid solar-powered, soil moisture-controlled daytime drip irrigation system is implemented in an olive grove located in Ezine, Çanakkale, Türkiye. The proposed irrigation system essentially includes a 12 Volt direct current (DC) submersible pump, two photovoltaic (PV) panels and a control unit. The control unit basically consists of a circuit breaker, a solar charge controller, a battery, a digital timer, and a soil moisture controller. The battery in the control unit serves to continuously supply power to control circuits, ensuring that the settings remain stable at all times. Since it does not drive the DC submersible pump, a low-capacity battery can be used, making the system more cost-effective. With the soil moisture controller, drip irrigation can be efficiently managed according to the preset soil moisture level. Thanks to the digital timer, the solar drip irrigation system can operate at scheduled intervals during the daytime on a weekly basis. Owing to the installed drip irrigation system, water needs of olive trees are met during the daytime by controlling soil moisture.

MATERIAL AND METHOD

Study Area

Çanakkale is located in the Marmara Region of Türkiye and holds a strategic position, connecting the continents of Asia and Europe. Çanakkale has 12 districts and the study is carried out in Ezine district of Çanakkale. The location of Ezine in Türkiye is shown in Figure 2.

Figure 2. The location of Ezine in Türkiye

Ezine is situated in the transitional zone between the Marmara and the Aegean regions. Known for its natural beauty and fertile plains, Ezine enjoys an advantageous location in terms of both sea and land transportation. Consequently, climatic characteristics of both regions are also reflected in Ezine. Winters are generally mild and rainy, with precipitation predominantly

occurring as rainfall. Meteorological records indicate that November, December, March, and April are the months with the highest precipitation. In contrast, summers are hot and dry. July and August are the warmest months, with average temperatures ranging between 25°C and 35°C, and precipitation is typically scarce during this period. Therefore, agricultural irrigation constitutes a significant necessity, particularly in the summer season. Furthermore, due to its settlement being surrounded by hills, Ezine exhibits relatively high average humidity levels (Şen, 2023).

The olive tree is a species that is sensitive to climate conditions. Ezine is one of the regions in Çanakkale where olive cultivation is carried out intensively. The mentioned irrigation study is applied on almost three-acre of olive grove in Ezine shown in Figure 3.

Figure 3. The olive grove in Ezine

Design and Realization of the Proposed System

In this study, the off-grid solar-powered system is implemented in an approximately three-acre olive grove in Ezine, Çanakkale, Türkiye which performs drip irrigation only during the daytime by taking soil moisture levels into account. The overall schematic of the proposed irrigation system is shown in Figure 4, and its photograph is presented in Figure 5, respectively.

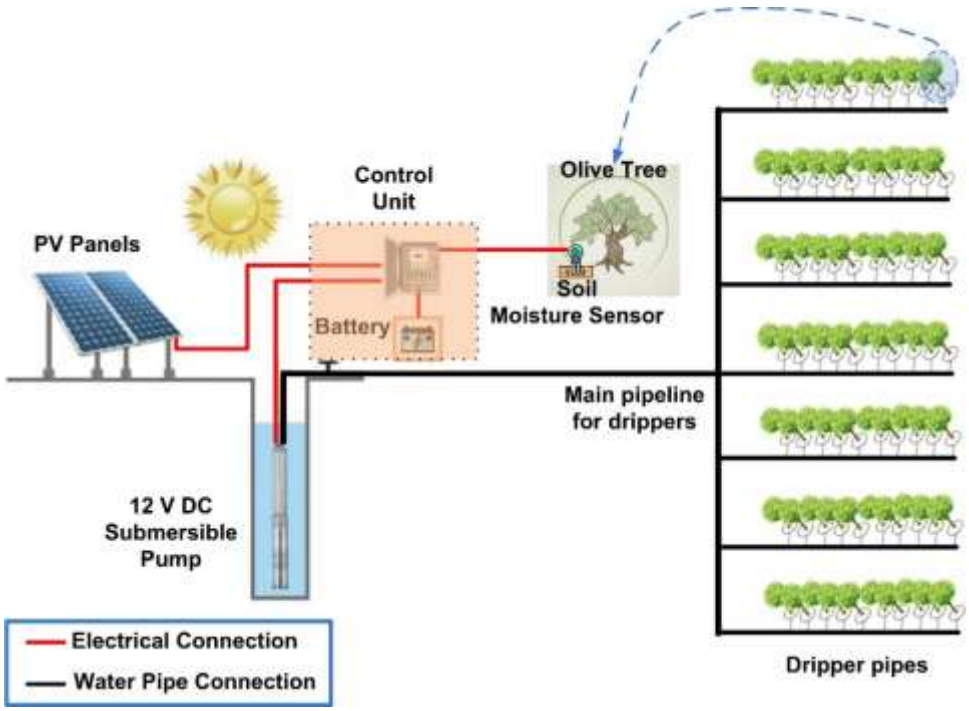

Figure 4. The overall scheme of the proposed irrigation system

Figure 5. Photograph of the proposed irrigation system

As illustrated in Figures 4 and 5, the electrical structure of the proposed irrigation system comprises three main parts, namely PV panels, the DC submersible pump, and the control unit. In the proposed irrigation system, there are two PV panels. Values of each PV panels are 12 Volt and 170 Watt. 12 Volt, 340 Watt DC source is obtained by connecting these PV panels in parallel. Characteristics of PV panel are shown in Table 1.

Table 1. Characteristics of PV panels

Name	Rating
Panel Maximum Power	205 W
Peak Voltage	21.45V
Peak Current	9.6 A
Open Circuit Voltage	25.92 V
Short Circuit Current	9.9 A

There is an artesian well with a depth of thirty-three meters in the mentioned olive grove. The water level is about six meters below the ground. 12 Volt DC submersible pump is located at thirteen meters below the ground. Characteristics of 12 Volt DC submersible pump are shown in Table 2.

Table 2. Characteristics of DC submersible pump

Name	Rating
Voltage	12 V
Power Consumption	130 W
Speed	2850 r/min
Maximum Flow Rate (Qmax)	2 m^3/h
Maximum Head (Hmax)	35 m

The last main part of the proposed irrigation system is the control unit which consists of the circuit breaker, the solar charge controller, the battery, the digital timer, and the soil moisture controller. Photograph of the control unit of the proposed irrigation system is shown in Figure 6.

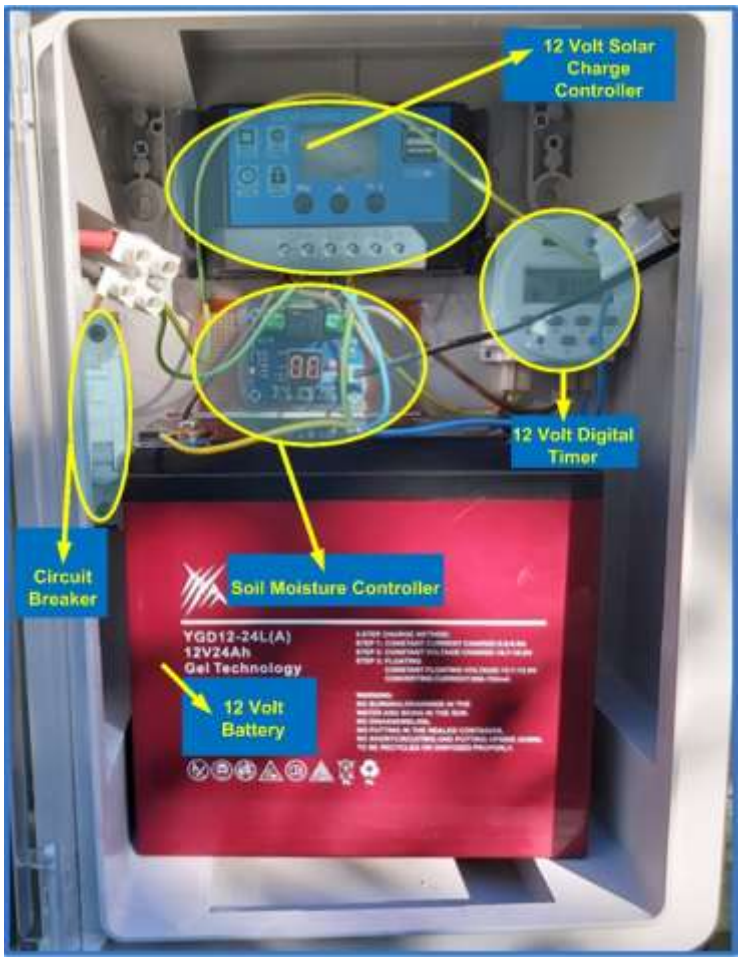

Figure 6. Control unit of the proposed system

The circuit breaker not only protects the system against electrical faults but also acts as an on-off controller for PV panels.

The solar charge controller serves to regulate energy transfer from PV panels to the battery, protecting the battery from overcharging. The solar charge controller's some characteristics are shown in Table 3.

Table 3. Some characteristics of solar charge controller

Name	Rating
Rated Charge Current	10 A
Operating Voltage	12/24Volt auto sensing/auto switching
Control Method	Pulse width modulation (PWM) pulse-duration modulation charge mode
Working Temperature	-35ºC to +60ºC

Another important component of the control unit is the battery. The system employs a 12-Volt, 24-Ah gel battery. A higher-capacity battery group is not selected, as the chosen battery is intended to continuously supply power only to control circuits.
The soil moisture controller is powered directly by the battery voltage, that is, 12 Volts. Through the probe connected to the soil moisture controller, the level of soil moisture in the root zone of the selected olive tree is measured. Using the adjustment buttons on soil moisture controller, the soil moisture value that will serve as a reference for drip irrigation can be set. Based on this set value, the relay in the soil moisture controller switches on and off to control the current flow of the DC submersible pump.
The digital timer like the soil moisture controller, is powered directly by the battery voltage. It can be programmed multiple times to allow current to flow at desired times throughout the week. In addition, if required, the current flow of the DC submersible pump can also be manually enabled or disabled.
The general electrical connection of the proposed irrigation system, introduced with its photograph in Figure 5, is illustrated in Figure 7.

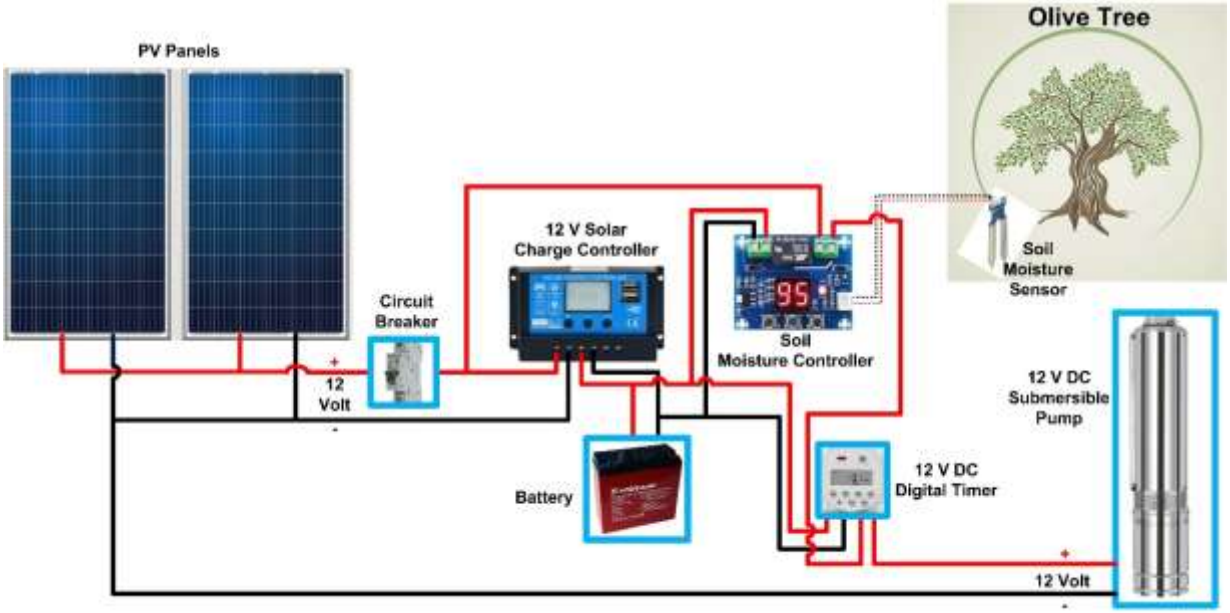

Figure 7. General electrical connection scheme of the proposed system

Operation of the Proposed System

The operating steps of the proposed daytime irrigation system are as follows:

PV panels are connected to the solar charge controller via the circuit breaker. The circuit breaker in the system has two main functions. Its first function is to electrically disconnect PV panels when needed. Its second function is to protect the entire system by cutting off the current flow in case of electrical faults.

The battery is charged through the solar charge controller during periods when sunlight is available. The solar charge controller's settings need to be adjusted according to the battery's specifications.

The battery continuously supplies energy needs of the soil moisture controller and the digital timer. In this way, settings of these two parts within the control unit remain unchanged.

The battery does not supply power to the DC submersible pump. Therefore, its capacity has been selected solely to continuously supply power to the control unit.

The soil moisture controller continuously measures the level of the soil moisture of the selected olive tree. If the measured soil moisture level is below the set moisture value, the relay inside the soil moisture controller allows the current flow from PV panels to the relevant terminal of the digital timer. However, if the measured value is above the set moisture value, it prevents the current flow from PV panels to the relevant terminal of digital timer.

The digital timer is set to allow the current flow from the soil moisture controller to the DC submersible pump between 09:00 and 18:00 every day of the week. During these specified time intervals, if the soil moisture controller permits the current flow, PV panels energize the DC submersible pump and drip irrigation begins. In contrast, when the soil moisture controller and the digital timer do not simultaneously allow the current flow, PV panels can not energize the DC submersible pump. Consequently, drip irrigation can not be performed.

As a result, it has been determined that olive trees in the mentioned olive grove are successfully irrigated using the drip irrigation method every day of the week between 09:00 and 18:00, taking into account soil moisture level.

CONCLUSIONS

This study provides an example of the development of sustainable irrigation practices in olive groves. In this study, the off-grid solar-powered, soil moisture-controlled daytime drip irrigation system is designed and installed for olive grove irrigation in Ezine district of Çanakkale province. The soil moisture-controlled irrigation is targeted only during daytime. Thus, since the low-capacity battery is used that only supplies continuous power to control circuits, the system is established with lower installation costs compared to alternatives with high-capacity battery units. Additionally, as irrigation is carried out based on soil moisture, water needs of olive trees are met at the most appropriate time, while unnecessary irrigation is prevented. Moreover, this study presents a model that can be applied not only to olive groves but also to different plant species and various climatic conditions. Therefore, implementing these solar-powered irrigation systems will contribute to the development of our farmers as well as the economic and agricultural growth of our country.

gorkemsen@trakya.edu.tr

ABSTRACT

Olive trees are grown mostly in countries bordering the Mediterranean basin, such as Türkiye, Spain, Italy, Greece, Tunisia, Portugal, Syria, Libya, Morocco and Algeria. Although the olive tree is a species resistant to drought conditions, it is one of the agricultural products that will be most affected by global climate change. Therefore, water resources should be managed carefully, and appropriate irrigation strategies should be implemented. The use of solar energy in agricultural irrigation is increasing day by day, as this energy is both an environmentally friendly approach and an economical solution in the long term. In this study, the installation of an off-grid solar-based, soil moisture-controlled 24-hour drip irrigation system is performed in an olive grove located in Ezine, Çanakkale. The drip irrigation system contains two photovoltaic (PV) panels (12 Volt, 340 Watt), a battery group (12 Volt), a 12 Volt submersible pump and a control unit. The control unit defines the operating conditions of the submersible pump and consists of a circuit breaker, a solar charge controller, a digital timer and a soil moisture controller. The solar charge controller allows PV panels to charge the battery group. The battery group provides the energy needs of both the control circuits and the submersible pump, enabling drip irrigation. To ensure 24/7 drip irrigation capability, the battery group must have sufficient power capacity. The designed system can be operated at various times throughout the day and night, owing to the digital timer. Thanks to the soil moisture controller, effective drip irrigation can be carried out by taking into account the predefined soil moisture threshold. In this application, the soil moisture controller constantly measures soil moisture using a sensor. If the soil moisture level falls below the specified threshold and the time is within the set time period, the control unit allows the battery group to power the submersible pump. If the soil moisture level exceeds the specified threshold or the time is outside the set time period, the control unit does not allow the battery group to power the submersible pump. With this solar-based irrigation system, olive trees' water needs are continuously met by considering soil moisture. Thus, an efficient, eco-friendly, cost-effective, and sustainable drip irrigation is realized and agricultural efficiency is increased. Additionally, this study can be used in any agricultural estate and the mentioned solar-based irrigation system will constantly support the development of the agricultural sector.

Keywords: Off-grid photovoltaic system, Solar based drip irrigation, Renewable energy, Sustainable production, Soil moisture-controlled system

INTRODUCTION

Water is a highly critical resource for agricultural production and accounts for about 70% of total freshwater use worldwide (Sidik et al., 2025). Agricultural irrigation systems are designed to mitigate adverse effects of insufficient rainfall and to promote the growth of crops or trees. In the developing world, crop yields in irrigated areas are consistently higher than those in rain-fed areas (Bhavsar et al., 2023).

While various agricultural irrigation methods exist, nowadays systems that both use water efficiently and provide crops or trees with the exact amount of irrigation they need have come to the forefront due to global climate change. Drip irrigation is a method that ensures significant water savings. Water is supplied drop by drop directly to the root zone of crops or trees. With its effective use, evaporation and surface runoff of water can be controlled (Ahmed and Fernando, 2017). Since it can be installed both above and below ground, it enables sufficient and efficient agricultural irrigation. However, the potential clogging of drippers can negatively affect irrigation efficiency (Junjie et al., 2012). Due to continuous reliance on inefficient traditional irrigation methods, significant water losses have occurred and pressure on water resources has increased, particularly in arid and semi-arid regions (Sidik et al., 2025). Therefore, the use of drip irrigation systems is important.

Agricultural irrigation conducted only through drip irrigation cannot be considered a fully water-efficient system on its own. Utilizing sensor technology in agricultural irrigation and establishing an appropriate automation system supports sustainable agricultural production (Bhavsar et al., 2023). In particular, integrating soil moisture sensors into irrigation systems enhances efficiency in irrigation management. Through the soil moisture sensor, the soil moisture level of the relevant crop or tree can be measured in real time. Based on the data obtained instantly, it can be used to irrigate them according to their needs (Sidik et al., 2025).

If agricultural irrigation is to be carried out with appropriate automation, the choice of the electricity source to be used becomes important. In agricultural irrigation, the power grid or fossil fuel-based generators are generally used. However, in rural areas, access to fossil fuels or the power grid is not always easy. Therefore, off-grid electricity sources are needed (Grant et al., 2022). The integration of renewable energy resources (RES) into agricultural irrigation systems supports the sustainability of agriculture.

It is possible to use solar energy, one of the RESs, to meet the electrical power demand of agricultural irrigation systems. Solar energy stands out as one of the most important RESs thanks to its almost zero operating costs, long service life, and inexhaustible energy supply (Şen, 2023). The use of solar energy reduces dependence on environmentally harmful fossil fuels (Sidik et al., 2025). Türkiye's geographical location provides a significant advantage for generating electrical power from solar energy (Şen, 2024). Figure 1 shows Türkiye's solar energy potential map.

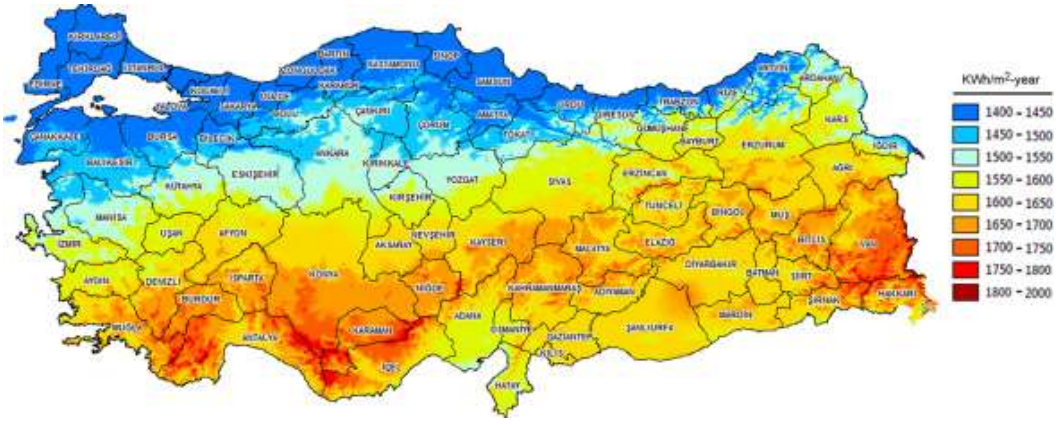

Figure 1. Türkiye's solar energy potential map (Kabalci et al., 2016)

Olive trees are a characteristic species of the Mediterranean basin, representing around 96% of the trees in the region. Olive trees are drought-resistant and have adapted well to arid and semi-arid areas with low water availability. Olive trees are traditionally cultivated using the dry farming method; nevertheless, the yield improvements provided by supplementary irrigation have led to growing interest in water use in olive cultivation. In olive trees, fruit development occurs in three main stages: flowering, pit hardening, and post-pit hardening. These stages differ in their tolerance to water stress. Flowering and post-pit hardening are water-sensitive stages. In contrast, pit hardening is recognized as a drought-tolerant stage. Therefore, additional irrigation during the water-sensitive stages of the plant cycle improves vegetative growth. It increases olive production, which also results in a greater amount of olive oil. The main reason for this increase is that the fruits are larger and there is a higher yield of fruit per tree (Yorulmaz et al., 2019).

In this study, the installation of an off-grid solar-based, soil moisture-controlled 24-hour drip irrigation system is performed in an olive grove located in Ezine, Çanakkale, Türkiye. The installed system contains two photovoltaic (PV) panels (12 Volt, 340 Watt), a battery group (12 Volt), a 12 Volt direct current (DC) submersible pump and a control unit. The control unit defines the operating conditions of the submersible pump and consists of a circuit breaker, a solar charge controller, a digital timer and a soil moisture controller. The battery group supplies energy to both the control circuits and the DC submersible pump, enabling drip irrigation. Thanks to the digital timer, the mentioned system can be operated at different times during the day and night. Irrigation is carried out effectively by considering the soil moisture threshold determined by the soil moisture controller. With this proposed irrigation system, olive trees' water needs are continuously met by controlling soil moisture.

DESIGN AND IMPLEMENTATION OF THE PROPOSED SYSTEM

Study Area

Çanakkale is located in the Marmara Region of Türkiye. Like Istanbul, it connects the continents of Asia and Europe. The city has many districts, one of which is Ezine. Ezine lies in the southwest of Çanakkale, along the coast of the Aegean Sea. Ezine's location within Türkiye is shown in Figure 2.

Figure 2. Ezine's location within Türkiye

Çanakkale is one of the leading areas in Türkiye in terms of olive cultivation. Ezine, in particular, is an important center for olive and olive oil production. The proposed solar-based agricultural irrigation system is established on approximately three acres of olive grove in Ezine, as shown in Figure 3.

Figure 3. The olive grove in Ezine in which the study is undertaken

General Structure of the System

In this study, a system capable of performing drip irrigation at any time of the day by taking soil moisture into account is implemented in an approximately 3-acre olive grove located in Ezine, Çanakkale, Türkiye. The structural schematic of the implemented irrigation system is shown in Figure 4, and image of the system is presented in Figure 5, respectively.

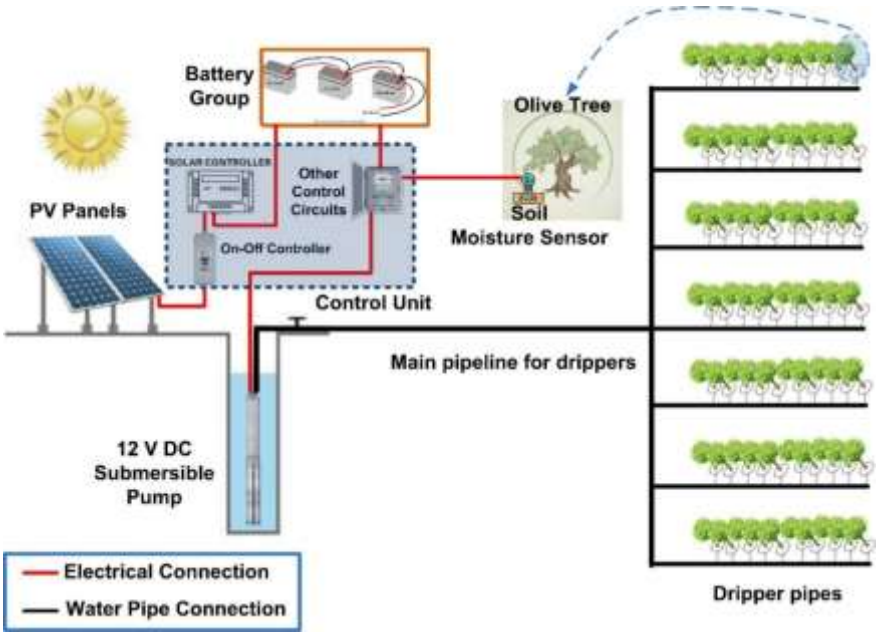

Figure 4. Structural schematic of the proposed solar-based irrigation system

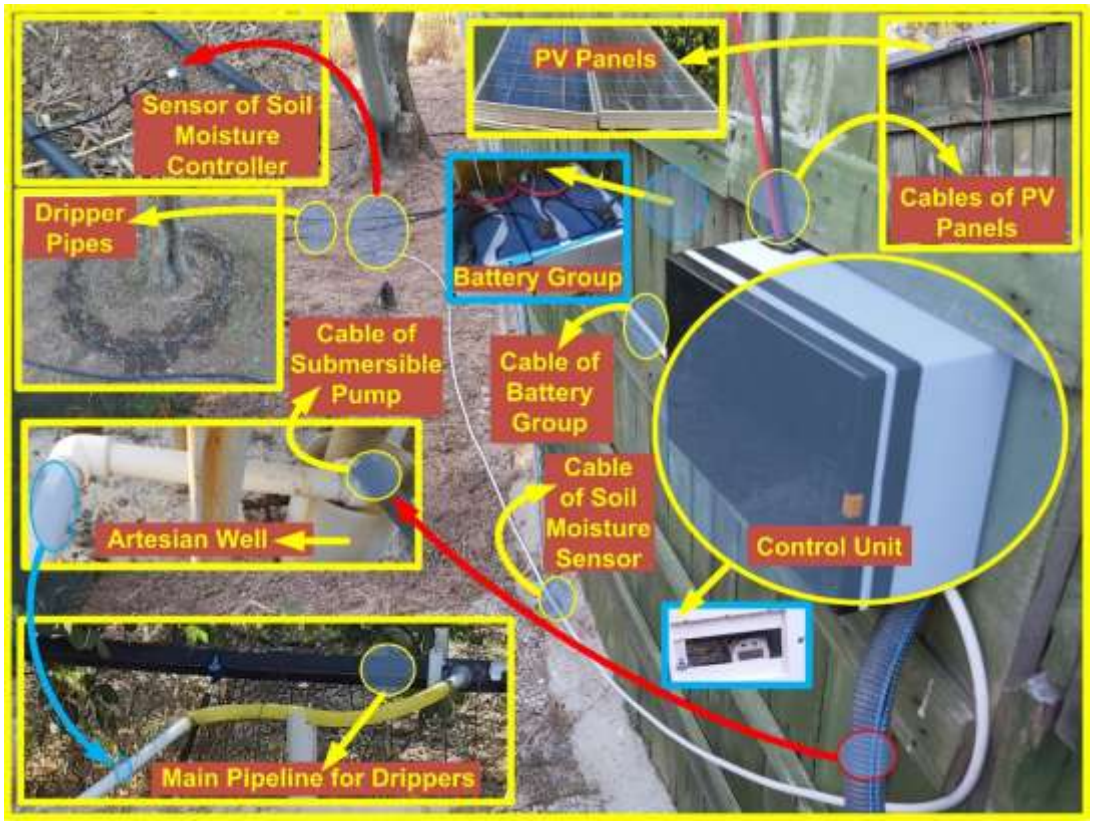

Figure 5. Image of the proposed solar-based irrigation system

As showed in Figures 4 and 5, the electrical configuration of the presented solar-based irrigation system comprises four main parts, namely PV panels, the battery group, the control unit and the DC submersible pump.
In the presented drip irrigation system, there are two PV panels and values of each PV panels are 12 Volt and 170 Watt. Also, these PV panels are connected in parallel to obtain 12 Volt, 340 Watt DC source. PV panels' technical parameters are shown in Table 1.

Table 1. Technical parameters of PV panels

Name	Rating
Panel Maximum Power	205 W
Peak Voltage	21.45V
Peak Current	9.6 A
Open Circuit Voltage	25.92 V
Short Circuit Current	9.9 A

The battery group consists of three 12 Volt, 100Ah gel batteries connected in parallel. The capacity of the battery group has been kept high because, in addition to supplying power to circuits in the control unit, it is also intended to supply energy requirements of the DC submersible pump.
Another important part of the presented solar-based irrigation system is the control unit which consists of the circuit breaker, the solar charge controller, the soil moisture controller and the

digital timer. Photograph of the control unit within the proposed solar-based irrigation system is shown in Figure 6.

Figure 6. Control unit within the proposed solar based irrigation system

Within the system, the circuit breaker fulfills two primary roles. Firstly, it protects the entire system in case of a possible electrical fault. Secondly, it acts as an on-off controller that disconnects or connects PV panels to the system whenever required.
The solar charge controller manages the energy transfer from PV panels to the battery group. It keeps the battery group safe from overcharging. Some parameters of the solar battery charge controller are shown in Table 2.

Table 2. Some parameters of solar charge controller

Name	Rating
Rated Charge Current	10 A
Operating Voltage	12/24Volt auto sensing/auto switching
Control Method	Pulse width modulation (PWM) pulse-duration modulation charge mode
Working Temperature	-35ºC to +60ºC

The digital timer and the soil moisture control circuit are powered by the voltage of battery group. Both of these elements of the control unit contain relays that perform switching in the main circuit. The terminals of these relays are connected in series and are electrically positioned between the battery group and the DC submersible pump. Thus, via these relays, the battery group either energizes the DC submersible pump or it doesn't. The digital timer can be

programmed multiple times during desired intervals of the week. Thus, the relay of the digital timer allows current flow during the specified time periods. The soil moisture control circuit, through its sensor, measures the soil moisture level in the root zone of the relevant olive tree. Using the buttons on the circuit, the soil moisture threshold for drip irrigation can be set. Based on this set soil moisture threshold, the relay inside the soil moisture controller allows current flow. As a result, for the battery group to energize the DC submersible pump and enable drip irrigation, both these relays mentioned must allow current flow.
The last main part of the presented solar-based irrigation system is DC submersible pump. There is an artesian well with a depth of thirty-three meters in the olive grove where the study is carried out. The water level is about six meters below the ground and DC submersible pump is located at thirteen meters below the ground. DC submersible pump's technical parameters are shown in Table 3.

Table 3. Technical parameters of DC submersible pump

Name	Rating
Voltage	12 V
Power Consumption	130 W
Speed	2850 r/min
Maximum Flow Rate (Qmax)	2 m^3/h
Maximum Head (Hmax)	35 m

The overall electrical connection scheme of presented solar-based irrigation system, introduced with its image in Figure 5, is shown in Figure 7.

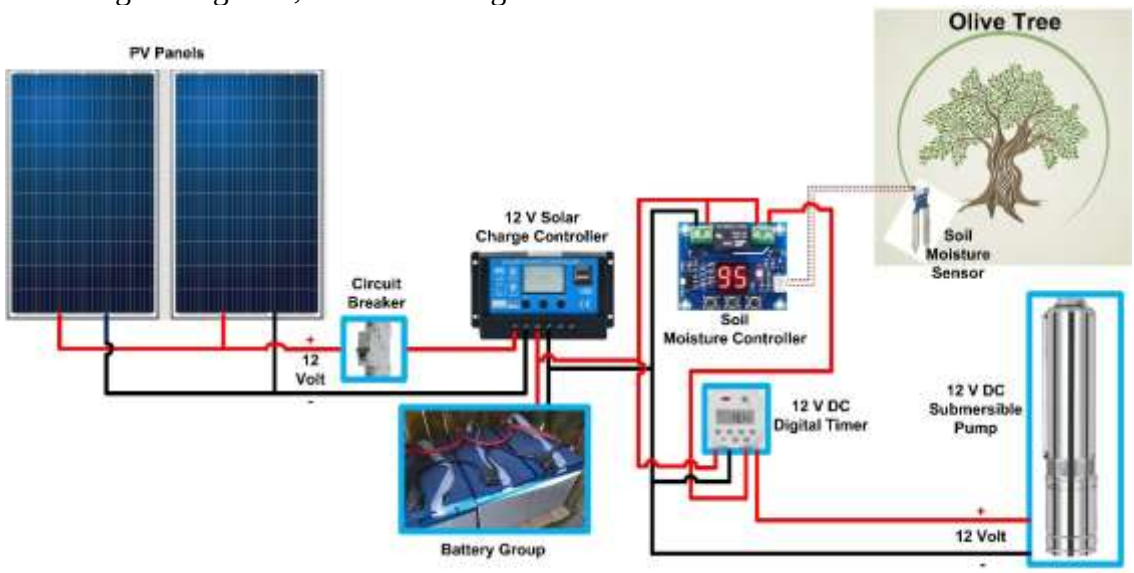

Figure 7. Overall electrical connection scheme of the presented solar-based irrigation system

Operation of the System

The operating steps of the proposed daily irrigation system are as follows:
The circuit breaker is electrically located between PV panels and the solar charge controller. This component protects the system by cutting off the circuit current in case of a possible electrical fault and also allows PV panels to be easily disconnected from the system electrically whenever needed.

The battery group is charged throughout the day via the solar charge controller. The solar charge controller is adjusted according to specifications of batteries that make up the battery group.

The battery group meets energy needs of both control circuits (the soil moisture controller and the digital timer) and the DC submersible pump. Since control circuits remain continuously powered, preset values for control are not erased. In addition, the battery group has been selected with a high energy capacity to meet the energy demand of the DC submersible pump.

The soil moisture controller continuously measures the soil moisture value of the selected olive tree. If the measured soil moisture level is below the specified threshold, the relay inside the controller allows the current from the battery group to flow to the relevant terminal of the digital timer. However, if the measured soil moisture level is above the specified threshold, the current flow from the battery group to the relevant terminal of the digital timer is not permitted.

The digital timer can be programmed to allow the current flow from the relay of soil moisture controller to the DC submersible pump at any time of the day, regardless of whether it is daytime or nighttime. During the programmed time intervals, if the soil moisture controller permits the current flow, the battery group energizes the DC submersible pump and drip irrigation begins. Otherwise, if both the soil moisture controller and the digital timer do not simultaneously allow the current flow, the battery group cannot energize the DC submersible pump. Consequently, drip irrigation cannot be performed.

As a result, it has been determined that olive trees in the mentioned olive grove are successfully irrigated using the solar-based drip irrigation method, taking into account the soil moisture level at any time of the day.

CONCLUSIONS

As impacts of global climate change on agricultural production continue to increase, priority is being given to the efficient management of water resources and the use of RESs. In this study, the off-grid solar-based, soil moisture-controlled 24-hour drip irrigation system is designed and installed for olive grove irrigation in Ezine district of Çanakkale province. The proposed system includes the battery group with high energy capacity and the digital timer. The use of these elements makes it possible to carry out agricultural irrigation around the clock. In addition, thanks to the soil moisture sensor integrated into the system, olive trees are irrigated only when needed. This approach not only prevents unnecessary use of water but also helps ensure optimal irrigation of olive trees. As a result, this application offers a holistic solution that brings together the principles of sustainability, efficiency, and environmental responsibility in agricultural production. This approach can help reduce the negative impacts of climate change and support food security. This practice, tested in the olive grove, can be adapted to agricultural areas of different scales or used for the irrigation of other crops. The proposed study is considered to contribute to the development of sustainable agriculture.

ABSTRACT

Humic substances are widely employed in agriculture due to their capacity to enhance crop yields and improve soil quality. Among these, humic acid often exhibits superior efficacy. This study aims to isolate and characterize humic substances, particularly humic acid, for subsequent agricultural applications. The raw material was cow manure compost pretreated with nitric acid, containing 36.68% C and 6.47% N. Characterization was performed using X-ray diffraction (XRD), Fourier-transform infrared spectroscopy (FTIR) and UV–visible (UV–Vis) spectroscopy. XRD patterns revealed ordered, graphite-like aromatic domains within the extracted humic acid, while UV–Vis and FTIR analyses confirmed the clear distinction between humic acid and fulvic acid and highlighted the higher aromaticity and structural complexity of humic acid compared with the more oxygen-rich, reactive fulvic acid. These features indicate that nitric-acid–assisted cow manure compost is a promising source of functional humic fractions for soil conditioning and sustainable agricultural use.

INTRODUCTION

The rapid growth and clustering of urban, agro-industrial and livestock activities in limited areas has greatly increased the generation and accumulation of organic wastes, which often become sources of soil, air and water pollution. To manage these wastes safely and efficiently, their recycling through agricultural use has received considerable attention, whether as organic fertilizers, soil amendments, or substrates for soilless cultivation systems (Sánchez-Monedero et al., 1996).Humic substances (HS) represent the highly transformed fraction of non-living natural organic matter, formed from complex organic compounds whose structures vary widely in complexity. They are often referred to as the “black gold of agriculture” because of their agronomic value (Cristina et al., 2020). Beyond their fertilizing effect, humic substances play a key role in the transport, immobilization and degradation of organic and mineral contaminants

such as pesticides, polycyclic aromatic hydrocarbons and heavy metals in soils and aquatic environments, a role that arises from their particular chemical and structural features (Koriko et al., 2013).

Humic substances are made of long carbon chains that resist microbial breakdown and are mainly composed of carbon, oxygen, hydrogen, nitrogen and sulphur. They contain many types of organic structures, such as polypeptides, polysaccharides, esters, ethers, phenols, lipids, quinones, aromatic rings, and various aliphatic compounds.

They are usually divided into three fractions based on solubility: humic acid, fulvic acid and humin. Humic acid consists of both aromatic and aliphatic acids, fulvic acid is smaller, more oxidized and soluble over a wide pH range, while humin is the heaviest fraction and remains insoluble in both acidic and alkaline solutions.

Their functional groups dissociate and give humic substances an overall negative charge, which allows them to strongly bind positively charged ions and molecules. Thanks to this chemical behaviour, they can improve soil fertility and water retention, stimulate root development and nutrient uptake, influence plant physiology and yield, and help remediate polluted soils and wastewater (Mosa et al., 2020).

In this context, the objective of the present study is to isolate and characterize humic substances in order to enable their subsequent use in agricultural systems.

MATERIALS AND METHODS

1.1. The preparation of the raw material

The raw material used in this study is caw manure chemically treated by nitric acid, as detailed by (Ghallab et al., 2024):

A fixed quantity of collected manure is weighed both before and after drying to calculate its moisture content. After this, the dried manure is ground in a ball mill to create a uniform texture. Particles under 250 micrometers are separated via sieving and stored in dry bags for future use.

Next, 3 grams of this dried, ground manure are combined with 15 mL of nitric acid (at the specified concentration of 0.5 M) to form a paste. The paste's pH is then adjusted to neutral using a potassium hydroxide solution. The final product is dried and stored for later application.

1.2. Separation of Humic Acid

The Humic Substances (HA: Humic Acid and FA: Fulvic Acid) were separated from manure compost according to (Gomes Junior et al., 2019) as follows:

The extraction was conducted using a solution of 0.1 mol L-1 NaOH (1:10, v: v) under a nitrogen (N_2) atmosphere. The mixture was stirred for 4 hours and then centrifuged at 3000 g for 20 minutes. The supernatant was acidified to pH 1.5 using 6 mol L^{-1} HCl and allowed to sit overnight at 4°C. After centrifugation, the supernatant (FA) was stored. The Has were solubilized and precipitated two more times, then treated for 16 hours with a solution of HCl: HNO3 diluted at 1:20 (v: v). The solution was added gradually under stirring until complete dissolution, noting the required volume. The HAs solution was then titrated to pH 7.0 using a solution of 0.1 mol L-1 KOH. Finally, then dried by lyophilization and stored.

1.3. Characterisation of Humic Acid

The crystalline structure and mineral composition of HA were evaluated via X-ray diffraction (XRD) on a Bruker D8 ADVANCE diffractometer. Measurements occurred at 25°C, scanning the 2θ range of 10–90° at 0.015° steps per second.

Ultraviolet (UV) and Fourier transform infrared (FTIR) spectroscopy were used to characterise humic acids. UV absorbance values were measured using a Jenway UV-visible spectrophotometer with plastic cuvettes (1cm x 1cm) at 25 ˚C. A Shimadzu IRAffinity-1S Fourier transform infrared spectrophotometer was used. Samples were analysed over the mid-infrared range from 400 to 4000 cm^{-1}.

RESULTS AND DISCUSSION

1.4. Characterization of Humic Acid by XDR

The XRD pattern in Fig. 1 shows a highly crystalline HA structure, with sharp peaks at 2θ = 24°, 28°, and 58°. These distinct peaks confirm ordered molecular arrangements in HA, despite its macromolecular nature and variable composition.

Key features include the prominent G band at ~2θ = 24°, linked to graphite-like aromatic groups (Sudiono et al., 2017), consistent with the (002) graphite peak seen in prior HA studies (Balmori et al., 2012). A secondary peak at ~28° and a broader, weaker one at 58° indicate HS-specific structures. Additional sharp, unidentified peaks suggest organic impurities or residual crystalline phases from extraction.

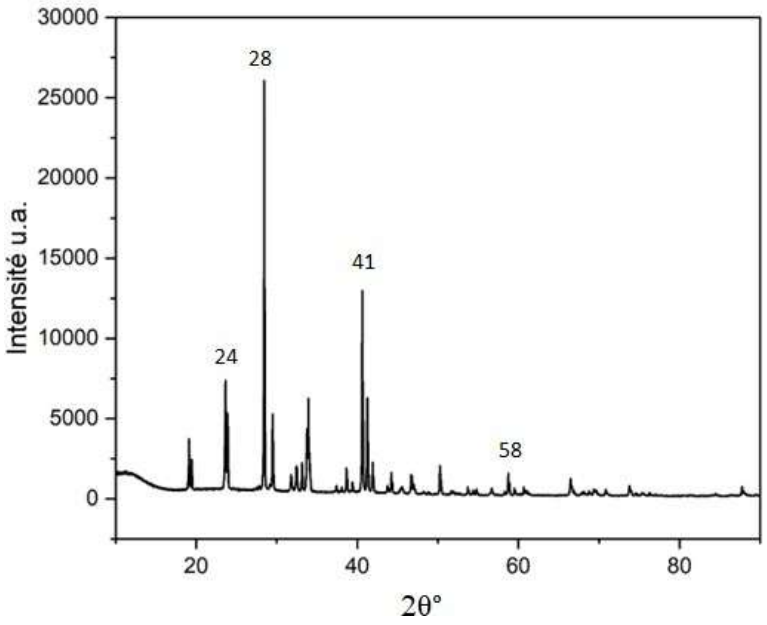

Figure 1. XRD Pattern of HA

1.5. Analysis of separated HS by Ultraviolet-Visible Spectroscopy

The E4/E6 ratio, based on absorbance at 472 and 665 nm, is a widely accepted parameter commonly used to characterize humic substances (HS), including humic acids (HA) and fulvic acids (FA). According to the literature, a ratio below 5 indicates the presence of HAs, which are known for their long carbon chains, high molecular weight, and aromatic structures. A ratio above 5 suggests the presence of FA, which are more oxygenated and carry more carboxylic groups. They are also generally lower in molecular weight and more chemically reactive (Koriko., 2010).

Table 1. Welt ratio Results

Abs	E_4 (465nm)	E_6 (665nm)	E_4/E_6
HA	0.087	0.02	4.35
FA	0.074	0.01	7.4

The data in (table 1) reflect these trends: the HA sample has an E_4/E_6 ratio of 4.35, confirming its identity as HA; the FA sample has a ratio of 7.4, indicating its identity as FA. These results align with previous studies' findings, including those by Aylaj et al. (2023). This validates the usefulness of the Welt ratio in distinguishing HS types based on their chemical characteristics and behaviour in soil systems.

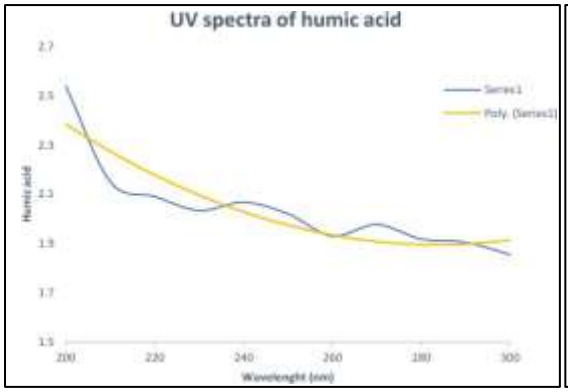

Figure 2a. spectra of HA from 200 to 300nm

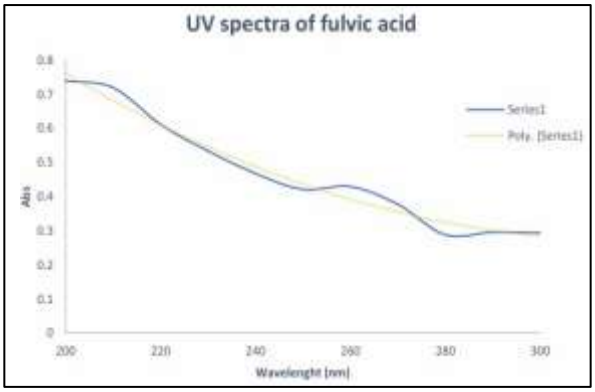

Figure 2b. UV spectra of FA from 200 to 300nm

The UV-Vis spectra of humic acid (HA) and fulvic acid (FA), recorded between 200 and 300 nm (Figures 2.a and 2.b), showed a steady drop in absorbance as the wavelength increased, which is a typical trait of humic substances. As noted by Uyguner et al (2007), these spectra tend to be broad and lack sharp peaks, with intensity gradually fading at higher wavelengths. Subtle shoulder bumps between 240 and 290 nm hint at the presence of aromatic or unsaturated structures like C=C, C=O, or N=N groups (Purmalis & Klavins, 2013). Interestingly, HA consistently absorbed more strongly than FA, particularly at shorter wavelengths, which points to its greater molecular complexity and larger size.

1.6. HA and FA Analysis using Fourier Transform Infrared Spectroscopy

The FTIR spectrum of humic acid (Figure 3.a) displays key peaks that reflect its complex molecular structure. A broad band between 3700–3400 cm^{-1} indicates O–H stretching, typical of hydroxyl groups in alcohols, phenols, and carboxylic acids. The peak near 2920 cm^{-1} corresponds to C–H stretching in aliphatic or methoxy groups, suggesting the presence of alkyl chains. A sharp peak at 1635 cm^{-1} is mainly associated with C=O stretching from carbonyl compounds and possibly C=C bonds in aromatic structures. A weaker band at 1380 cm^{-1} points to CH_3 bending vibrations, while peaks in the fingerprint region—such as those around 993, 800, and 472 cm^{-1}—are linked to aromatic C–H out-of-plane bending and possibly sulfur-containing groups (Koriko., 2010).

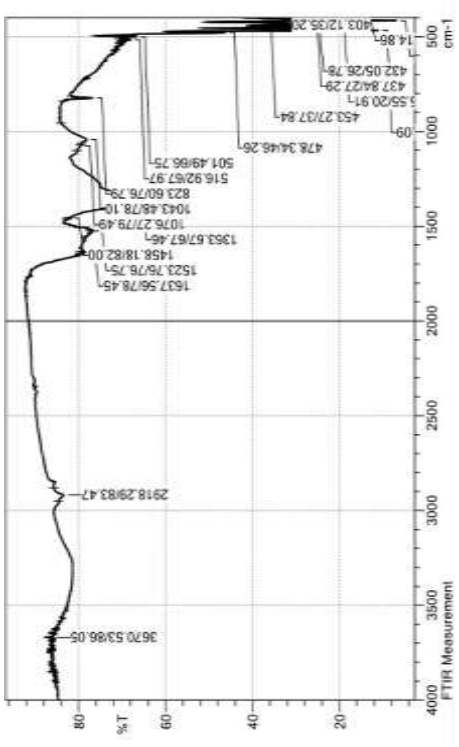

Figure 3.a. FTIR spectrum of HA

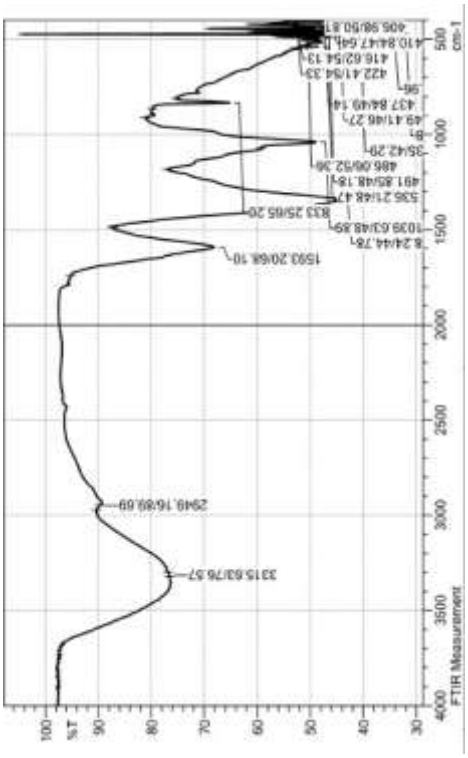

Figure 3.b. FTIR spectrum of FA

The FTIR spectrum of fulvic acid (Figure 3.b) shows several notable differences compared to that of humic acid. A broad peak around 3315 cm^{-1} indicates O–H stretching, pointing to the presence of hydroxyl groups, carboxylic acids, and phenols—similar to HA but slightly shifted. The band at 2949 cm^{-1} corresponds to C–H stretching vibrations from aliphatic chains or methoxy groups, suggesting FA also contains alkyl structures. A distinct peak at 1593 cm^{-1} is linked to C=C or C=O stretching in aromatic or conjugated systems, which appears more prominent in FA, indicating a greater presence of such structures. Additional peaks between 1170 and 1030 cm^{-1} are associated with C–O–C bonds, typical of esters or carbohydrates. Finally, signals below 600 cm^{-1} suggest the presence of aromatic or possibly sulfur-containing groups.

Both HA and FA share some functional groups, but FA is more reactive and contains more oxygen-based functional groups, such as phenols and carboxyls. Meanwhile, HA shows a more complex molecular structure, with more diverse functional groups, including sulphur-containing components and a higher degree of aromaticity. These differences in structure and functionality make each substance unique in its chemical behaviour and potential applications (Niu et al., 2019).

CONCLUSION

The study successfully isolated humic substances, particularly humic acid, from nitric-acid–treated cow manure compost and provided a detailed structural characterization using XRD, UV–Vis and FTIR spectroscopy. XRD analysis revealed that the extracted humic acid retains ordered, graphite-like aromatic domains together with additional crystalline features, indicating a structured but chemically heterogeneous macromolecule.

UV–Vis measurements, including the E4/E6 ratio and spectral shape, confirmed the clear differentiation between humic acid and fulvic acid, in line with their expected molecular size, degree of condensation and oxygenation, and supported their correct assignment as distinct humic fractions. FTIR spectra further highlighted both shared and distinct functional groups in HA and FA, showing that fulvic acid is richer in oxygen-containing, more reactive moieties, whereas humic acid displays greater aromaticity and a broader diversity of functional groups, including possible sulphur-containing structures.

Taken together, these results demonstrate that cow manure compost, after nitric-acid pretreatment, is a suitable and valuable source of structurally well-defined humic fractions with complementary properties, making them promising candidates for use as soil conditioners and functional inputs in sustainable agriculture. The distinct structural features and reactivities of HA and FA identified in this work can guide their targeted application in improving soil quality, nutrient dynamics and remediation of contaminated environments

ABSTRACT

Daffodil (*Narcissus tazetta* L.) is an important geophyte for cut-flower production, landscape design, potted-plant use, and the perfumery and cosmetics industries because of its natural distribution across the Mediterranean Basin, showy flower clusters, and characteristic fragrance. The presence of native and naturalized Narcissus taxa in Türkiye makes this plant group important not only as ornamental material but also as a genetic resource with a long-standing place in collective cultural memory through its distinctive scent. This study aimed to characterize the volatile aroma profiles of naturally occurring N. tazetta flowers from Adana and Mersin provinces and to compare regional differences. Volatile organic compounds in the flower samples were analyzed using headspace solid-phase microextraction coupled with gas chromatography–mass spectrometry (HS-SPME/GC-MS), classified by chemical group, and evaluated according to their relative percentages in the total volatile fraction. The results revealed clear chemical differentiation between the Adana and Mersin populations. Ketones were dominant in the Adana samples (56.26%), whereas the Mersin samples exhibited a more balanced profile comprising ketones (37.90%), alcohols (33.47%), and terpenes (15.56%). The Adana population was characterized by a high proportion of 1-(2-methylphenyl)ethanone, while the Mersin population contained higher levels of linalool (21.15%) and (E)-β-ocimene (9.65%). These findings indicate that natural N. tazetta populations warrant further evaluation for aromatic genotype selection, ornamental breeding, perfumery and cosmetic applications, and conservation of genetic resources.

Keywords: Aroma profile, Daffodil, HS-SPME/GC-MS, Natural population, *Narcissus tazetta* L, Volatile organic compounds.

1. INTRODUCTION

Narcissus L. is a bulbous geophyte genus in the family Amaryllidaceae, with a broad distribution extending from the Mediterranean Basin to southern Europe, North Africa, and parts of Asia. Although the Iberian Peninsula is regarded as a major center of diversity for the

genus, *Narcissus tazetta* L. is among the species notable for its extensive range, from the Mediterranean coasts to China and Japan (Fernandes, 1968; Davis, 1984; Blanchard, 1990; Mathew, 2002; Kington, 1989; Rivera et al., 2003). The occurrence of native and naturalized Narcissus taxa in the flora of Türkiye makes the country an important reservoir of genetic resources for the genus (Alp et al., 2015).

N. tazetta is considered one of the most widespread naturally occurring daffodil species in Türkiye. Alp et al. (2015) reported that the species occurs naturally along the Black Sea, Aegean, Marmara, and Mediterranean coastal belts as well as in Southeastern Anatolia, and that two subspecies and double-flowered forms are found in Anatolia. More recently, Zeybekoğlu et al. (2025) investigated *N. serotinus* s.l. populations from southwestern Türkiye using a cytogenomic approach and demonstrated pronounced cytogenetic diversity associated with polyploidy and hybridization in this taxonomically complex group, emphasizing the importance of Türkiye as a region for speciation and hybridization within Narcissus.

Historically, daffodils have been cultivated in Anatolia and throughout the Mediterranean cultural landscape for the pleasant fragrance of their flowers, becoming part of urban culture and traditional garden heritage. Different forms were reportedly cultivated in southern Anatolia during the Roman period and in İstanbul during the Ottoman era, and some forms were subsequently introduced to Europe through İstanbul (Baytop and Mathew, 1984; Zarifikhosroshahi et al., 2021). Today, daffodils are used as garden perennials, cut flowers, potted plants, and outdoor ornamentals; their fragrant flowers also have value for the perfumery and cosmetics industries (Hanks, 2002; Zarifikhosroshahi et al., 2021).

Floral scent is a complex trait produced by varying proportions and combinations of volatile organic compounds. These compounds may function as ecological signals in plant–pollinator interactions while also having economic value in the perfumery, cosmetics, aromatherapy, and ornamental-plant sectors (Jurgens et al., 2000; Kim et al., 2000). Headspace solid-phase microextraction (HS-SPME), particularly when coupled with GC-MS, is widely used for floral scent analysis because it allows volatile compounds to be sampled with minimal disturbance of the natural scent profile (Barták et al., 2003; Chen et al., 2013). However, the quantitative composition of floral volatiles may be influenced by geographic environment, ecological conditions, harvest time, and flowering stage (Edris et al., 2008).

In a previous study on aroma compounds of *N. tazetta* ecotypes originating from Türkiye, volatile constituents of flowers collected from İzmir, Siirt, and Şırnak/Cizre were identified by HS-SPME/GC-MS, with β-ocimene and benzyl acetate reported among the principal aroma compounds (Zarifikhosroshahi et al., 2021). That study demonstrated that natural ecotypes from different regions of Türkiye may differ in aroma composition. Nevertheless, the comparative aroma profiles of natural populations from Adana and Mersin, both located within the Mediterranean coastal belt, merit separate investigation.

The aim of this study was therefore to determine the volatile organic compound profiles of naturally occurring *N. tazetta* flowers from Adana and Mersin provinces using HS-SPME/GC-MS, compare differences in chemical groups and dominant compounds between the two regions, and evaluate the findings in relation to aromatic genotype selection, ornamental plant breeding, perfumery and cosmetics applications, and conservation of natural populations.

2. MATERIALS AND METHODS

2.1. Plant material and sampling

The plant material consisted of *N. tazetta* flowers collected from naturally occurring populations in Adana and Mersin provinces. Samples were obtained during the natural flowering period from healthy, fully opened flowers. The two locations were selected because both provinces are situated within the Mediterranean coastal zone, fall within the natural distribution range of *N. tazetta*, and contain local populations traditionally recognized for their pronounced fragrance. After collection, flowers were transported to the laboratory under conditions designed to minimize the loss of volatile compounds, and analyses were conducted without delay.

2.2. HS-SPME/GC-MS analysis

Volatile organic compounds in the flower samples were determined by headspace solid-phase microextraction coupled with gas chromatography–mass spectrometry (HS-SPME/GC-MS). HS-SPME is a rapid, solvent-free sample-preparation technique in which volatile compounds released from floral material into the headspace are adsorbed onto a coated fiber. Compared with thermal extraction methods such as hydrodistillation, this approach is preferred in floral-scent studies because it can provide a closer representation of the flower's natural volatile profile (Barták et al., 2003; Chen et al., 2013; Zarifikhosroshahi et al., 2021).

During analysis, volatile compounds released from the flower samples were adsorbed onto an SPME fiber and subsequently thermally desorbed into the GC-MS system for separation and identification. Compound identification was based on retention time, retention index, and mass-spectral library matches. Identified compounds were classified into the major chemical groups of aldehydes, alcohols, esters, acids, ketones, and terpenes.

2.3. Data evaluation

Each compound detected in the Adana and Mersin samples was evaluated according to its relative percentage of the total volatile compounds. First, the overall distributions of the major chemical groups were compared, after which the principal compounds within each group were examined. The findings were interpreted in terms of regional differences in aroma profile, potential chemotypic differentiation, and aromatic genotype selection. Because the study was descriptive and comparative in nature, the results were evaluated on the basis of relative volatile-compound percentages.

3. RESULTS

3.1. Regional distribution of volatile-compound groups

The volatile-compound composition of naturally occurring N. tazetta flowers differed between the Adana and Mersin populations. Ketones were the dominant chemical group in the Adana population, accounting for 56.26% of the total profile. In the Mersin population, ketones accounted for 37.90%, whereas alcohols (33.47%) and terpenes (15.56%) occurred at substantially higher proportions than in Adana (Table 1).

Table 1. Distribution of volatile-compound groups in naturally occurring N. tazetta flowers from Adana and Mersin (%)

Chemical group	Adana (%)	Mersin (%)	Regional pattern
Aldehydes	–	0.40	Detected only at a low level in Mersin
Alcohols	25.51	33.47	Higher in Mersin
Esters	11.32	12.17	Similar in the two regions
Acids	0.46	0.50	Very low and similar in both regions
Ketones	56.26	37.90	Markedly higher in Adana
Terpenes	6.45	15.56	Markedly higher in Mersin

3.2. Dominant aroma compounds

Among the compounds identified, 1-(2-methylphenyl)ethanone was the most abundant ketone in both regions. It represented 56.26% of the total volatile compounds in Adana and 37.71% in Mersin. Linalool was markedly more abundant in Mersin (21.15%) than in Adana (11.33%). Similarly, (E)-β-ocimene accounted for 9.65% in Mersin but only 2.77% in Adana. Benzyl acetate was detected at comparable levels in Adana (3.08%) and Mersin (2.76%) (Table 2).

Table 2. Major volatile compounds detected in naturally occurring N. tazetta flowers from Adana and Mersin (%)

Chemical group	Compound	Adana (%)	Mersin (%)	Interpretation
Ketone	1-(2-Methylphenyl)ethanone	56.26	37.71	Dominant compound defining the Adana profile
Alcohol	Linalool	11.33	21.15	Key compound contributing to the floral character of Mersin
Ester	Benzyl acetate	3.08	2.76	Comparable levels in both regions
Ester	Hydrocinnamyl acetate	5.08	5.44	High and similar in both regions
Terpene	(E)-β-Ocimene	2.77	9.65	Markedly higher in Mersin
Terpene	3,7-Dimethyl-1,3,6-octatriene	1.47	3.33	Higher in Mersin
Alcohol	1,8-Cineole	1.44	4.06	Higher in Mersin
Alcohol	Benzenepropanol	3.62	5.11	Higher in Mersin

3.3. Detailed results by compound group

Among aldehydes, hexanal was detected only in the Mersin samples, at 0.40%. Although present at a low level, hexanal may contribute green and fresh odor notes. No aldehyde was detected in the Adana samples at a reportable proportion of the total profile.

Alcohols constituted an important compound group in both regions; however, their total proportion was higher in Mersin (33.47%) than in Adana (25.51%). This difference was mainly attributable to higher levels of linalool, 1,8-cineole, and benzenepropanol in the Mersin

samples. The particularly high linalool content in Mersin (21.15%) suggests that this population may be distinguished by a stronger floral scent character.

The total ester fractions were similar in Adana (11.32%) and Mersin (12.17%). Benzyl acetate and hydrocinnamyl acetate were among the major esters in both populations. Previous studies have identified benzyl acetate as one of the characteristic aroma compounds of N. tazetta and other Narcissus taxa; its occurrence in both the Adana and Mersin populations is therefore consistent with the literature (Mookherjee et al., 1989; Chen et al., 2013; Zarifikhosroshahi et al., 2021).

Ketones were the principal aroma-compound group in the Adana population. Their total proportion was 56.26% in Adana compared with 37.90% in Mersin. The high value observed in Adana was largely attributable to 1-(2-methylphenyl)ethanone, indicating that the Adana population has a distinctive ketone-dominated chemical profile.

The Mersin population was clearly distinguished by its terpene fraction. Total terpenes accounted for 15.56% in Mersin compared with 6.45% in Adana. This difference was primarily associated with the high proportion of (E)-β-ocimene in Mersin (9.65%). β-Ocimene has previously been reported as an important aroma compound in daffodils (Melliou et al., 2007; Chen et al., 2013; Ruíz-Ramón et al., 2014; Zarifikhosroshahi et al., 2021).

3.4. Detailed list of compounds

Table 3. Volatile compounds identified in Adana and Mersin samples and their relative abundances (%)

Chemical group	Compound	Adana (%)	Mersin (%)
Aldehydes	Hexanal	–	0.40
Alcohols	2-Ethyl-1-hexanol	0.12	–
Alcohols	Benzyl alcohol	0.63	–
Alcohols	1,8-Cineole	1.44	4.06
Alcohols	Linalool	11.33	21.15
Alcohols	Benzeneethanol	0.72	0.35
Alcohols	α-Terpineol	2.97	–
Alcohols	Benzenepropanol	3.62	5.11
Alcohols	Geraniol	0.11	–
Alcohols	O-Methoxybenzyl alcohol	0.19	0.18
Alcohols	2-Methoxy-benzeneethanol	3.11	1.77
Alcohols	3-Phenyl-2-propen-1-ol	–	0.20
Alcohols	2-Methoxy-benzenepropanol	1.27	0.65
Esters	(E)-3-Hexen-1-ol acetate	–	0.38
Esters	Acetic acid, hexyl ester	–	0.25
Esters	Benzyl acetate	3.08	2.76
Esters	Acetic acid, nonyl ester	–	0.21
Esters	Acetic acid, 2-phenylethyl ester	2.22	1.80
Esters	Hydrocinnamyl acetate	5.08	5.44
Esters	(Z)-3-Phenyl-2-propenoic acid, methyl ester	0.24	–
Esters	(E)-Cinnamyl acetate	–	0.22
Esters	Benzoic acid methyl ester	0.15	–
Esters	Isoeugenyl acetate	0.14	–
Esters	Benzyl benzoate	0.65	0.87
Acids	Acetic acid	0.46	0.50
Ketones	1-(2-Methylphenyl)ethanone	56.26	37.71
Ketones	4-(4-Methoxyphenyl)-2-butanone	–	0.19
Terpenes	Limonene	–	0.23
Terpenes	(E)-β-Ocimene	2.77	9.65

Terpenes	3,7-Dimethyl-1,3,6-octatriene	1.47	3.33
Terpenes	1,3,8-Para-menthatriene	0.29	0.31
Terpenes	2,6-Dimethyl-2,4,6-octatriene	–	0.87
Terpenes	1,3-Methoxy-benzene	0.10	–
Terpenes	1-Methoxy-4-(1-propenyl)-benzene	1.82	1.17

-: not detected

4. DISCUSSION

This study compared the volatile aroma profiles of naturally occurring N. tazetta flowers from Adana and Mersin provinces. The results showed that the two populations differed in both the overall distribution of volatile-compound groups and the identity of their dominant compounds. These findings support the initial expectation that natural populations may exhibit regional differentiation in aroma profile. The dominance of ketones and the high proportion of 1-(2-methylphenyl)ethanone in the Adana population indicate a ketone-dominated chemical character, whereas the higher proportions of alcohols and terpenes in Mersin—particularly linalool and (E)-β-ocimene—suggest that these compounds play a greater role in defining the Mersin aroma profile.

The most striking finding was that ketones accounted for more than half of the total volatile profile in the Adana samples. In contrast, the lower ketone proportion and higher alcohol and terpene fractions in Mersin demonstrate that pronounced regional chemical differentiation may occur within the same species. This supports the view that natural populations should be evaluated not only on the basis of morphological and phenological traits but also according to their volatile-compound profiles when selecting aromatic genotypes.

4.1. Odor characteristics of the identified chemical groups

The sensory meaning of an aroma profile becomes more informative when the relative abundance of chemical groups is considered together with odor descriptors reported in the literature for the compounds that constitute those groups. Acetophenone-derived ketones, including 1-(2-methylphenyl)ethanone, which dominated the Adana profile, are generally associated with sweet, balsamic, almond-like, and heavy floral notes. The ketone-rich Adana profile may therefore be expected to produce an intense, sweet, full-bodied scent impression largely shaped by a single dominant compound.

In the Mersin population, linalool is associated with fresh, sweet, and floral notes; 1,8-cineole with cool, camphoraceous and eucalyptus-like notes; and (E)-β-ocimene with warm, herbaceous, and airy-floral notes. Hexanal, detected only in Mersin, may add a fresh-cut green-grass character that enhances perceived freshness. Benzyl acetate, which occurred at similar proportions in both populations, is a characteristic floral constituent of daffodil and jasmine scents and may therefore provide a shared floral identity. Taken together, the Mersin profile points toward a fresher, floral-terpenic, relatively complex, lighter, and more airy scent impression.

4.2. Potential effects of fragrance on human perception in landscape and cut-flower use

In landscape settings, fragrance is generally perceived outdoors at some distance from the plant, with volatile compounds dispersed by air movement. A Mersin-type profile dominated by highly volatile compounds with relatively low odor thresholds, such as linalool and (E)-β-ocimene, may have greater potential to create a fresh, pleasant, and relaxing scent impression

around walkways, seating areas, and recreational spaces. Such fresh-floral emissions may contribute to a positive and invigorating user experience in outdoor environments. By contrast, the ketone-rich, intensely sweet Adana profile may be perceived less as a broadly dispersed fresh scent and more as a pronounced, full-bodied fragrance at close range, potentially making it more suitable for specialized settings where strong scent perception in close proximity is desired.

In cut-flower and indoor use, fragrance is perceived within a confined space and typically at close range. Under these conditions, the intense and persistent character of the ketone-dominated Adana profile could readily fill an indoor environment; however, dominance by a single heavy-sweet note could, over time, be perceived as overpowering by some users. In contrast, the fresher, more balanced, floral-terpenic Mersin profile may provide a lighter and more refined scent impression that remains pleasant over a longer period indoors. The two populations may therefore offer different perceptual advantages depending on the distance and spatial context in which the fragrance is experienced.

4.3. Comparison with previous studies and methodological–sensory limitations

In the earlier study of Turkish ecotypes, β-ocimene and benzyl acetate were reported as major aroma constituents in samples from İzmir, Siirt, and Şırnak/Cizre, while both the number and relative abundance of compounds varied among locations (Zarifikhosroshahi et al., 2021). In the present study, the main differentiation between the Adana and Mersin samples was associated less with a β-ocimene–benzyl acetate axis and more with variation in ketones, linalool, and terpenes. Such differences may be related to ecological conditions at the collection sites, genetic structure of the populations, flowering stage, harvest time, and analytical conditions. Edris et al. (2008) likewise reported that the quantitative composition of floral aroma can vary with geographic environment and harvest time.

An important limitation is that odor perception cannot be explained solely by the percentage composition of volatile compounds. Odor thresholds differ substantially among compounds, and constituents such as linalool and (E)-β-ocimene may contribute disproportionately to perceived scent even when present at relatively low concentrations. In addition, synergistic and masking interactions among compounds may make the overall odor impression differ from the simple sum of individual components. Because the present study did not include a sensory panel or gas chromatography–olfactometry (GC-O), the interpretations of odor character and potential human perception presented above should be regarded as predictions based on odor descriptors reported in the literature and should be validated through sensory testing. Furthermore, HS-SPME/GC-MS results can be influenced by technical factors such as fiber type, extraction time, temperature, sample quantity, and the phenological stage of the flowers.

4.4. Conservation and genetic resource value

The findings demonstrate that natural daffodil populations in Türkiye should be regarded not only as components of floristic diversity or sources of ornamental plant material but also as valuable genetic resources in terms of aroma profile. Alp et al. (2015) reported that natural Narcissus populations in Türkiye occur particularly along the Taurus Mountains within the Mediterranean climatic zone and that native and naturalized populations are exposed to pressures such as urbanization, removal of gardens, and uncontrolled collection from the wild.

In this context, the distinct aroma profiles observed in the Adana and Mersin populations, together with their potential suitability for different uses, provide an additional scientific rationale for conserving and domesticating local populations. Populations that are differentiated by volatile-compound profile may be maintained in ex situ collections, developed as controlled propagation material, and incorporated into ornamental breeding programs.

5. CONCLUSIONS

In this study, the volatile aroma profiles of naturally occurring N. tazetta flowers from Adana and Mersin provinces were characterized using HS-SPME/GC-MS and the two populations were compared. The results showed that the populations exhibited distinct chemical profiles in terms of both volatile-compound groups and dominant constituents.

Ketones were the dominant chemical group in the Adana population (56.26%), with 1-(2-methylphenyl)ethanone alone accounting for 56.26% of the profile. In the Mersin population, ketones represented 37.90%, alcohols 33.47%, and terpenes 15.56%; linalool (21.15%) and (E)-β-ocimene (9.65%) were particularly prominent.

This chemical differentiation also points to two contrasting tendencies in scent character. The ketone-rich Adana profile may be associated with a sweet, full-bodied, and intense fragrance, whereas the Mersin profile, rich in linalool, 1,8-cineole, and (E)-β-ocimene, suggests a fresher, floral-terpenic, and more airy character. On this basis, Mersin-type populations with fresher and more diffusible fragrance profiles may be especially suitable for landscape settings around walking and resting areas, while Adana-type populations with stronger and more persistent fragrance may be more appropriate for cut-flower and specialized uses where scent is intended to be perceived at close range. These interpretations, however, are predictions based on odor descriptors reported for the identified compounds and should be validated through sensory analysis.

The study is limited to samples from two locations and did not include sensory evaluation. Accordingly, the findings represent the volatile-compound profiles of the sampled Adana and Mersin populations under the specific sampling conditions used here, and direct conclusions regarding fragrance preference or perceived scent intensity should not be drawn solely from chemical percentages. Broader generalization will require comparative analyses across multiple years, flowering stages, and a larger number of natural populations.

Based on the present findings, future studies should conduct multi-location aroma screening of natural N. tazetta populations; complement chemical analyses with gas chromatography–olfactometry (GC-O) and sensory panel tests to account for odor thresholds and synergistic effects; incorporate genotypes with contrasting fragrance and use profiles into ex situ collections; and develop domestication programs based on controlled propagation.

ABSTRACT

Gilaburu (*Viburnum opulus* L.) is a multipurpose shrub species in the family Adoxaceae that can be used as a fruit crop, ornamental plant, medicinal plant, and source of functional food ingredients. This study was conducted to determine selected pomological and chemical characteristics of gilaburu fruits grown in Tuşba district of Van Province and to evaluate the quality potential of the species under high-altitude, semi-arid conditions. Mean fruit weight, fruit length, fruit width, and cluster weight were 0.57 g, 9.30 mm, 10.19 mm, and 34.96 g, respectively. The fruit flesh ratio was 87.04%, and mean seed weight was 0.07 g. Color measurements yielded L*, a*, b*, Chroma, and Hue values of 27.32, 35.20, 26.68, 44.24, and 36.86°, respectively. Chemical analyses showed total soluble solids (TSS) of 13.3%, titratable acidity of 2.00%, and pH of 3.51. The findings indicate that gilaburu fruits grown under Van/Tuşba conditions, with their high flesh ratio, pronounced red coloration, suitable TSS content, and acidic character, have potential for use in juice, vinegar, fermented beverages, jam, marmalade, and as functional food ingredients. Owing to its showy flowers, red fruit clusters, and autumn foliage coloration, gilaburu also stands out as a multipurpose shrub that can provide both aesthetic and productive functions in edible landscape designs.

Keywords: Edible landscapes, Functional food, Gilaburu, Pomological characteristics, Semi-arid area, *Viburnum opulus* L.

1. INTRODUCTİON

Interest in functional foods, local genetic resources, alternative fruit species capable of adapting to climate change, and multifunctional landscape plants has increased steadily in recent years. Population growth, food-security concerns, urbanization pressure, and the effects of climate change on agricultural production have created a need to consider not only conventional high-yielding crops but also wild or semi-domesticated species with high nutritional and ecological value. In this context, edible fruit-bearing shrubs offer considerable potential for both food production and landscape design.

Gilaburu (*Viburnum opulus* L.) is a deciduous, perennial species in the family Adoxaceae that typically grows as a shrub. Internationally, the species is known by common names such as European cranberrybush, guelder rose, snowball tree, and cramp bark, whereas in Türkiye it is known by regional names including gilaburu, gilaboru, gilebor, and giligili (Kajszczak et al., 2020; Karabulut and Kaynarca, 2024). Its natural distribution extends across Europe, North Africa, northern Asia, Russia, and parts of Türkiye. In Türkiye, it is traditionally recognized

particularly in Kayseri and several other regions, where the fruits are processed into local products.

Gilaburu fruits are bright red, sour, and astringent, and are characterized by high acidity. Although these sensory properties limit direct fresh consumption, the fruits can be processed into products such as juice, fermented beverages, vinegar, jam, marmalade, pickles, tea, and dietary supplements (Güney and Gündeşli, 2022; Karabulut and Kaynarca, 2024). Previous studies have shown that gilaburu fruits are rich in phenolic compounds, organic acids, flavonoids, anthocyanins, vitamins, minerals, and various other bioactive constituents (Kajszczak et al., 2020; Ömeroğlu Gülada et al., 2025). Accordingly, the species is regarded as a valuable raw material for the functional food industry because of its antioxidant, antimicrobial, anti-inflammatory, and other biological activities.

Gilaburu is noteworthy not only for food and medicinal uses but also from a landscape architecture perspective. Its shrub form, showy white flowers, bright red fruit clusters, and autumn foliage coloration give the plant high visual value. The edible landscape approach is a sustainable landscape concept in which fruit, vegetables, medicinal and aromatic plants, and edible ornamentals are integrated according to aesthetic design principles, thereby combining productive and visual functions (Concklin et al., 2025; Zheng and Chou, 2023). In this context, gilaburu stands out as a multifunctional shrub capable of providing both aesthetic value and edible products.

Ecologically, *V. opulus* is most commonly associated with moist habitats, streambanks, forest clearings, and soils rich in organic matter. Nevertheless, selection studies conducted in the Kayseri region reported that gilaburu genotypes occur at elevations of 1,290–1,645 m, indicating that the species can also be considered for high-altitude environments (Gündoğar, 2013). Van Province, by contrast, differs markedly from typical gilaburu habitats because of its high elevation, continental climate, cold winters, dry summers, and semi-arid ecological conditions. Determining the quality characteristics of gilaburu fruits grown in Tuşba district, Van Province, is therefore important for evaluating the species' performance outside its typical natural habitat and its potential for adaptation.

The aim of this study was to determine selected pomological and chemical characteristics of gilaburu fruits grown in Tuşba district, Van Province, and, based on the findings, to assess the species' potential for adaptation, functional-food use, and edible-landscape applications under high-altitude, semi-arid conditions.

2. MATERİALS AND METHODS

2.1. Plant Material

The study material consisted of mature fruit samples collected from gilaburu (*Viburnum opulus* L.) plants grown in Tuşba district of Van Province. Tuşba is located in the Eastern Anatolia Region and is characterized by high elevation, a continental climate, cold winters, dry summers, and semi-arid ecological conditions. In this respect, the study area differs from the moist natural habitats with which *V. opulus* is generally associated. Fruit samples were collected at full maturity, when the fruits had developed their characteristic red color (Figure 1.). Healthy, undamaged fruit clusters representative of the plants were selected for sampling. The collected material was transported to the laboratory under appropriate conditions, and analyses were conducted shortly thereafter.

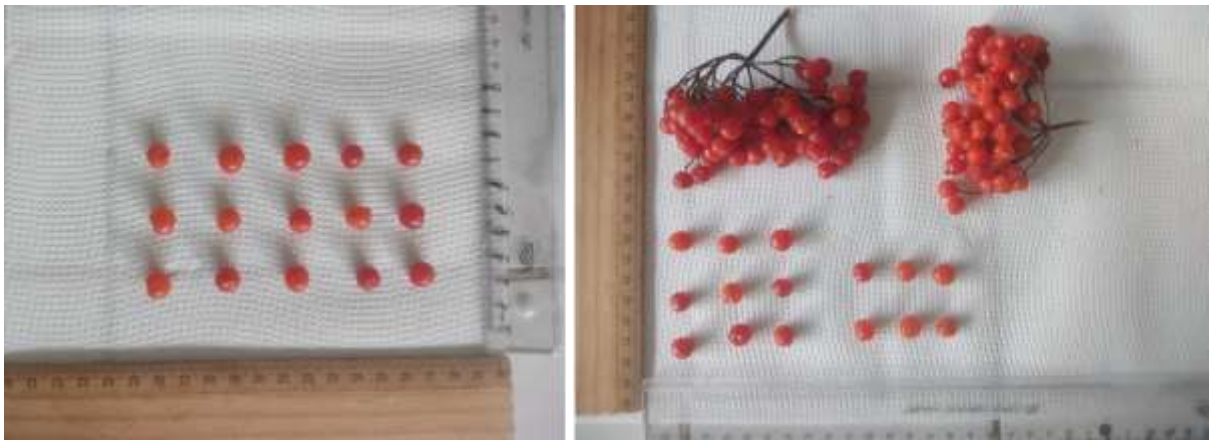

Figure 1. Fruits used as material.

2.2. Pomological Analyses

Pomological analyses included fruit weight, fruit length, fruit width, skin thickness, cluster weight, fruit flesh ratio, and seed characteristics. Fruit weight was measured in grams (g) using a precision balance (Polat et al., 2024). Fruit length and width were measured in millimeters (mm) with a digital caliper. Cluster weight was determined by weighing intact fruit clusters, and skin thickness was measured with a digital caliper.

Seed weight was determined by separating the seeds from the fruits and weighing them on a precision balance. Fruit flesh ratio was calculated as a percentage (%) by subtracting seed weight from fruit weight and dividing the resulting value by fruit weight. These parameters were used to assess the suitability of the fruit for fresh-market and processed products.

2.3. Color Analyses

Fruit skin color was measured on five fruits randomly selected from each of three replicates to represent the genotype, using a Minolta CR-400 colorimeter (Minolta Co., Tokyo, Japan). Measurements were expressed in the CIELAB color space as L*, a*, and b* values. L* indicates lightness on a scale from black (0) to white (100), while a* and b* define chromatic coordinates in the color plane perpendicular to L*. Positive a* values indicate red and negative a* values green; positive b* values indicate yellow and negative b* values blue. Before measurement, the instrument was calibrated using a standard white calibration plate. Chroma (C*), which describes color saturation or vividness, and Hue angle (h°), which describes the dominant color component, were calculated from the measured a* and b* values (Polat et al., 2024).

$C^* = (a^{*2} + b^{*2})^{1/2}$, $h^\circ = \tan^{-1}(b^*/a^*)$

2.4. Chemical Analyses

Pieces were taken from randomly selected fruits and pressed to obtain juice. The juice was filtered and pooled to produce a homogeneous juice sample.

Total soluble solids (TSS): TSS content was determined as °Brix using a digital refractometer (Atago, Japan). A portion of fruit juice was placed on the refractometer prism, and the reading was recorded as percentage TSS (Uzun et al., 2015).

Titratable acidity: A 1 mL aliquot of fruit juice was titrated with 0.1 N NaOH to pH 8.1, and titratable acidity was expressed as a percentage of malic acid (Cemeroğlu, 2007).

pH determination: A 10 mL fruit juice sample was transferred to a suitable container, and the electrode of a digital pH meter was immersed in the sample. The value was recorded after the reading had stabilized.

2.5. Data Analysis

The data obtained in the study were evaluated using descriptive statistical methods. For each trait, the mean, minimum, maximum, standard deviation (SD), and coefficient of variation (CV, %) were calculated. The findings were interpreted in terms of fruit quality, suitability for processed products, functional-food potential, and the feasibility of growing gilaburu under high-altitude, semi-arid conditions.

3. RESULTS

The pomological, color, and chemical characteristics of gilaburu (*Viburnum opulus* L.) fruits grown in Tuşba district, Van Province, are presented in Table 1.

Table 1. Pomological, color, and chemical characteristics of gilaburu fruits grown in Tuşba district, Van Province.

Characteristic	Mean	Min.	Max.	SD	CV (%)
Fruit weight (g)	0.565	0.520	0.610	0.031	5.48
Fruit length (mm)	9.298	8.900	9.700	0.273	2.94
Fruit width (mm)	10.185	9.800	10.600	0.259	2.54
Skin thickness (mm)	0.430	0.380	0.480	0.032	7.44
Cluster weight (g)	34.955	29.820	40.910	5.020	14.36
Fruit flesh ratio (%)	87.035	84.800	89.200	1.820	2.09
Seed weight (g)	0.073	0.060	0.090	0.010	13.70
Seed length (mm)	7.763	7.400	8.100	0.228	2.94
Seed width (mm)	8.693	8.300	9.100	0.254	2.92
Seed thickness (mm)	1.823	1.780	1.860	0.022	1.22
L* (Lightness)	27.315	25.100	29.800	1.520	5.57
a* (Redness)	35.203	32.700	37.500	1.620	4.60
b* (Yellowness)	26.678	20.900	32.100	5.348	20.05
Chroma (Saturation)	44.243	41.200	47.100	1.945	4.40
Hue angle (°)	36.863	34.200	39.100	1.610	4.37
TSS (%)	13.300	13.200	13.400	-	-
Titratable acidity (%)	2.003	1.980	2.040	0.026	1.31
pH	3.513	3.500	3.520	-	-

SD: Standard deviation; CV: Coefficient of variation; TSS: Total soluble solids

For pomological characteristics, mean fruit weight was 0.565 g, with values ranging from 0.520 to 0.610 g. Mean fruit length and width were 9.298 mm and 10.185 mm, respectively. These results indicate that the fruits were slightly wider than they were long, giving them a nearly round morphology. Mean skin thickness was 0.430 mm, ranging from 0.380 to 0.480 mm. Mean

cluster weight was 34.955 g, with a range of 29.820–40.910 g. Among the pomological traits, cluster weight had the highest coefficient of variation (14.36%), indicating greater sample-to-sample variability than the other parameters.

The mean fruit flesh ratio was 87.035%. Its low coefficient of variation (2.09%) indicates that this trait was highly consistent among samples. Mean seed weight was 0.073 g, while mean seed length, width, and thickness were 7.763, 8.693, and 1.823 mm, respectively. The very low coefficient of variation for seed thickness (1.22%) indicates that this was one of the most stable traits among the samples.

For fruit skin color, the mean L* value was 27.315, indicating a relatively dark appearance. The positive and high a* value (mean 35.203) reflects pronounced red coloration. The mean b* value was 26.678. Mean Chroma was 44.243, indicating high color saturation, while the mean Hue angle was 36.863°. Taken together, these color parameters show that gilaburu fruits grown under Tuşba conditions had a vivid, saturated, and visually attractive red color. Among the color traits, b* showed the greatest variation (20.05%).

For chemical characteristics, mean titratable acidity was 2.003%, with values ranging from 1.980 to 2.040%. The low coefficient of variation for acidity (1.31%) indicates that the fruits were highly homogeneous in this respect. Mean TSS was 13.300%, and mean pH was 3.513. A TSS value of approximately 13% together with a pH of around 3.5 indicates that the fruits had a distinctly acidic character.

4. DİSCUSSİON

The findings of this study show that gilaburu (V. opulus) can produce fruit under the conditions of Tuşba district, Van Province, and that these fruits possess quality attributes suitable for processing. Given that the species is most commonly associated with moist habitats and soils rich in organic matter, the results obtained in a high-altitude, semi-arid environment are noteworthy in terms of the ecological adaptability of gilaburu. They suggest that the species may be considered not only in its traditional growing regions but also in other ecological settings where suitable microclimatic and management conditions can be provided.

Overall, the pomological characteristics of fruits grown under Tuşba conditions were consistent with the typical morphology of gilaburu fruit. Their nearly round shape, occurrence in clusters, and high fruit flesh ratio (87.04%) support the species' potential for processed products. Selection studies conducted in the Kayseri region have shown that gilaburu genotypes can be evaluated at high elevations and may differ substantially in fruit quality characteristics (Gündoğar, 2013). The present findings likewise indicate that ecological conditions, genotype, and growing environment may play important roles in determining fruit characteristics.

A high fruit flesh ratio is an important characteristic that enhances the suitability of gilaburu for processed products such as juice, purée, vinegar, fermented beverages, jam, and marmalade. The relatively low seed proportion compared with the flesh may also be considered advantageous in terms of processing yield. In this context, the Tuşba samples showed a profile more suited to processed-product development than to direct fresh consumption. The astringent and sour taste of gilaburu fruit can limit fresh consumption; however, these same characteristics may contribute desirable flavor and acidity balance in fermented or heat-processed products.

Color parameters provide important indications of both visual quality and landscape value. The high Chroma value (44.24) and pronounced a* value (35.20) indicate a vivid, saturated red fruit color, a feature of value for both consumer perception and potential use as a natural color source in the food industry. Numerous studies have reported that gilaburu is rich in phenolic compounds, anthocyanins, and other bioactive constituents (Kajszczak et al., 2020; Karabulut and Kaynarca, 2024; Ömeroğlu Gülada et al., 2025). The high red color intensity observed here

may therefore be regarded not only as an indicator of visual quality but also as a preliminary finding warranting more detailed investigation of pigment content and functional compounds.

The chemical characteristics show that gilaburu fruits grown in Tuşba had a distinctly acidic character and a soluble-solids content suitable for processed products. A pH of 3.51 and titratable acidity of 2.00% may offer technological advantages in products such as juice, vinegar, fermented beverages, and jam. Arslan et al. (2018) reported a TSS content of 11.3% and a pH of 3.20 for wild-growing gilaburu fruits from Ardahan and its surroundings. The higher pH observed in the present study suggests that the chemical characteristics of gilaburu fruits may vary with growing region. Such differences may result from genotype, ecological conditions, growing environment, and harvest time. Nevertheless, the functional-food potential of gilaburu cannot be comprehensively characterized on the basis of TSS, pH, and titratable acidity alone. Future studies should therefore determine phenolic content, anthocyanin content, organic-acid profiles, antioxidant capacity, mineral composition, and sensory properties to provide a more complete assessment of the nutritional and functional value of gilaburu fruits.

This study also provides a useful basis for evaluating the suitability of gilaburu for edible landscape design. The edible landscape approach integrates food production with aesthetic and ecological functions within the same design; plants are expected not only to yield edible products but also to contribute visual quality, support pollinators, and create seasonal landscape effects (Concklin et al., 2025; Zheng and Chou, 2023). With its shrub form, showy white flowers, bright red fruit clusters, autumn foliage coloration, and edible fruits, gilaburu is particularly well suited to this approach and stands out as a multifunctional shrub that can serve both productive and aesthetic purposes in high-altitude, semi-arid regions.

The study was based on a limited number of samples, and the results should therefore be regarded as a preliminary assessment of gilaburu fruits grown under Tuşba conditions. Studies covering multiple years, different locations, and larger sample groups will be needed to evaluate the regional adaptability of the species more reliably. In addition, separate assessment of irrigation, soil properties, management conditions, genotypic variation, and microclimatic effects will be important for explaining the performance of gilaburu in semi-arid, high-altitude environments.

5. CONCLUSİON

This study showed that gilaburu (Viburnum opulus L.) fruits grown in Tuşba district, Van Province, possess quality characteristics that may be valuable under high-altitude, semi-arid conditions. The results demonstrate that the species can produce fruit under these ecological conditions, that the fruits have characteristics suitable for processed products, and that the plant has noteworthy potential for edible landscape design.

With a high fruit flesh ratio (87.04%), pronounced red coloration (Chroma: 44.24), acidic character (titratable acidity: 2.00%; pH: 3.51), and total soluble solids content of 13.3%, gilaburu fruits have potential for use in juice, vinegar, fermented beverages, jam, marmalade, and as functional food ingredients. Although their astringent and sour taste may restrict fresh consumption, these same attributes can become advantages in processed products by contributing characteristic flavor, color, and acidity balance.

The results suggest that Viburnum opulus may be considered as an alternative fruit species for Tuşba and other high-altitude, semi-arid areas with similar conditions. Because of its showy flowers, red fruit clusters, autumn foliage coloration, and edible fruits, the species may also be used as a multipurpose shrub in edible landscape applications, where it can combine aesthetic and productive functions.

This study provides preliminary evidence regarding the cultivation potential of gilaburu outside its typical natural habitat. To establish regional adaptation more reliably, future studies should include multiple years and locations, larger sample sizes, and advanced biochemical analyses, including antioxidant capacity, total phenolic content, anthocyanin content, organic-acid profiles, mineral composition, and sensory evaluation.

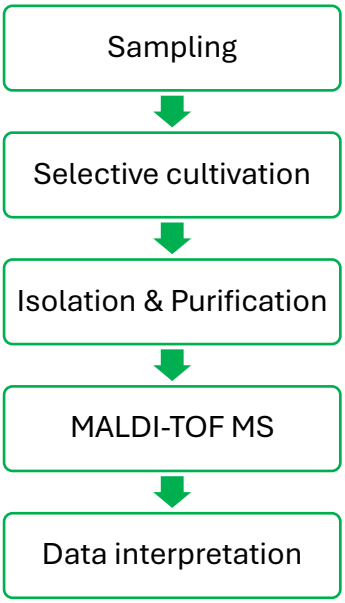
ABSTRACT

Biofilms formed on food-contact surfaces in dairy processing environments represent a major challenge to food safety due to their ability to harbor persistent microorganisms that can withstand routine cleaning and disinfection procedures. The present study aimed to identify the cultivable microbiota associated with biofilm-positive environmental samples collected from dairy processing facilities by integrating conventional microbiological cultivation with matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). Environmental swab samples previously confirmed as biofilm-positive were cultured on Bengal Rose Chloramphenicol Agar, de Man, Rogosa and Sharpe (MRS) Agar, Baird-Parker Agar supplemented with Egg Yolk Tellurite, Coliform Chromogenic Agar, and Tryptic Soy Agar. Colonies displaying distinct morphological characteristics were purified and identified by MALDI-TOF MS. A total of **47 representative isolates** were successfully identified, corresponding to **14 bacterial species** belonging to **eight genera**. The identified microbiota was dominated by members of the genera ***Staphylococcus, Enterococcus, and Escherichia, while Citrobacter, Corynebacterium, Klebsiella, Enterobacter, and Rothia*** were recovered less frequently. The predominant species included *Staphylococcus aureus*, *Escherichia coli*, *Enterococcus faecalis*, *Enterococcus hirae*, *Staphylococcus saprophyticus*, *Citrobacter freundii*, *Corynebacterium falsenii*, and *Klebsiella oxytoca*. Additional isolates comprised *Staphylococcus lugdunensis*, *Staphylococcus warneri*, *Staphylococcus haemolyticus*, *Staphylococcus carnosus*, *Enterobacter cloacae*, and *Rothia kristinae*. The recovery of hygiene indicator bacteria together with opportunistic pathogens demonstrates the high microbial diversity associated with dairy biofilms and emphasizes their potential role as reservoirs of persistent contamination. The combined approach enabled comprehensive characterization of microorganisms colonizing biofilm-positive surfaces, demonstrating the coexistence of diverse bacterial and fungal populations within dairy processing environments. Selective culture media facilitated the targeted isolation of specific microbial groups, while MALDI-TOF MS provided rapid, accurate, and reproducible identification, significantly reducing the time required for microbial characterization compared with conventional biochemical methods. The findings contribute to a better understanding of microbial persistence in food-processing environments and provide valuable information for improving environmental monitoring programs, optimizing sanitation protocols, and developing effective biofilm control strategies to enhance dairy product safety and quality.

Keywords: Biofilms; Dairy processing environment; MALDI-TOF MS; Selective culture media; Microbial identification; Food safety.



INTRODUCTION

Biofilms formed on food-contact surfaces in dairy processing environments represent a major challenge to food safety due to their ability to harbor persistent microorganisms that can withstand routine cleaning and disinfection procedures. Product contamination by pathogenic and spoilage bacteria has been linked to the presence of biofilms [2]. Microorganisms on wet surfaces have the ability to aggregate, grow into microcolonies, and produce biofilm. Biofilms are matrix protected microbial communities, often attached to a surface. It is the key feature that distinguishes a biofilm from attached bacteria and facilitates increased resistance to disinfecting agents, UV-radiation and desiccation [1].

This study aimed to identify the cultivable microbiota associated with biofilm-positive environmental samples collected from Albanian dairy processing facilities by integrating conventional microbiological cultivation with matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF MS).

MATERIAL AND METHOD

Environmental swab samples previously confirmed as biofilm-positive were collected from dairy processing environments. The samples were cultured on a range of selective and non-selective culture media to facilitate the recovery of different microbial groups, including **Bengal Rose Chloramphenicol Agar (BRCA), de Man, Rogosa and Sharpe (MRS) Agar, Baird-Parker Agar supplemented with Egg Yolk Tellurite, Coliform Chromogenic Agar,** and **Tryptic Soy Agar (TSA).** Following incubation, colonies exhibiting distinct morphological characteristics were selected and subjected to purification on **TSA** to obtain isolated cultures suitable for subsequent identification. The purified isolates were identified using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). The resulting identification data were subsequently analyzed using descriptive statistics to summarize the distribution of the recovered isolates according to bacterial species and genus (figure 1).

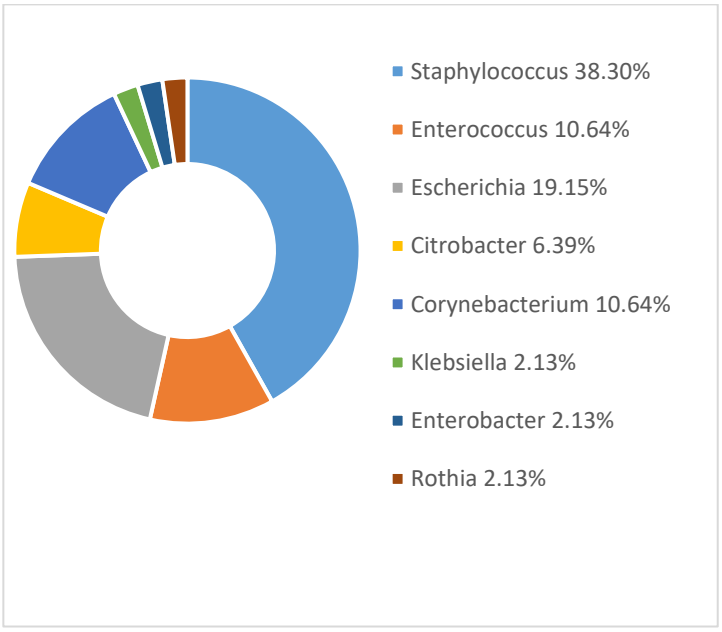


Figure 1. Study workflow *Figure 2. Distribution of 47 isolates across 8 genera*

RESULTS AND DISCUSSION

The microbiological characterization of biofilm-positive surfaces revealed a diverse bacterial community comprising 47 isolates, 14 species belonging to eight genera (figure 2). The microbial profile was predominantly represented by *Staphylococcus*, *Enterococcus*, and *Escherichia*, genera frequently associated with food-processing environments and capable of persisting on environmental surfaces. Their recovery from biofilm-positive sites indicates that these microorganisms may contribute to the establishment and maintenance of microbial communities on surfaces within dairy-processing facilities.

The detection of potentially pathogenic or opportunistic microorganisms, including *Staphylococcus aureus*, *Escherichia coli*, and *Enterococcus* spp., is of particular relevance from a food-safety perspective. Their presence on environmental surfaces may represent a potential source of cross-contamination, particularly when such sites are located in areas with direct or indirect contact with equipment or food products. The association of these microorganisms with biofilm-positive surfaces is also important because biofilm-associated cells can be more difficult to remove through routine cleaning and disinfection procedures, potentially contributing to their persistence within the processing environment.

In addition to the predominant genera, the recovery of *Citrobacter*, *Corynebacterium*, *Klebsiella*, *Enterobacter*, and *Rothia* demonstrates the heterogeneous nature of the microbiota associated with biofilm-positive surfaces. The presence of multiple bacterial genera suggests that dairy-processing biofilms should be considered complex microbial communities rather than populations dominated by a single organism. Such diversity may reflect differences in surface characteristics, environmental conditions, nutrient availability, moisture, and cleaning practices across sampling locations.

MALDI-TOF MS provided species-level identification of the recovered isolates and allowed the characterization of the microbial diversity associated with the biofilm-positive samples. The technique offered a rapid and reproducible approach for identification and was particularly useful for distinguishing closely related bacterial isolates within the recovered microbiota. Its application therefore represents a valuable tool for environmental microbiological monitoring and for obtaining a more detailed characterization of microorganisms associated with biofilm formation.

CONCLUSIONS

Biofilm-positive environments in Albanian dairies harbor a diverse microbiota comprised of 47 isolates, 14 species and 8 genera.
The predominance of *Staphylococcus*, *Enterococcus* and *Escherichia* underscores their key role in biofilm persistence.
Selective culture media combined with MALDI-TOF MS provides a powerful approach for comprehensive microbial characterization
These findings support the improvement of environmental monitoring, sanitation protocols and biofilm control strategies to enhance dairy product safety and quality.

ABSTRACT

Listeria monocytogenes remains a major concern in dairy processing due to its persistence on environmental surfaces and its potential to contaminate ready-to-eat products. This study evaluated an integrated workflow combining selective culture, conventional PCR and MALDI-TOF MS for the confirmation of *Listeria* isolates recovered from Albanian dairy processing environments. A total of 100 environmental swab samples were collected from three Albanian dairy processing plants. Following a two-step enrichment and selective cultivation protocol, presumptive colonies were confirmed by conventional PCR targeting the 16S rRNA and hly genes and subsequently identified by MALDI-TOF MS. Among the 100 environmental samples, **13 samples produced presumptive** *Listeria* **colonies** after selective cultivation. PCR analysis confirmed the presence of **nine** *Listeria* **spp. isolates and one** *Listeria monocytogenes* **isolate**, while the remaining presumptive colonies were PCR-negative. MALDI-TOF analysis demonstrated that *Listeria innocua* was the predominant environmental species (90%), whereas *L. monocytogenes* represented only 10% of confirmed isolates. Positive isolates originated from both food-contact and non-food-contact surfaces, indicating multiple potential contamination niches within dairy facilities. The findings demonstrate that integrating selective culture with molecular and proteomic confirmation significantly improves the reliability of environmental *Listeria* surveillance. The combined workflow provides an effective approach for identifying contamination hotspots, supporting targeted sanitation strategies, improving routine microbiological monitoring, and strengthening food safety management systems in dairy processing plants

Keywords: *Listeria monocytogenes*; *Listeria innocua*; dairy industry; environmental monitoring; PCR; MALDI-TOF MS.

INTRODUCTION

Microbial life abounds on surfaces in both natural and industrial environments, one of which is the food industry. A solid substrate, water and some nutrients are sufficient to allow the construction of a microbial fortress, a so-called biofilm. [1]

The foodborne pathogen *Listeria monocytogenes*, responsible for listeriosis a rare but severe infection disease, can survive in the food processing environment for month or even years. So-

called persistent *L. monocytogenes* strains greatly increase the risk of (re)contamination of food products, and are therefore a great challenge for food safety. [2]

Listeria monocytogenes is able to form biofilms on various surfaces and this ability is thought to contribute to persistence in the environment and on contact surfaces in the food industry. Extracellular DNA (eDNA) is a component of the biofilm matrix of many bacterial species and was shown to play a role in biofilm establishment of *L. monocytogenes*. [4]

In dairy-processing environments, the organism may be introduced through raw materials, water, animals, personnel or equipment and may persist in wet and difficult-to-clean niches such as drains, floors, pipes, hoses, joints and equipment surfaces.

Detection of presumptive *Listeria* colonies by selective culture is useful for recovery of viable microorganisms but does not by itself provide reliable species-level identification. Molecular methods can provide additional confirmation, while MALDI-TOF MS can support rapid species-level identification of cultured isolates. An integrated workflow therefore combines complementary information from culture, molecular detection and proteomic identification

MATERIAL AND METHOD

Sampling strategy

Environmental samples were collected from three Albanian dairy companies. Sampling covered six processing zones: reception, pasteurization, production, packaging, storage and cooling room. Sampling sites were selected with a focus on critical locations associated with product spoilage and potential cross-contamination. Samples were collected following routine cleaning and disinfection procedures.

Enrichment and selective cultivation

Samples were processed using a two-step enrichment and selective cultivation workflow. The first enrichment was performed in Half Fraser Broth, followed by plating on RapidLMono and PALCAM selective media. After evaluation of the first plating step, a second enrichment was performed in Full Fraser Broth, followed by a second plating step on RapidLMono and PALCAM. Colonies with morphology compatible with *Listeria* were considered presumptive isolates and were selected for further confirmation.

Conventional PCR and gel electrophoresis

Presumptive isolates were subjected to conventional PCR targeting 16S rRNA and hly. The 16S rRNA target was used for confirmation of the *Listeria* genus, while hly was included as a virulence-associated target relevant to *L. monocytogenes*. PCR products were evaluated by gel electrophoresis. Isolates producing the expected molecular confirmation pattern were retained for downstream identification.

MALDI-TOF MS identification

PCR-confirmed isolates were subjected to MALDI-TOF MS for species-level identification. The resulting protein spectral profiles were compared with the available reference database, allowing assignment of isolates to *Listeria* species.

Table 1: From sampling to species identification results

Analytical stage	n	%
Environmental samples	100	100%

Presumptive *Listeria* samples	13	13%
PCR-confirmed isolates	10	10%
L. innocua among confirmed isolates	9	90%
L. monocytogenes among confirmed isolates	1	10%

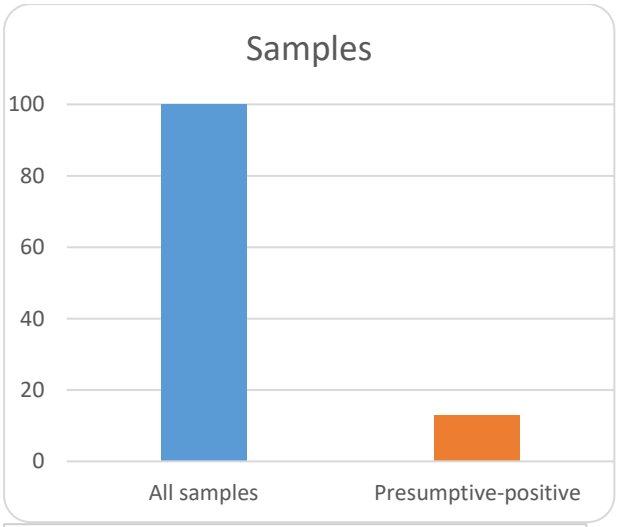

Figure 1. Presumptive isolates

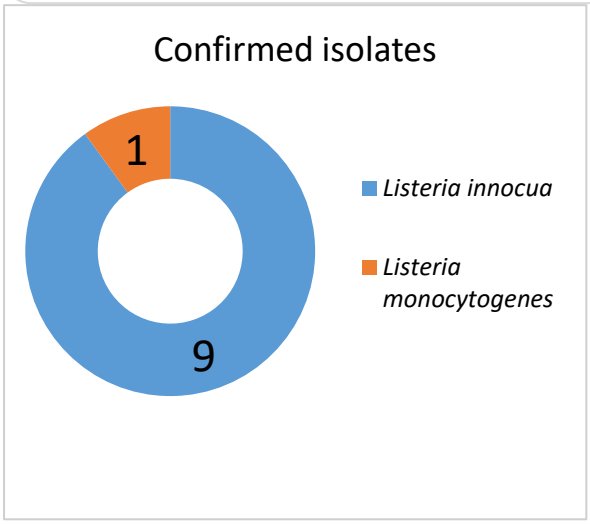

Figure 2. MALDI-TOF results

RESULTS AND DISCUSSION

A total of 100 environmental swabs were investigated. Presumptive *Listeria* colonies were recovered from 13 samples, corresponding to a presumptive-positive rate of 13% (figure 1).

Of the 13 presumptive colonies, 10 were confirmed by PCR, corresponding to a confirmation rate of 76.9% among presumptive colonies. The confirmed set comprised nine other *Listeria spp*. isolates and one *Listeria monocytogenes* isolate according to the study workflow and subsequent species-level identification.

MALDI-TOF MS identified nine of the 10 confirmed isolates as *Listeria innocua* and one as *Listeria monocytogenes* (figure 2). Therefore, *L. innocua* accounted for 90% of confirmed isolates and *L. monocytogenes* for 10%. *L. innocua* was the predominant *Listeria* species recovered from the investigated dairy-processing environments.

Positive isolates originated from different environmental surface types, including both food-contact and non-food-contact surfaces. Food-contact sites represent a potential direct route to product contamination, whereas non-food-contact sites may function as environmental reservoirs or transfer points. The distribution of positive sites indicates that environmental monitoring should not be restricted to direct food-contact surfaces.

The present study demonstrates the value of an integrated analytical strategy for environmental surveillance of *Listeria* in dairy-processing facilities. The three analytical stages used in this study provide complementary information. Selective culture supports recovery of viable presumptive isolates; PCR provides molecular confirmation; and MALDI-TOF MS enables rapid species-level identification of cultured isolates. The combination can therefore increase confidence in environmental surveillance compared with reliance on a single analytical method.

CONCLUSIONS

A total of 100 environmental samples were investigated across three Albanian dairy plants.
Thirteen samples (13%) yielded presumptive *Listeria* colonies.
Ten isolates were confirmed by PCR.
L. innocua predominated (90%) among confirmed isolates while *L. monocytogenes* represented 10%.
Positive isolates were recovered from both food-contact and non-food-contact surfaces.
The combination of selective culture, PCR and MALDI-TOF MS provides a practical integrated strategy for environmental *Listeria* surveillance.

ABSTRACT

Biphenylene nanotubes (BPNTs) have recently emerged as promising one-dimensional carbon nanostructures owing to their unique non-hexagonal topology. BPNTs are carbon allotropes composed of alternating four-, six-, and eight-membered carbon rings. BPNTs offer a clear alternative to Carbon Nanotubes (CNTs) because their high surface reactivity is well suited to sensor applications. This study aims to comprehensively evaluate the potential of pristine BPNTs and Al-, Si-atom-doped BPNTs (Al-BPNTs) and (Si-BPNTs) for nanosensor applications by examining their structural, electronic, and quantum-chemical properties using Density Functional Theory (DFT) calculations. As reported, pristine BPNTs are semi-metallic, irrespective of their chirality. Changes in the electronic band gap (E_g), the density of states (DOS) of pristine BPNT, and the charge density difference (CDD) due to Al-, Si- atom doping have been observed in both gas and water phases. The results reveal that the BPNT exhibits intrinsic metallic behaviour with a high density of states at the Fermi level, making it a highly sensitive platform for nanosensor applications. Doping effects are dominant. A widening of the band gap is observed with Si- atom doping. The Fermi energy level and HOMO-LUMO energies change slightly, and the sensor signal remains detectable. These findings demonstrate that atomic doping provides a practical strategy for tuning the electronic properties of BPNTs for future nanosensor designs.

Keywords: Metal -Doped Biphenylene Nanotubes (BPNTs), Sensors, DFT

INTRODUCTION

The biphenylene network contains four-, six- and eight-membered carbon rings. Hudspeth et al. (2010) examined its sheet and one-dimensional derivatives, including nanotubes; Fan et al. (2021) subsequently synthesized the two-dimensional network. Atomic doping changes its electronic and catalytic behaviour (Ren et al., 2022). Esfandiarpour et al. (2022) investigated CO_2 adsorption on pristine, Al- and Si-doped BPNTs, providing a gas-phase reference for the isolated supports.

Related nanotube studies connect optimized geometries and charge distributions with frontier orbitals in BMSF-BENZ, tretinoin and Aldara systems (Al-Sawaff et al., 2021; Genç et al., 2025; Dalgic et al., 2025). Here, pristine, Al- and Si-doped BPNTs are compared in gas and implicit water using the same hydrogen-terminated cluster. The analysis covers geometry, cohesive energy, electrostatic potential, frontier orbitals and charge redistribution, together with the effect of hydrogen polarization functions.

MATERIAL AND METHOD

The neutral clusters contain 56 atoms: $C_{48}H_8$ or $C_{47}H_8M$ (M = Al, Si), with eight terminal hydrogens and a dopant fraction of 2.083%. Pristine and Si-BPNT are restricted singlets; Al-BPNT has 303 electrons and is an unrestricted doublet. For Al, $\langle S^2 \rangle$ is 0.9232–0.9333 before annihilation and 0.7692–0.7706 afterward (pure doublet: 0.75). The alpha-HOMO of Al-BPNT is singly occupied.

DFT calculations (Hohenberg and Kohn, 1964; Kohn and Sham, 1965) used Gaussian 09, Revision E.01 for clusters and A.02 for some isolated atoms. M06-2X (Zhao and Truhlar, 2008) was used with gas/6-31G(d) (G-d), gas/6-31G(d,p) (G-dp) and water/6-31G(d) (W-d). The (d,p) basis adds hydrogen polarization (Hariharan and Pople, 1973). Water used the integral equation formalism polarizable continuum model (IEFPCM) with ε = 78.3553 (Tomasi et al., 2005; Scalmani and Frisch, 2010).

Geometry optimization and harmonic frequency analysis used default integration settings for clusters and UltraFine for isolated atoms in water. Final optimizations met all four convergence criteria. Some subsequent frequency jobs exceeded the maximum-displacement threshold while satisfying both force criteria.

The signed cohesive energy per atom was calculated from cluster and neutral isolated-atom SCF energies at the corresponding basis set and environment:

$$E_{coh} = \frac{E_{cluster} - \Sigma_A n_A E_A(atom)}{N}, \quad N = 56 \quad (1)$$

N = 56 includes hydrogens. More negative E_{coh} indicates stronger binding relative to triplet C and Si, and doublet Al and H references. Energies used 1 hartree = 27.211386245988 eV. The gas-to-water change was $E_{water}(R_{water}) - E_{gas}(R_{gas})$ at 6-31G(d). This energy difference includes continuum polarization and geometry relaxation.

The gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) was evaluated separately for each spin channel s:

$$E_{g,s} = \varepsilon_{LUMO,s} - \varepsilon_{HOMO,s} \quad (2)$$

Chemical potential (μ), hardness (η) and electrophilicity (ω) were estimated from frontier orbitals (Parr and Pearson, 1983; Parr et al., 1999):

$$\mu = \frac{\varepsilon_{HOMO} + \varepsilon_{LUMO}}{2}; \quad \eta = \frac{E_g}{2}; \quad \omega = \frac{\mu^2}{2\eta} \quad (3)$$

The Fermi-energy estimate was $E_{F,s} = \mu_s$, and the work-function estimate was $\Phi_s \approx -E_{F,s}$ with $E_{vac} = 0$. For Al, these are spin-channel estimates. Changes in E_g and Φ were calculated relative to pristine BPNT under the same condition:

$$\Delta X\ (\%) = 100 \times \frac{X_{doped} - X_{pristine}}{X_{pristine}} \quad (4)$$

Gas (G-d) and water (W-d) density of states (DOS) spectra span −10 to +3 eV. For Al, $0.5(DOS_\alpha + DOS_\beta)$ is shown with the alpha gap. Natural population analysis (NPA) used total density, including both Al spin populations (Reed et al., 1985). GaussView (Dennington et al., 2009) displayed structures, orbitals and molecular electrostatic potentials (MEP), mapped from −0.025 to +0.025 a.u.

Charge density difference (CDD) maps used Multiwfn (Lu and Chen, 2012; Lu, 2024) and VESTA (Momma and Izumi, 2011):

$$\Delta\rho_{def}(r) = \rho_{BPNT}(r) - \sum_A \rho_{A,ref}(r - R_A) \quad (5)$$

Positive and negative deformation densities denote accumulation and depletion relative to free atoms. The ±0.004 e/bohr³ maps were compared with NPA charges; neutral C and H reference densities were gas-phase quintet and doublet states, respectively.

RESULTS AND DISCUSSION

Optimized geometries and cohesive energies

All nine structures retain the BPNT framework and have 162 positive harmonic frequencies; the lowest frequencies range from 110.040 to 127.432 cm^{-1}. Figure 1 compares the optimized gas and water structures. The Si-C distances are shorter than Al-C distances under every condition (Table 1). Water slightly lengthens the Al-C contacts, whereas the Si-C distances change in both directions.

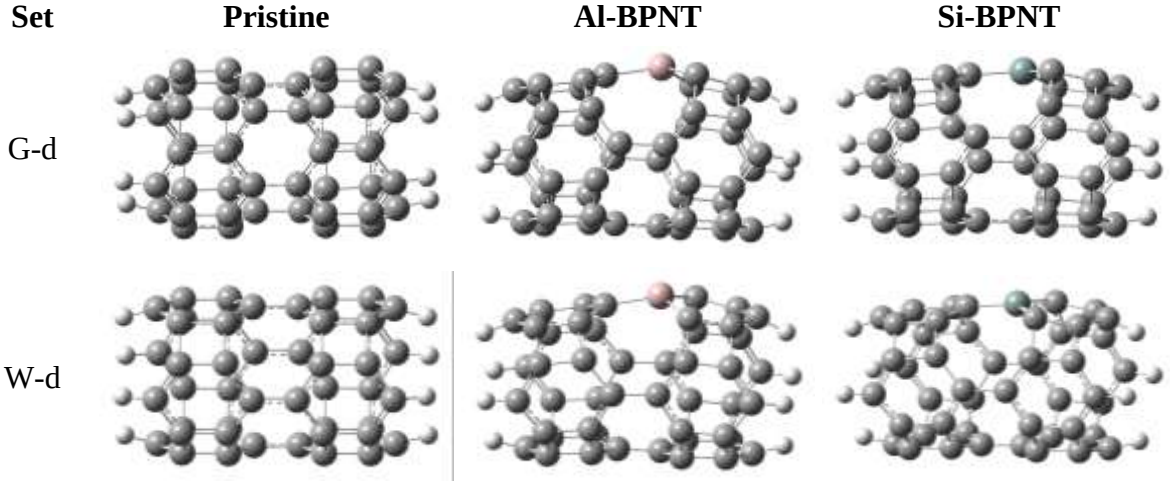

Figure 1. Optimized structures in gas (G-d, top) and water (W-d, bottom). Carbon is grey, hydrogen white, Al pink and Si teal.

Table 1. Local geometry, dopant NPA charge, lowest harmonic frequency and cohesive energy.

Set	Model	M–C range (Å)	q_M (e)	ν_{min} (cm^{-1})	E_{coh} (eV $atom^{-1}$)
G-d	Pristine	—	—	127.432	−6.110
G-d	Al	1.857–1.881	+1.756	115.367	−6.005
G-d	Si	1.735–1.773	+1.747	112.797	−6.027
G-dp	Pristine	—	—	121.337	−6.115
G-dp	Al	1.857–1.881	+1.756	115.517	−6.010
G-dp	Si	1.735–1.773	+1.747	112.878	−6.032
W-d	Pristine	—	—	122.394	−6.097
W-d	Al	1.861–1.884	+1.781	116.372	−5.991
W-d	Si	1.739–1.769	+1.794	110.040	−6.013

M–C spans the three nearest carbon atoms. Cohesive energies include all 56 atoms.

Cohesive energies become less negative in the order pristine, Si-BPNT and Al-BPNT. Pristine BPNT thus has the strongest binding relative to the selected atomic references. The gas-to-water cluster energy changes are −6.873, −7.524 and −7.212 kcal mol^{-1} for pristine, Al- and Si-BPNT, respectively.

Molecular electrostatic potential

The MEP maps show an approximately symmetric distribution for pristine BPNT and local changes near the dopants (Figure 2). The two gas-phase basis sets give similar patterns. Water changes the contrast over the central framework, particularly for Si-BPNT.

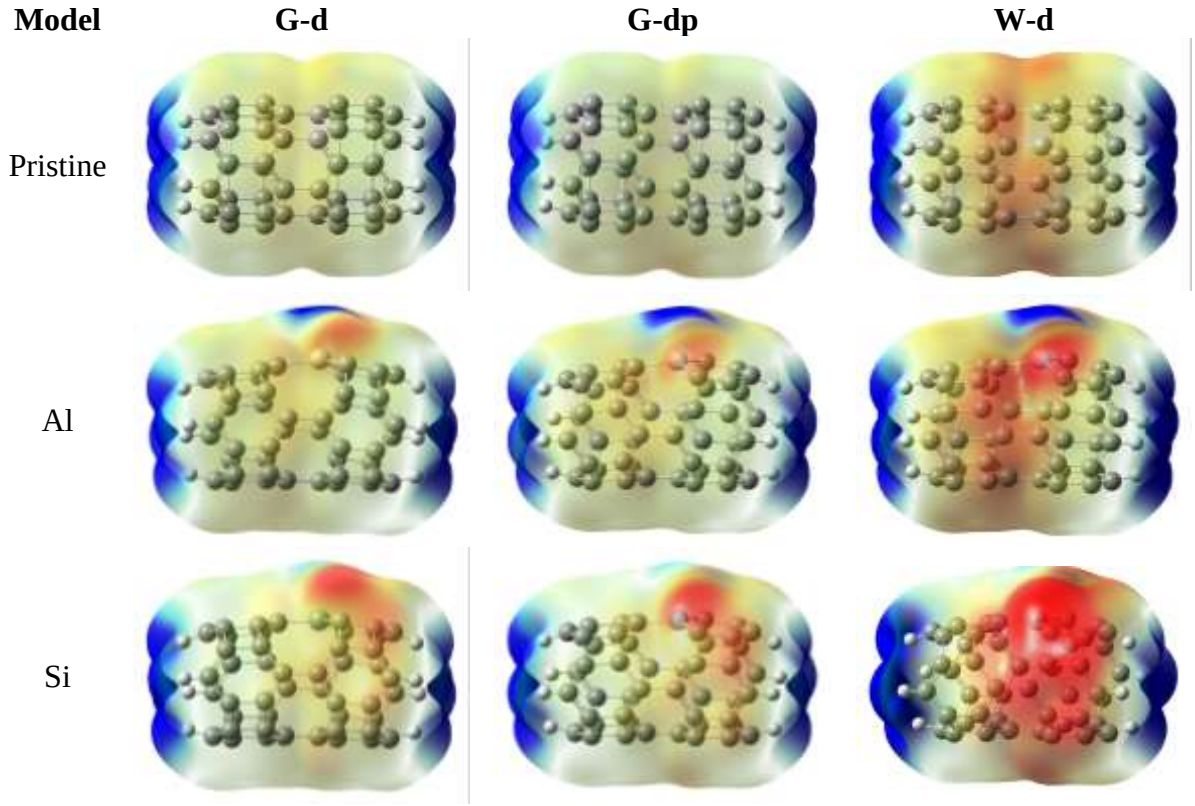

Figure 2. MEP maps in gas and water; potential range −0.025 to +0.025 a.u.

Frontier orbitals and density of states

The G-d frontier gaps are 2.522 eV for pristine BPNT, 2.654 eV for Al α and 2.497 eV for Si-BPNT (Table 2). Al raises both alpha frontier levels, especially the LUMO, widening the gap. Si lowers both levels and stabilizes the LUMO more strongly, narrowing the gas-phase gap. The Al beta gap is larger than the alpha gap.

Table 2. Frontier orbital energies and molecular gaps (eV).

Set	Model	Spin	HOMO	LUMO	Gap
G-d	Pristine	α = β	−5.285	−2.763	2.522
G-d	Al	α	−5.208	−2.554	2.654
G-d	Al	β	−5.232	−2.492	2.740
G-d	Si	α = β	−5.346	−2.849	2.497
G-dp	Pristine	α = β	−5.281	−2.761	2.520
G-dp	Al	α	−5.206	−2.553	2.653
G-dp	Al	β	−5.230	−2.490	2.741
G-dp	Si	α = β	−5.344	−2.848	2.496
W-d	Pristine	α = β	−5.290	−2.755	2.535
W-d	Al	α	−5.218	−2.538	2.680
W-d	Al	β	−5.234	−2.478	2.757
W-d	Si	α = β	−5.382	−2.807	2.575

Adding hydrogen polarization functions changes the gaps by no more than about 0.002 eV. In water, both dopants increase the gap relative to pristine BPNT. The gas-to-water gap increases are approximately 0.013, 0.026 and 0.077 eV for pristine, Al α and Si-BPNT, respectively. The largest change occurs for Si. Figure 3 compares the nearby occupied and virtual levels. These are molecular gaps of finite clusters, rather than periodic band gaps.

Water lowers the Si-BPNT HOMO by 0.035 eV and raises its LUMO by 0.042 eV, giving the 0.077 eV increase in their separation. The two shifts act in opposite directions, so their midpoint changes much less than the gap. The gas-to-water changes in the Fermi-energy estimate are 0.0008, 0.0025, 0.0058 and 0.0033 eV for pristine BPNT, Al alpha, Al beta and Si-BPNT, respectively.

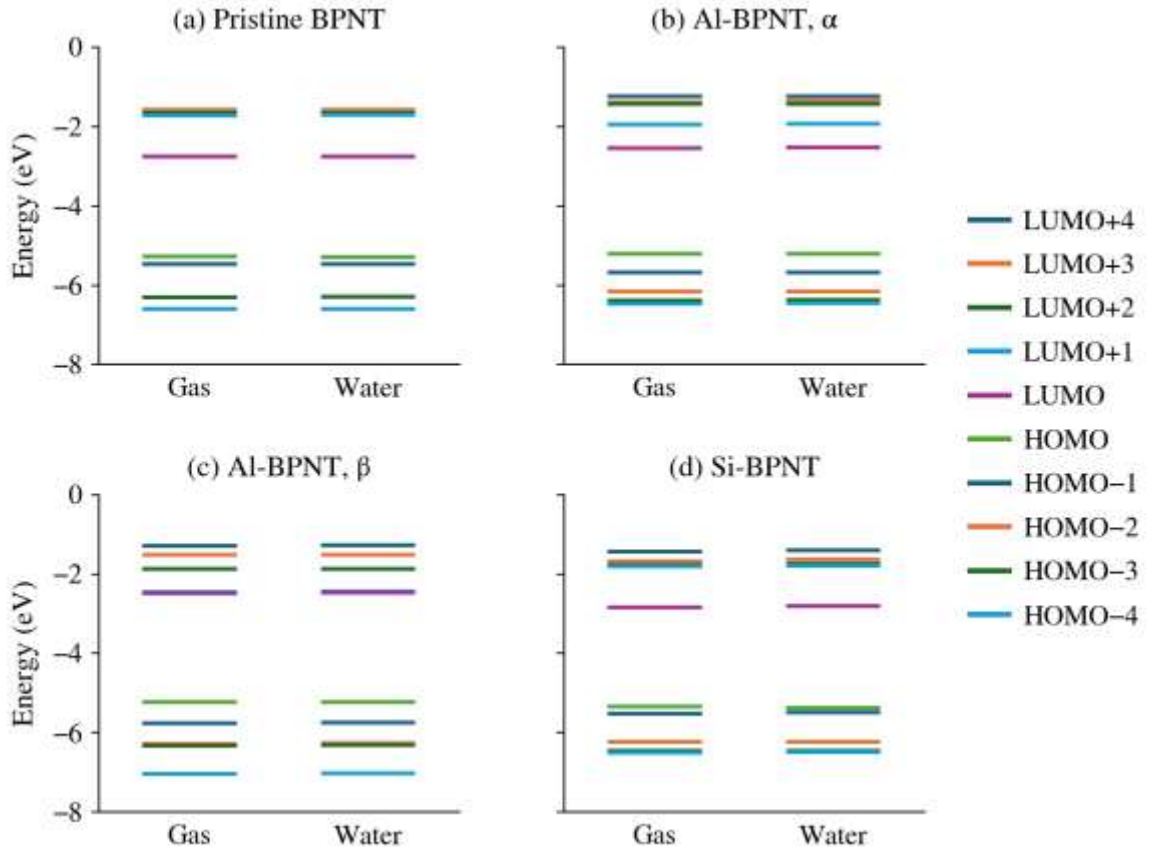

Figure 3. Orbital energies in gas (G-d) and water (W-d) at 6-31G(d). Colours identify levels from HOMO−4 to LUMO+4; Al alpha and beta channels are shown separately.

Figure 4 compares the gas and water DOS spectra. The principal peak patterns and the separation of occupied and virtual levels are retained in water, while the frontier gap increases for each model. Al retains distinct alpha and beta contributions. These spectra describe discrete levels of hydrogen-terminated clusters. The metallic tubes reported by Hudspeth et al. (2010) concern extended structures; the present finite-cluster gaps do not establish metallic transport.

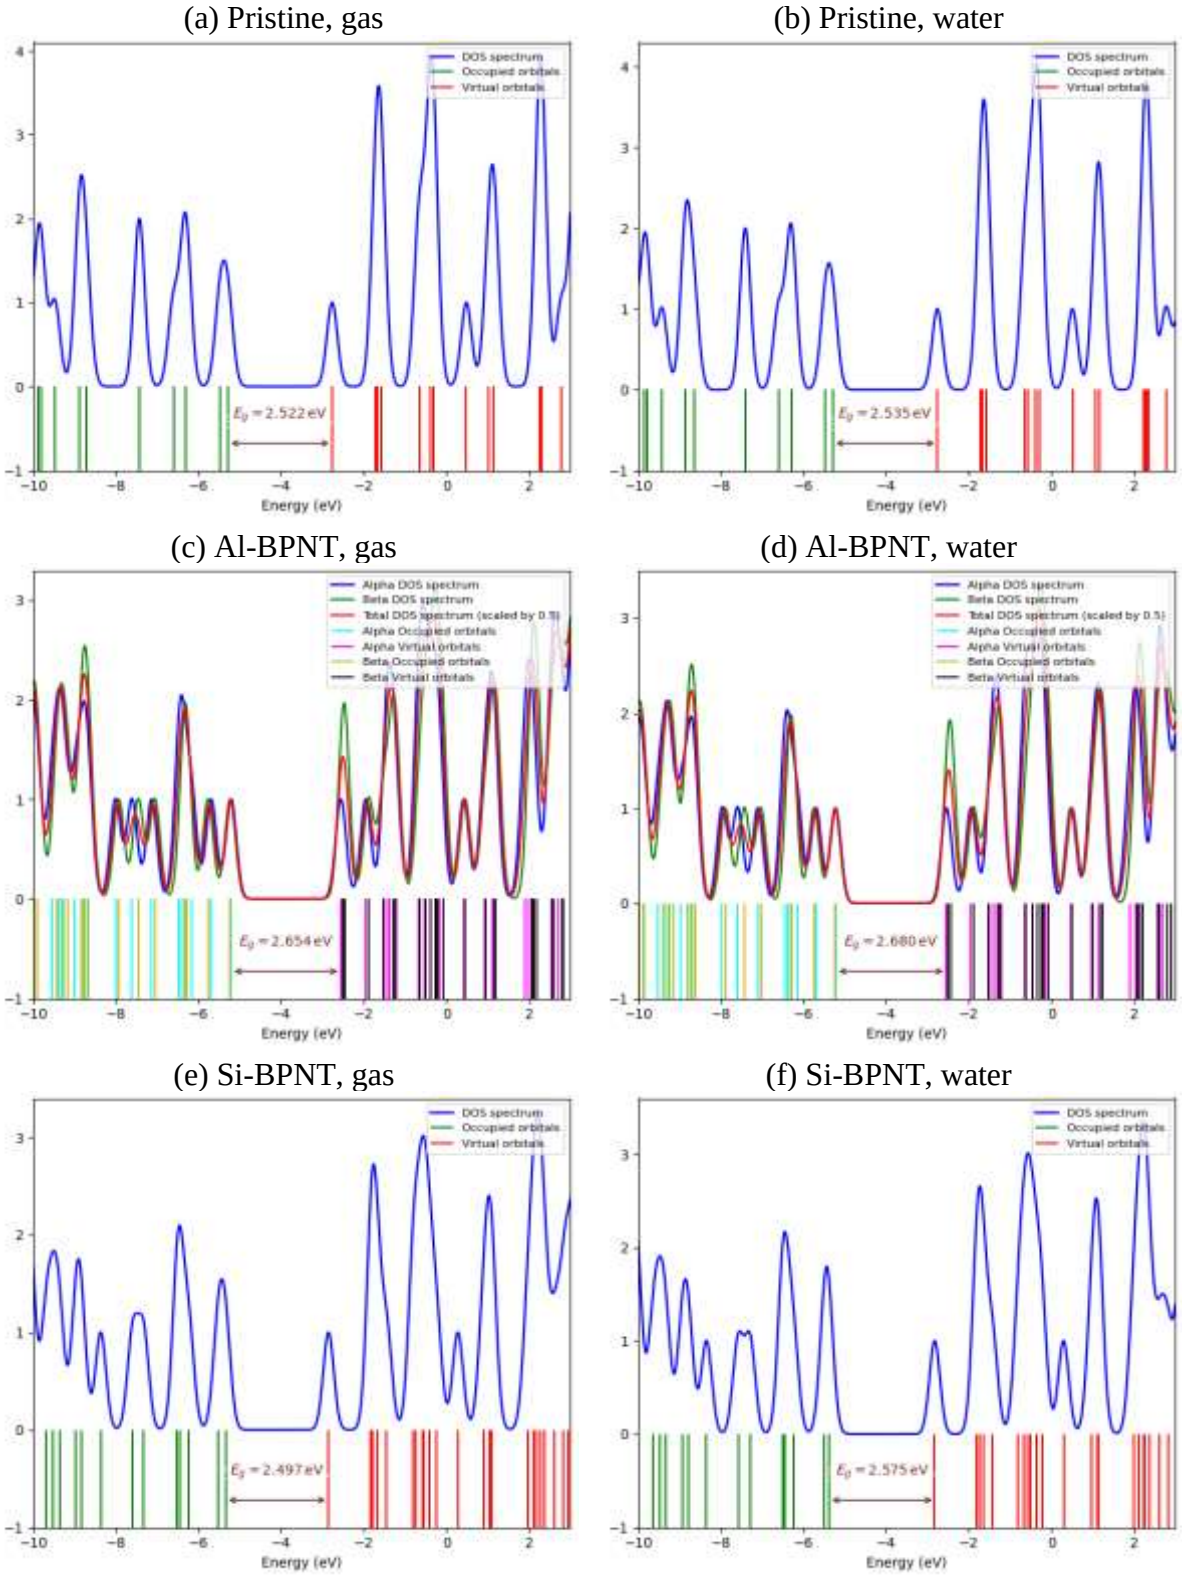

Figure 4. DOS spectra at M06-2X/6-31G(d): gas (left) and water (right). Sticks mark occupied and virtual levels. For Al, the red curve is $0.5(DOS_\alpha + DOS_\beta)$; gap labels refer to alpha orbitals.

In the orbital surfaces (Figure 5), the pristine HOMO extends relatively evenly over the framework, whereas Al-BPNT has a more asymmetric distribution. The Al alpha-HOMO is the singly occupied orbital; its spatial pattern therefore describes the open-shell channel.

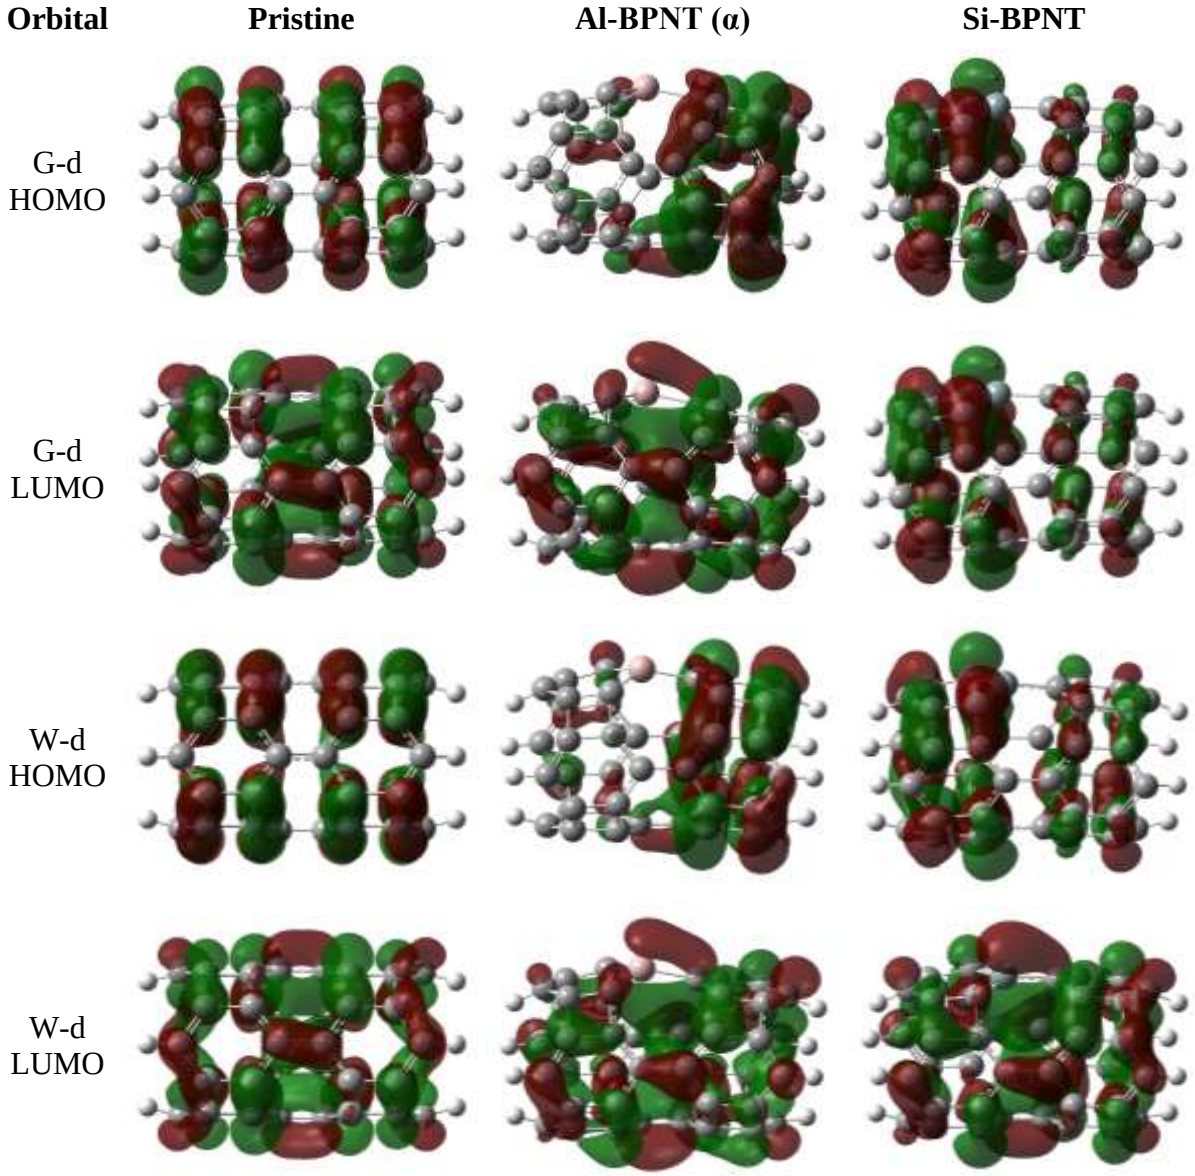

Figure 5. HOMO and LUMO surfaces in gas (G-d) and water (W-d). Alpha orbitals are shown for Al in both phases. Red and green denote opposite orbital phases.

Quantum molecular descriptors

Si-BPNT has the most negative chemical potential, the largest work-function estimate and the highest electrophilicity under all three conditions (Table 3). Al has the greatest hardness in both spin channels. At G-d, the work-function estimate decreases by 3.549% for Al α and increases by 1.840% for Si. The Si gap change switches from negative in gas to positive in water, whereas its work-function change remains positive.

Table 3. Orbital-based descriptors (eV) and changes relative to pristine BPNT (%).

Set	Model	$E_F = \mu$	η	ω	Φ	ΔE_g (%)	ΔΦ (%)
G-d	Pristine	−4.024	1.261	6.419	4.024	—	—
G-d	Al α	−3.881	1.327	5.675	3.881	5.237	−3.549
G-d	Al β	−3.862	1.370	5.442	3.862	8.654	−4.023
G-d	Si	−4.098	1.249	6.723	4.098	−0.976	1.840
G-dp	Pristine	−4.021	1.260	6.416	4.021	—	—
G-dp	Al α	−3.879	1.327	5.672	3.879	5.277	−3.521
G-dp	Al β	−3.860	1.370	5.436	3.860	8.750	−4.005
G-dp	Si	−4.096	1.248	6.721	4.096	−0.946	1.865
W-d	Pristine	−4.023	1.267	6.385	4.023	—	—
W-d	Al α	−3.878	1.340	5.613	3.878	5.726	−3.591
W-d	Al β	−3.856	1.378	5.394	3.856	8.751	−4.147
W-d	Si	−4.094	1.287	6.512	4.094	1.569	1.779

$\Phi \approx -E_F$ with $E_{vac} = 0$. Al α and β are separate spin-channel estimates; $\Delta X = 100(X_{doped} - X_{pristine})/X_{pristine}$.

These quantities provide an electronic reference for comparing the isolated supports in sensing applications. A detectable signal depends on the support–analyte response and cannot be inferred from the isolated-support descriptors alone.

Charge redistribution

The deformation-density surfaces show a repeated pattern along pristine BPNT in gas and water (Figure 6). Al produces pronounced changes near the protruding doped region, whereas Si retains a more regular outline. These patterns accompany the local bond-length differences. The Al and Si NPA charges rise from +1.756 and +1.747 e in gas to +1.781 and +1.794 e in water, respectively. The increases are +0.025 e for Al and +0.047 e for Si, consistent with the stronger solvent-induced change in the Si frontier gap. The surface maps locate redistribution relative to free atoms; NPA provides the corresponding atom-centred population comparison.

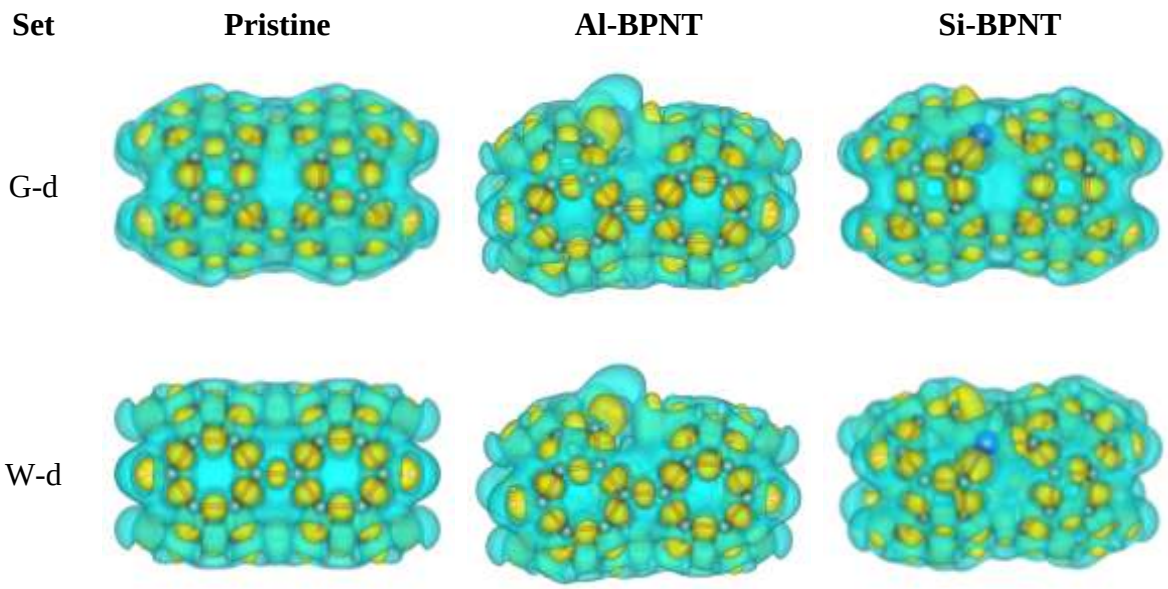

Figure 6. Deformation densities in gas (G-d, top) and water (W-d, bottom) at ±0.004 e/bohr³. Yellow and cyan denote accumulation and depletion relative to the free-atom reference in equation (5).

Comparison with published BPNT results

Table 4 compares the isolated supports with Esfandiarpour et al. (2022) at gas-phase M06-2X/6-31G(d,p). The earlier model contains 120 framework sites and eight hydrogens, compared with 48 sites and eight hydrogens here; the dopant fractions are 0.833% and 2.083%, respectively. Both studies give the gap order Al > pristine > Si. Al raises the gap by about 0.133 eV here and 0.19 eV in the earlier work, while Si lowers it by about 0.024 and 0.06 eV.

Table 4. Isolated BPNT comparison at M06-2X/6-31G(d,p): this work and Esfandiarpour et al. (2022).

Quantity	Pristine		Al		Si	
	This work	2022	This work	2022	This work	2022
HOMO (eV)	−5.281	−5.32	−5.206	−5.15	−5.344	−5.31
LUMO (eV)	−2.761	−3.11	−2.553	−2.75	−2.848	−3.16
Gap (eV)	2.520	2.21	2.653	2.40	2.496	2.15
E_{coh} (eV atom^{-1})	−6.115	−8.10	−6.010	−8.06	−6.032	−8.04
Mean M–C (Å)	—	—	1.873	1.86	1.757	1.75
q_M (e)	—	—	+1.756	+1.70	+1.747	+1.71

Current Al frontier values are alpha-channel values; the published pair is not spin-labelled. Mean M–C uses the three nearest carbon atoms. Published values are from Tables 3–4 and sections 3.2–3.3; atomic-reference states for the published cohesive energies are unspecified.

The mean Al-C and Si-C distances agree closely with the reported 1.86 and 1.75 Å, and both studies give dopant charges near +1.7 e. Pristine BPNT has the most negative cohesive energy in both studies, but the Al/Si order differs. Absolute cohesive energies depend on cluster composition and isolated-atom reference states, which limits direct numerical comparison.

The present pristine, Al and Si gaps exceed the 2022 values by approximately 0.31, 0.25 and 0.35 eV, respectively. The agreement is therefore strongest for the direction of the doping effect, local bond lengths and dopant charges.

CONCLUSIONS

Al and Si doping modify the local geometry and electronic structure of finite BPNTs. Si-C contacts are shorter than Al-C contacts, and cohesive energies are most negative for pristine BPNT, followed by Si-BPNT. Al widens the frontier gap in both media. Si narrows the gas-phase gap but widens it relative to pristine BPNT in water. Si also yields the largest work-function estimate and the larger solvent-induced gap and dopant-charge changes. The MEP, orbital and deformation-density maps locate the electronic redistribution around the dopants. The small Fermi-energy shifts and distinct gap responses characterise doping and solvent effects on the isolated supports.

ABSTRACT

The development of efficient adsorbent materials for CO_2 capture is essential for reducing industrial carbon emissions and improving carbon-capture process efficiency. In this study, density functional theory (DFT) calculations were performed to investigate CO_2 adsorption on pristine and Al-, Si-, and Zn-doped biphenylene nanotubes (BPNTs) under gas-phase and aqueous-environment conditions. The aqueous environment was represented using the IEFPCM implicit-solvent model. The effects of heteroatom doping on structural stability, adsorption behavior, regeneration characteristics, and electronic properties were evaluated. The adsorption configurations and the energetic and electronic descriptors obtained from the available molecular calculations were used to characterize the interactions between CO_2 and the nanotube surfaces. Recovery time was estimated to assess the regeneration characteristics of the investigated adsorbents. The obtained results were subsequently evaluated using integrated Analytic Hierarchy Process (AHP) and Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) Multi-Criteria Decision-Making (MCDM) methods for comparative material selection. Five criteria, including adsorption distance, adsorption energy, recovery time, band-gap energy, and first hyperpolarizability, were considered in the decision-making process. These criteria represented CO_2-adsorbent interaction strength, regeneration capability, and electronic response. Their relative importance was determined using the AHP by aggregating expert assessments. The consistency analysis showed that the pairwise comparison structure was acceptable. The AHP results indicated that adsorption energy was the most influential criterion, followed by recovery time. The calculated criterion weights were incorporated into separate TOPSIS method for the gas and water phases. The TOPSIS evaluation indicated that Zn-doped BPNT ranked first under gas-phase conditions, whereas Al-doped BPNT achieved the highest rank in the water phase. These results demonstrated that the ranking of the investigated BPNTs varied depending on the environmental conditions. The integration of DFT-derived descriptors with AHP and TOPSIS provided a systematic framework for the comparative evaluation and selection of BPNTs for CO_2 adsorption.

INTRODUCTION

The biphenylene network contains four-, six- and eight-membered carbon rings. Its experimentally prepared two-dimensional network differs from the hexagonal lattice of graphene (Fan et al., 2021). Earlier calculations also examined the electronic properties of the sheet and its one-dimensional derivatives (Hudspeth et al., 2010). Curving this framework into a nanotube changes the local environment of its carbon atoms. Substitution by another element introduces a further change at the adsorption site.

Esfandiarpour et al. (2022) studied CO_2 adsorption on pristine, Al-doped and Si-doped biphenylene nanotubes. They found stronger adsorption for the Al-substituted structure and considered its electronic sensing response. Their work provides a direct comparison for the present calculations. The additional Zn model and the gas–water comparison extend the set of adsorption environments considered here.

Related nanotube studies show how dopants affect different adsorbates. Genç et al. (2025a) examined formaldehyde on Zn-doped carbon nanotubes. Genç et al. (2025b) compared tretinoin adsorption on Al-doped nanotubes in gas, water and n-octanol. Şentürk Dalgıç (2025) analysed the local N–Si interaction between imiquimod and a Si-doped nanotube. These studies combine structural and electronic results with an examination of the contact region. Their adsorption mechanisms depend on the adsorbate and cannot be assumed for CO_2.

Adsorption strength alone does not determine the preference for a reusable adsorbent. Strong binding favours retention but can delay release. The analytic hierarchy process (AHP) assigns weights through pairwise comparisons (Saaty, 1977). The technique for order preference by similarity to an ideal solution (TOPSIS) then ranks alternatives using those weights (Hwang and Yoon, 1981). Turan and Özkan (2025) applied multicriteria methods to amine-based solid sorbents for CO_2 capture. Here, AHP–TOPSIS is applied to molecular descriptors calculated for four nanotube hosts.

The comparison uses adsorption distance, adsorption energy, estimated recovery time, frontier orbital gap and static first hyperpolarizability. Optimized geometries, frontier orbitals and selected electron-density maps support the interpretation. Gas and implicit water are evaluated separately. The aim is to identify how the preferred host changes when the dielectric environment and the relative importance of binding and release are considered.

MATERIAL AND METHOD

Molecular models and calculations

The pristine biphenylene nanotube (BPNT) model contained 48 carbon atoms and eight terminating hydrogens. One carbon atom was replaced by Al, Si or Zn to form $C_{47}H_8M$. A single CO_2 molecule was added to each host. The four complexes were optimized in the gas phase and in implicit water, giving eight 59-atom systems. The same substitution site was used throughout.

Calculations employed M06-2X with the 6-31G(d) basis set in Gaussian 09 (Zhao and Truhlar, 2008; Hariharan and Pople, 1973; Rassolov et al., 1998; Frisch et al., 2009). Water was represented by the integral-equation-formalism polarizable continuum model, IEFPCM (Cancès et al., 1997). The complexes were neutral. Pristine, Si and Zn systems were restricted singlets; Al systems were unrestricted doublets. Harmonic frequency calculations gave no imaginary frequencies for the eight optimized complexes. They therefore correspond to local minima for the configurations examined.

The electronic adsorption energy was calculated from the optimized complex and separately optimized fragments:

$$E_{ads}=E_{complex}-E_{host}-E_{CO_2} \quad (1)$$

The zero-point-corrected adsorption energy, $E_{ads,0}$, was obtained by applying the same difference to the electronic energy plus zero-point energy. Negative values indicate stabilization relative to the separated fragments. Each fragment reference used the same environment as its complex. No counterpoise correction was applied. The reported values therefore retain basis-set superposition error.

The recovery-time indicator was estimated at 298.15 K:

$$\tau = \frac{1}{\nu_0} \exp\left(\frac{|E_{ads,0}|}{k_B T}\right) \quad (2)$$

The attempt frequency ν_0 was 3×10^{12} s^{-1}, and k_B was $8.617333262 \times 10^{-5}$ eV K^{-1}. $E_{ads,0}$ was expressed in eV in Eq. (2). This estimate substitutes the binding-energy magnitude for a desorption barrier. No transition state was calculated. The resulting times are model indicators rather than measured regeneration rates.

Electronic response and interaction maps

The frontier orbital gap was defined as $E_g = \varepsilon_{LUMO} - \varepsilon_{HOMO}$. Separate α and β gaps were obtained for the open-shell Al complexes. The larger within-channel gap, $\max(E_{g,\alpha}, E_{g,\beta})$, was used as the single TOPSIS descriptor. The other systems were closed shell. These values describe finite molecular clusters and are not periodic band gaps.

Static first hyperpolarizability was calculated from the Cartesian response tensor:

$$\beta_0 = \sqrt{\beta_x^{\,2} + \beta_y^{\,2} + \beta_z^{\,2}} \quad (3)$$

Here $\beta_x = \beta_{xxx} + \beta_{xyy} + \beta_{xzz}$, $\beta_y = \beta_{xxy} + \beta_{yyy} + \beta_{yzz}$ and $\beta_z = \beta_{xxz} + \beta_{yyz} + \beta_{zzz}$. The conversion was 1 atomic unit = 8.6393×10^{-33} esu. The values are molecular static responses. They do not represent a bulk optical susceptibility or an experimental CO_2 uptake.

Reduced density gradient and noncovalent interaction (RDG/NCI) maps were used to inspect the contact region (Johnson et al., 2010). Their colour assignment follows $\mathrm{sign}(\lambda_2)\rho$, where λ_2 is the second eigenvalue of the density Hessian. The electron localization function (ELF) describes spatial localization on a scale from 0 to 1 (Becke and Edgecombe, 1990). Selected two-dimensional ELF sections were compared with the interaction surfaces. The maps were used for interpretation and were not entered into TOPSIS.

Charge-density difference (CDD) was defined as $\Delta\rho = \rho_{complex} - \rho_{host} - \rho_{CO_2}$. Fragment geometries were fixed at their positions in the optimized complex. CDD isosurfaces were displayed at $|\Delta\rho| = 0.0004$ a.u.

Criterion weights and ranking

Three reciprocal pairwise-comparison matrices were aggregated by taking the geometric mean of their corresponding entries. Each column of the group matrix was normalized. The row averages gave the weights in Table 1. Consistency was evaluated from the mean componentwise ratio of Aw to w. The group consistency ratio was 0.08293, below the adopted 0.10 threshold (Saaty, 1977).

Table 1. Criteria, preference directions and AHP weights.

Criterion	Descriptor	Preference	Weight (%)
K_1	Minimum distance	Minimum	11.50
K_2	Adsorption energy	Minimum	52.02
K_3	Recovery time	Minimum	27.26
K_4	Adopted orbital gap	Minimum	5.97
K_5	First hyperpolarizability	Maximum	3.25

The distance criterion was the shortest atom-pair separation between CO_2 and the host. Minimizing the signed adsorption energy favours stronger binding. Minimizing recovery time favours faster release. Recovery time is derived from adsorption energy, so these two criteria are coupled. Hyperpolarizability adds a preference for electric response.

The gas and water decision matrices were normalized separately. For alternative i and criterion j, vector normalization and weighting gave

$$r_{ij}=\frac{x_{ij}}{\sqrt{\Sigma_i {x_{ij}}^2}}, v_{ij}=w_j r_{ij} \quad (4)$$

The positive ideal contained the minimum weighted values for K_1–K_4 and the maximum for K_5. The negative ideal used the opposite values. Euclidean distances D^+ and D^- were calculated from these two ideals. The closeness coefficient was

$$C_i=\frac{D_i^-}{D_i^+ + D_i^-} \quad (5)$$

Alternatives were ranked by decreasing C_i (Hwang and Yoon, 1981). Recovery times entered the normalization directly, without a logarithmic transformation. Because each environment has its own ideal solutions, a gas-phase coefficient and a water coefficient are not a common absolute performance scale.

Weight sensitivity was tested by changing each criterion weight by ±20% of its base value, one at a time. The other weights were rescaled proportionally to keep their sum equal to one. This produced ten scenarios in each environment.

RESULTS AND DISCUSSION

Optimized structures and adsorption

Figure 1 compares the eight optimized structures. Al and Zn form the shorter contacts with a CO_2 oxygen atom. Pristine BPNT and the Si-substituted host retain more distant adsorption geometries.

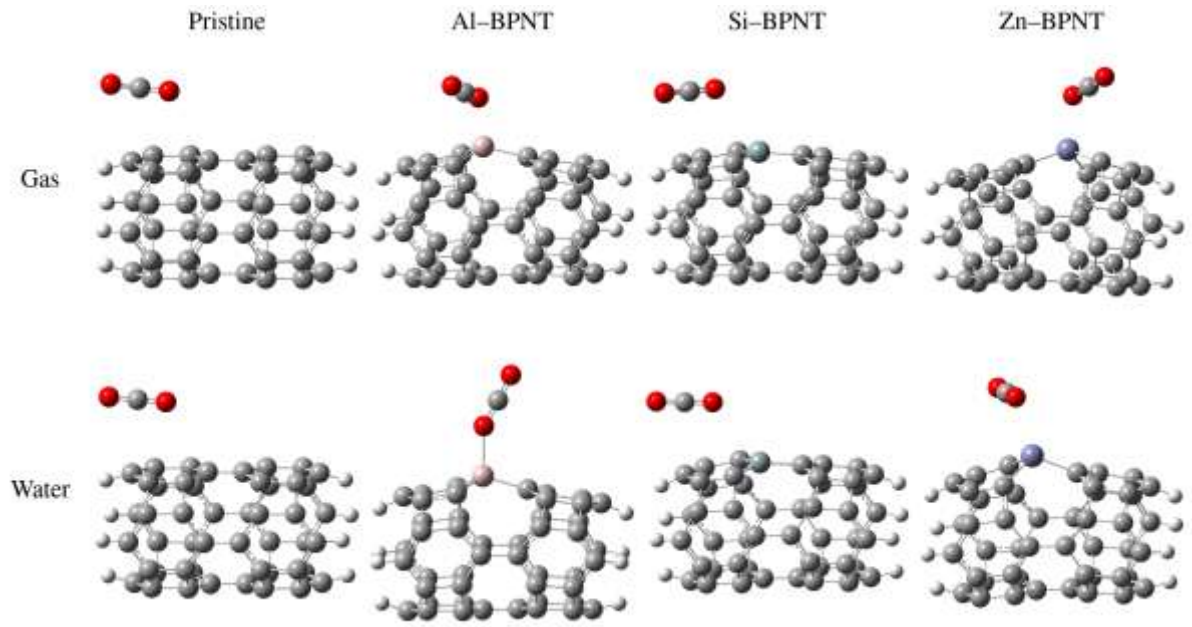

Figure 1. Optimized BPNT–CO_2 complexes. Gas-phase structures are in the upper row and implicit-water structures in the lower row. Columns show pristine, Al, Si and Zn hosts.

The Al–O distance decreases from 2.097 Å in the gas phase to 2.019 Å in water. The Zn–O bond distance changes in the opposite direction, increasing from 2.256 to 2.489 Å. For aqueous Si-BPNT, the shortest interfragment distance is 3.065 Å between carbon atoms; its Si–O distance is 3.164 Å. The minimum-distance definition therefore matters when comparing the four adsorption sites.

CO_2 remains nearly linear in every optimized complex. The largest bending occurs for gas-phase Al-BPNT–CO_2, where the O–C–O angle is 176.55°. The adsorbate remains molecular in all eight structures. Table 2 gives the five descriptors used in the decision analysis.

Table 2. Calculated descriptors for the gas (G) and implicit-water (W) complexes.

Complex	d_{min} **(Å)**	$E_{ads,0}$ **(eV)**	**τ (s)**	E_g **(eV)**	**β₀ (10^{-30} esu)**
G Pristine	3.033	−0.1616	1.795×10^{-10}	2.5238	3.599
G Al	2.097	−0.5313	3.190×10^{-4}	2.7437	24.978
G Si	3.104	−0.2067	1.038×10^{-9}	2.5255	19.075
G Zn	2.256	−0.4160	3.584×10^{-6}	2.4581	74.800
W Pristine	3.063	−0.0973	1.468×10^{-11}	2.5361	18.657
W Al	2.019	−0.5856	2.641×10^{-3}	2.7883	48.990
W Si	3.065	−0.1692	2.413×10^{-10}	2.5874	63.252
W Zn	2.489	−0.1042	1.921×10^{-11}	2.5965	289.909

Al has the most negative $E_{ads,0}$ in both environments (Figure 2). Its binding strengthens from −12.252 to −13.505 kcal mol^{-1} in water, consistent with its shorter oxygen contact. Gas-phase Zn binds more strongly than Si and pristine BPNT. In water, however, the Zn value becomes much less negative, changing from −9.593 to −2.402 kcal mol^{-1}. The longer Zn–O distance accompanies this loss of stabilization.

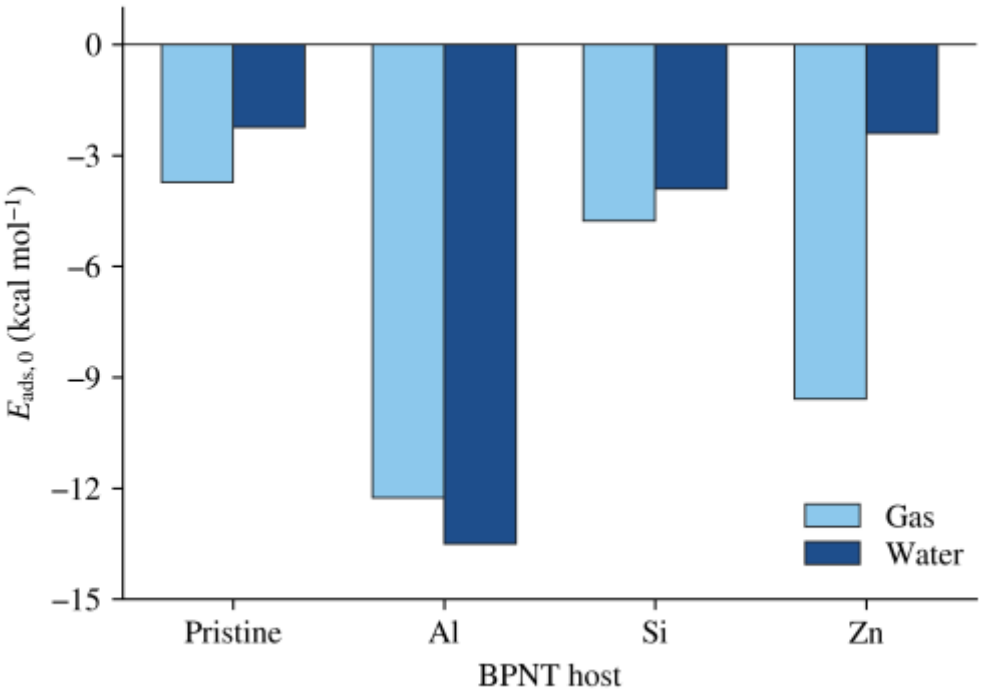

Figure 2. Zero-point-corrected adsorption energies. Gas is shown in light blue and implicit water in dark blue. Values use separately optimized fragment references.

Pristine and Si-BPNT also bind less strongly in water, but their changes are smaller than that of Zn. The adsorption-energy order is Al > Zn > Si > pristine in the gas phase. It changes to Al > Si > Zn > pristine in water, where the order denotes decreasing binding strength. The solvent response is therefore specific to the substituted site.

Recovery time follows the binding-energy magnitude exponentially. Al has the longest estimate in both environments: 3.190×10^{-4} s in the gas phase and 2.641×10^{-3} s in water. Gas-phase Zn gives 3.584×10^{-6} s. The much shorter aqueous estimates for the other hosts follow their weaker calculated binding. These small values should not be read as experimentally achievable device switching times.

For the hosts shared with Esfandiarpour et al. (2022), the gas-phase binding order agrees: Al > Si > pristine.

Orbital gaps and first hyperpolarizability

Zn has the smallest gas-phase gap, 2.4581 eV. Pristine and Si-BPNT have similar values near 2.52 eV. Al gives α and β gaps of 2.6936 and 2.7437 eV; the latter enters Table 2. In water, the Al gaps are 2.7202 and 2.7883 eV. The β gaps enter TOPSIS.

Pristine BPNT has the smallest aqueous gap, 2.5361 eV. The Si and Zn gaps increase to 2.5874 and 2.5965 eV. These changes modify the electronic criterion but receive a relatively small weight in TOPSIS. A smaller molecular gap alone does not establish a measurable conductivity response.

The Al electronic trend differs from the earlier BPNT–CO_2 calculation. Esfandiarpour et al. (2022) reported a gap decrease after adsorption. For the present finite model, the Al α gap increases from 2.654 to 2.694 eV. Agreement in adsorption strength therefore does not establish agreement in sensing response. Cluster size, the basis set and the open-shell orbital treatment remain relevant to this comparison.

The first hyperpolarizability follows a different order from adsorption strength. Gas-phase Zn has the largest β_0, 74.800×10^{-30} esu, followed by Al, Si and pristine BPNT. Water increases β_0

for all four systems. Zn reaches 289.909 × 10^{-30} esu, while Si exceeds Al in the aqueous comparison. The Zn structure thus retains a large electric response even when its CO_2 binding becomes weak.

Selected interaction regions

Figures 3 and 4 show the CDD isosurfaces for the eight complexes. The maps locate electron-density redistribution around CO_2 and the neighbouring nanotube framework. They do not quantify the net charge transferred between the fragments.

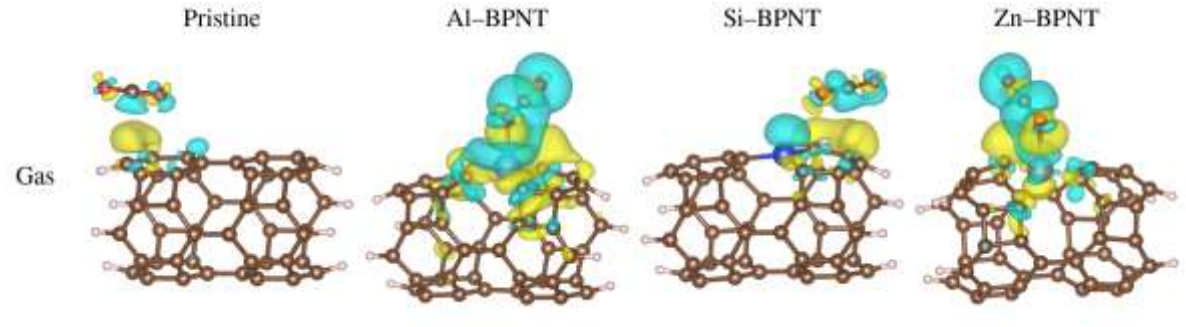

Figure 3. Charge-density-difference isosurfaces in the gas phase at $|\Delta\rho|$ = 0.0004 a.u. Panels show pristine, Al, Si and Zn hosts from left to right.

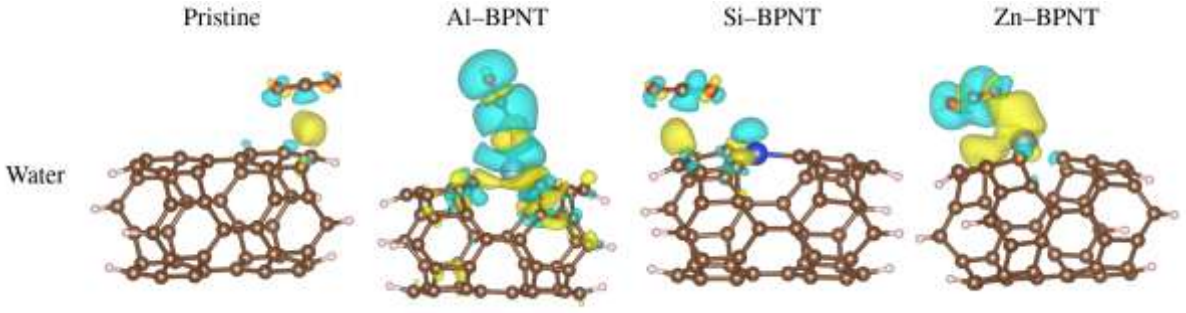

Figure 4. Charge-density-difference isosurfaces in implicit water at $|\Delta\rho|$ = 0.0004 a.u. Panels show pristine, Al, Si and Zn hosts from left to right.

Figure 5 compares gas-phase Zn and aqueous Al, the leading alternatives under the base weights. In the Zn RDG/NCI surface, the contact contains green and blue regions. These are consistent with a low-density interaction that includes an attractive contribution near the dopant. The aqueous Al surface also shows an attractive contribution near CO_2, together with a small repulsive region around the local framework.

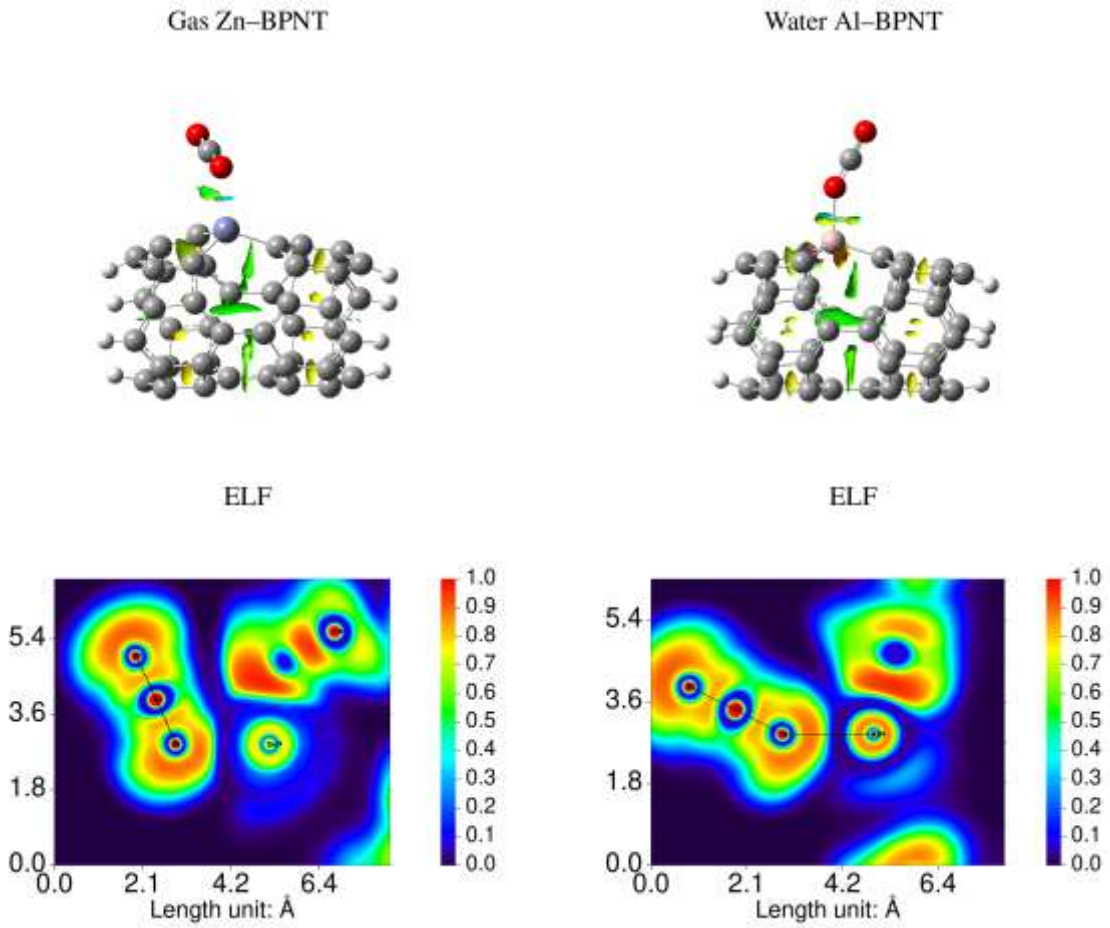

Figure 5. RDG/NCI surfaces (upper panels) and ELF sections (lower panels) for the gas Zn and aqueous Al complexes. In RDG/NCI, blue indicates attractive and red repulsive regions; green marks weak interactions. ELF uses a 0–1 scale. The original section extents are retained.

The ELF sections contain regions of high localization around the constituent atoms. The interfragment region is less localized than these atomic regions. This pattern is consistent with polarized adsorption contacts rather than a uniformly localized electron pair between the fragments. A two-dimensional section does not establish an ELF basin population or a complete bond topology (Becke and Edgecombe, 1990).

The intraring NCI features belong to the nanotube framework and are distinct from the CO_2–host contact (Johnson et al., 2010).

AHP–TOPSIS ranking

Adsorption energy and recovery time account for 79.28% of the total weight. Their opposing preference directions dominate the selection. Al benefits from its strong binding and short contact, but its longer estimated release time lowers its score. Table 3 and Figure 6 show the resulting rankings.

Table 3. TOPSIS closeness coefficients and ranks under the base weights.

Host	**Gas C_i**	**Gas rank**	**Water C_i**	**Water rank**
Pristine	0.5043	3	0.4008	4
Al	0.4938	4	0.5975	1
Si	0.5385	2	0.4453	2
Zn	0.7978	1	0.4068	3

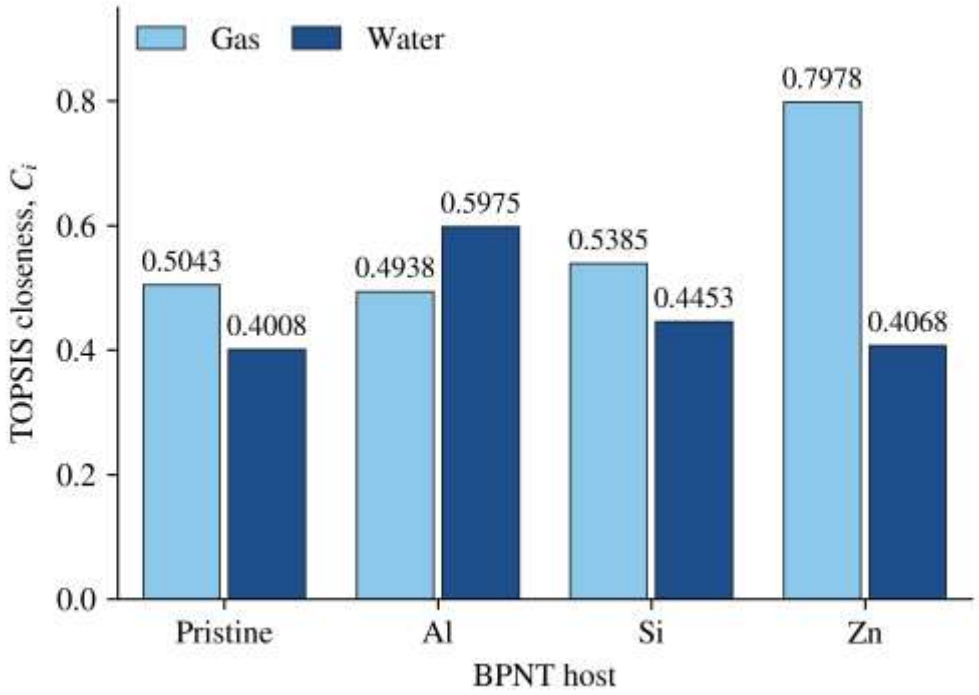

Figure 6. TOPSIS closeness coefficients. Gas is shown in light blue and implicit water in dark blue. Each environment is normalized independently; a larger coefficient is preferred within that environment.

The gas-phase order is Zn > Si > pristine > Al. Zn combines substantial binding with a shorter recovery estimate than Al. It also has the smallest adopted gap and the largest β_0. Al ranks fourth despite having the strongest adsorption. This position follows from the selected balance between retention and release.

The aqueous order is Al > Si > Zn > pristine. Al retains strong binding while Zn loses much of its adsorption stabilization. The high aqueous Zn hyperpolarizability contributes only weakly because of its small criterion weight. Al therefore becomes the preferred alternative under the same weights used for the gas-phase comparison.

Zn remains first in all ten gas-phase weight perturbations. In water, Al remains first in nine scenarios. Reducing the adsorption-energy weight by 20%, from 0.5202 to 0.4162, places Si first. A finer scan locates the Al–Si crossover near a weight of 0.442. The aqueous preference therefore depends more on the weight assigned to adsorption energy.

An acceptable AHP consistency ratio checks the coherence of the pairwise judgements; it does not validate the quantum-chemical method. TOPSIS compares the available alternatives against the selected criteria rather than estimating absolute capture performance.

The implicit-water calculation represents dielectric polarisation. It contains no explicit solvent molecules and cannot describe competitive water adsorption. The finite clusters also provide no adsorption capacity, gas selectivity or repeated-cycle measurements.

CONCLUSIONS

Al substitution yields the strongest calculated CO_2 adsorption in the gas phase and in implicit water. Its shorter aqueous Al–O contact is associated with stronger binding. Zn shows the greatest solvent-induced weakening, although it has the largest first hyperpolarizability in both environments. Adsorption strength and electric response therefore indicate different host preferences.

The five-criterion evaluation ranks Zn first in the gas phase and Al first in water under the base AHP weights. Gas-phase Zn remains first across the range of tested weight changes. The aqueous result is less stable, and Si becomes preferred when the adsorption-energy weight is sufficiently reduced. Verification with explicit environments and adsorption measurements is needed before assigning capture or regeneration performance.

ABSTRACT

In this study, the adsorption behaviour of thiophene molecules on pristine and metal-doped biphenylene nanotubes (BP-NTs and metalBP-NTs) was investigated using density functional theory (DFT) calculations. The Al-, Si- and Zn-doped BP-NTs were considered. The structural, electronic, and energetic properties of the thiophene/BP-NT and thiophene/metal-doped BP-NT systems were examined to elucidate how different dopant atoms influence the interaction mechanism between thiophene and the nanotube surface. Different configurations, corresponding adsorption energies, equilibrium geometries, charge transfer, and electronic structure were also studied. The results reveal that thiophene adsorption on pristine BP-NT is relatively weak, whereas substitutional doping with Al, Si and Zn significantly modifies the adsorption characteristics of the nanotube. In particular, dopant atoms create active adsorption sites and enhance interactions between the thiophene molecule and the Biphenylene nanotube (BPNT) surface, changing adsorption energy and charge redistribution. Furthermore, electronic structure analysis shows that thiophene adsorption induces noticeable changes in the density of states (DOS) and the electronic properties of doped nanotubes. Among the investigated systems, Al-, Si-, and Zn-doped BPNTs exhibit different sensitivities to thiophene, indicating that the nature of the dopant plays a crucial role in controlling adsorption properties. These findings suggest that doped BPNTs have considerable potential as detecting and sensing materials for thiophene.

Keywords: Thiophene, Biphenylene nanotubes, Sensors, DFT

INTRODUCTION

Thiophene is an organosulfur compound found in petroleum-derived fuels. Researchers investigate thiophene adsorption as a potential approach to reduce fuel sulfur content. Thiophene adsorption is important, particularly for fuel desulfurization. To understand catalyst behaviour, thiophene adsorption onto metal surfaces or catalysts can occupy active sites and

influence catalytic reactions. Therefore, studying thiophene adsorption is important for understanding catalyst-poisoning mechanisms.
To investigate adsorption mechanisms, thiophene interacts with a surface via physisorption or chemisorption; understanding its adsorption energy, molecular orientation, and electronic structure provides valuable insight into molecule–surface interactions.
For sensor applications, thiophene interactions with metal, metal oxide, or carbon-based surfaces can contribute to the development of sensors for detecting sulphur-containing compounds.
The electronic properties of thiophene are important. Because thiophene contains a π-electron system, its adsorption onto metals and two-dimensional materials can induce charge transfer and alter the electronic structure. These effects make thiophene adsorption relevant to molecular electronics and sensing applications.
In some studies, there is particular interest in the interaction between thiophene and carbon-based nanostructures, such as fullerenes, carbon nanotubes (CNTs) and graphene sheets, and thiophenes (Nogueira et al., 2007; Denis et al., 2010; Al-Sawaff, Z. H., 2021; Al-Sawaff, Z. H., 2022; Farhami, N, 2022, Dalgic Senturk et al. 2023, Dalgic Senturk et al. 2025) .
To the best of our knowledge, no theoretical data are available on thiophene adsorption onto BP-NTs. Therefore, theoretical studies of the interaction between BP-NTs and thiophenes are needed.
In this study, we used recently developed BP-NT structures (Dalgic Senturk et al., 2026) to investigate the interaction between thiophenes and alternative CNTs, including BP-NTs.

MATERIAL AND METHOD

In this study, DFT was utilised to investigate the adsorption of thiophene on BP-NTs using the Gaussian 09W package (Frish et al., 2009) and visualised in Gauss View (Dennington et al., 2008).

The pristine BPNT model comprises 48 carbon atoms and eight hydrogens terminating the open ends. Replacing one framework carbon at the selected site with Al, Si, or Zn gives $C_{47}H_8M$ (M = Al, Si or Zn). All models are neutral. We treated pristine, Si- and Zn-BPNT as restricted singlets, while Al-BPNT, with 303 electrons, as an unrestricted doublet.

We optimised the first thiophene and pristine/doped BP-NTs independently. The complexes were formed by positioning the active atoms at various sites on the BP-NTs. We performed all geometry optimisations, frequency, and single-point (SP) calculations using the M062X functional with the 6-31G(d) level of theory.

Recent studies have shown that the M062X/6-31G(d) method is preferred for molecular interactions because it performs better than traditional functionals [8, 19-21]. In this context, the M062X/6-31G(d) method is considered to provide more reliable results for accurately describing weak/non-covalent interactions and for including long-range corrected energy. The adsorption energies (E_{ads}) of thiophene on pristine and doped BP-NTs without any correction have been calculated by the following formula:

$$E_{ads} = E_{complex(Thiophene\ /BP-NTs)} - \left(E_{Thiophene} + E_{BP-NTs}\right) \quad (1)$$

Where $E_{Thiophene}$ and $E_{BP\text{-}NTs}$ are the isolated energies of the thiophene and pristine and doped BP-NTs, respectively. The total energy of the Thiophene/BP-NT complexes after optimisation is represented by $E_{complex}$ (Thiophene/BP-NTs). The basis-set superposition error (BSSE) correction to the Eads, obtained by the counterpoise (CP) method, is denoted Eads (BSSE).

The Molecular Orbital (MO) analysis was complemented by density of states (DOS) calculations performed with the GaussSum software (O'Boyle et al. 2008). To determine the sensing mechanism of the BP-NTs, the variation in the Eg bandgap due to the adsorption process of thiophene is taken into account by:

$$\%\Delta E_g = \left(\frac{Eg2-Eg1}{Eg1}\right) x100 \quad (2)$$

Where the Eg1 and Eg2 values correspond to the Eg values of BP-NTs and complex structures which are composed from thiophene and BP-NTs, respectively. Both % ΔEg and %ΔΦ values represent the percentage changes in bandgap and work function of the complexes relative to BP-NTs, respectively, and are listed in Table 2. The %ΔΦ value can be determined using the same logic as for band gap energies, as shown in Eq. (2).

RESULTS AND DISCUSSION

The thiophene molecule and pristine and doped BP-NTs optimised with the M062X functional level and the 6-31G(d) basis set are shown in Figure 1 and Figure 2, respectively. Frequency analyses confirmed that the optimised thiophene and BP-NT structures are stable, as no imaginary frequencies were observed.

Figure 1. The optimized structures of Thiophene

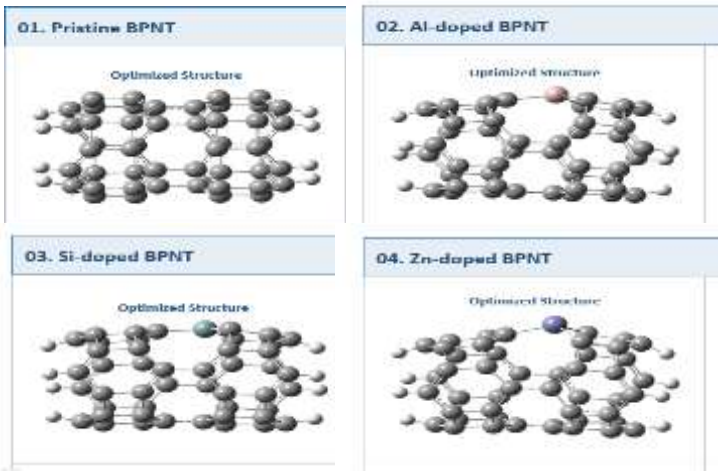

Figure 2. The optimised structures of BP-NTs

To investigate thiophene adsorption behaviour, we considered several initial orientations and adsorption positions on pristine and doped BP-NT surfaces. Figure 3 shows the optimised representative configurations for pristine BP-NT, Al-BPNT, Si-BPNT, and Zn-BPNT,

designated as Complexes 1–4, respectively. The structural analysis considered both weakly bound and more strongly interacting configurations. The calculated adsorption, interaction, and deformation energies provide a quantitative basis for comparing how different dopant atoms affect thiophene–BP-NT interactions.

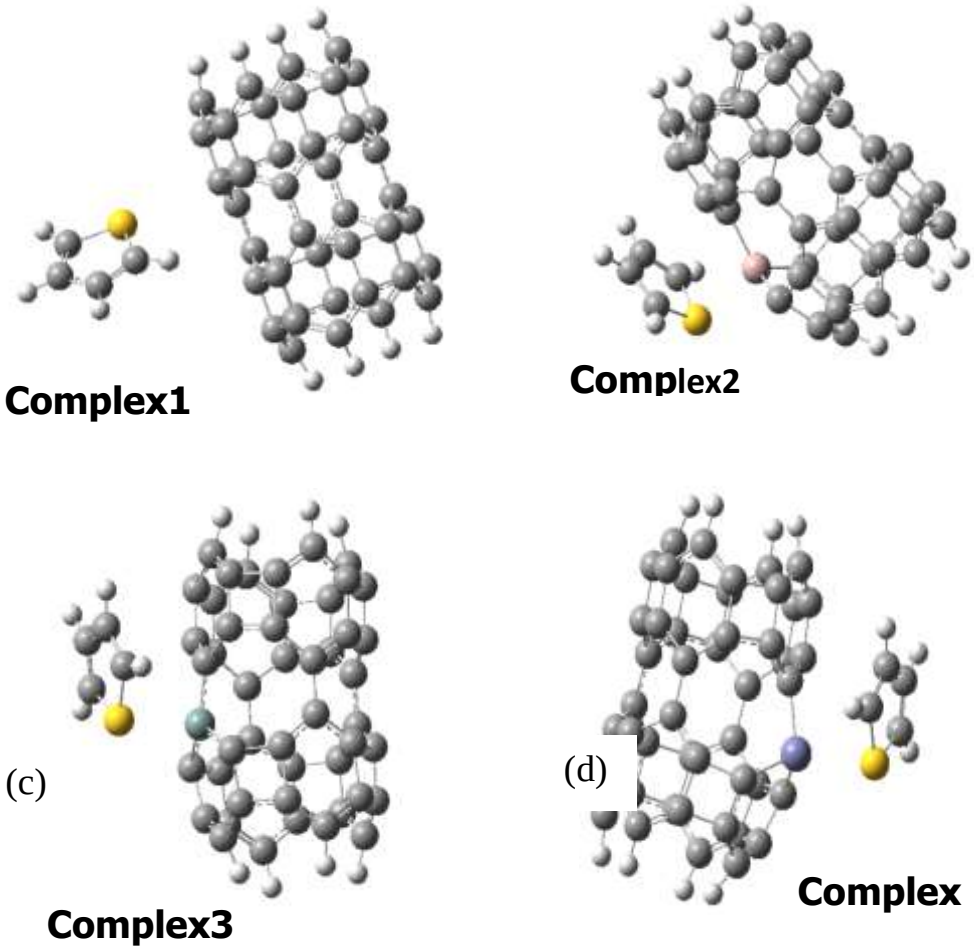

Figure 3. The optimized geometries of the complex structures composed of thiophene with BP-NTs a) Pristine BP-NT (complex1), b) Al-BPNT (complex2) c) Si-BPNT (complex3) d) Zn-BPNT (complex4).

The investigation of the adsorption process, the interaction, and deformation energies are also calculated (refer to Dalgic Senturk, 2023).

The complexes shown in Figure 3 are identified as having positive frequencies in the single-point (SP) calculations. Four complexes, from both physisorption and chemisorption categories, are presented here. The calculated energetic parameters are summarised in Table 1. Table 1 presents the bond distances, along with the calculated, without BSSE-corrected, adsorption, interaction, and deformation energies in kcal/mol for the gas phase. For pristine BP-NT, the adsorption energy of thiophene is −4.115 kcal/mol, while the corresponding interaction energy is −4.014 kcal/mol and the deformation energy is only 0.100 kcal/mol. The relatively small adsorption energy indicates that thiophene interacts weakly with the pristine BP-NT surface. The small deformation energy further indicates that the adsorption process produces only a minor structural perturbation of the individual components.

Substitutional doping yields markedly different behaviour. For Al-doped BP-NT, the adsorption energy decreases to −18.079 kcal/mol, with an interaction energy of −20.175 kcal/mol and a deformation energy of 2.096 kcal/mol. Thus, replacing a carbon atom with Al markedly increases the magnitude of the thiophene–nanotube interaction relative to the pristine system. The larger deformation energy also indicates that structural relaxation of the interacting components contributes more significantly to the final complex than in pristine BP-NT. For Si-BPNT, the calculated adsorption energy is −10.705 kcal/mol, whereas the interaction and deformation energies are −13.161 kcal/mol and 2.455 kcal/mol, respectively. The interaction is therefore stronger than that calculated for pristine BP-NT but weaker than that obtained for Al-BPNT. The larger deformation contribution compared with pristine BP-NT suggests that Si substitution also modifies the local geometry and electronic environment around the adsorption site.

Table 1. Bond distances (Å), adsorption energy (Eads) without BSSE, interaction energy (Eint), deformation energy (Edef) for the complexes, the change in enthalpy (ΔH) and Gibbs Free energy (ΔG). (All energies are in kcal/mol).

Structure	d (Å)	Eads (kcal/mol)	Eint	Edef	ΔH	ΔG
complex1	3.101	-4.115	-4.014	-0.100	**-3.296**	>0
complex2	2.532	-18.079	-20.175	2.096	-17.364	-6.766
complex3	2.552	-10.705	-13.161	2.455	-10.170	>1.324
complex4	2.619	-14.878	-16.226	1.347	-14.171	-3.483

The Zn-doped BPNT exhibits an adsorption energy of −14.878 kcal/mol, an interaction energy of −16.226 kcal/mol, and a deformation energy of 1.347 kcal/mol. The magnitude of the Zn-associated adsorption energy is substantially larger than that of pristine BP-NT and lies between the Al- and Si-doped systems in the calculated series. These results demonstrate that substitutional metal doping creates adsorption environments that interact more strongly with thiophene than the undoped BP-NT surface. Overall, the calculated adsorption energies indicate that substitutional doping substantially alters the interaction strength. Across the investigated systems, values range from approximately −4.1 to −18.1 kcal/mol, showing that the dopant's chemical nature strongly influences thiophene adsorption. The corresponding interaction energies follow the same general trend, confirming that enhanced adsorption is associated with changes in the underlying molecule–surface interaction rather than structural deformation alone.

Deformation energies should also be considered when interpreting adsorption energies. The pristine BP-NT complex has the smallest deformation energy, whereas the doped systems show larger values. In particular, Si-BPNT has a deformation energy of 2.455 kcal/mol, followed by Al-BPNT (2.096 kcal/mol) and Zn-BPNT (1.347 kcal/mol). < intermolecular interactions and the structural relaxation required to accommodate thiophene at the modified adsorption site.

The calculated enthalpy changes further support the differences observed across the systems. The calculated values are −3.296 kcal/mol for thiophene/pristine BP-NT, −17.364 kcal/mol for thiophene/Al-BPNT, −10.170 kcal/mol for thiophene/Si-BPNT, and −14.171 kcal/mol for thiophene/Zn-BPNT. The substantially more negative enthalpy changes observed for the Al-,

Si-, and Zn-doped systems indicate that substitution alters the energetic environment experienced by thiophene. The Al-containing system shows the largest magnitude of calculated enthalpy change, followed by Zn and Si. This trend aligns with the adsorption-energy results and indicates that metal substitution can significantly alter the thermodynamic driving force for thiophene–BP-NT association. The reported Gibbs free-energy values also differ between the systems. For the Al-doped complex, the calculated value is −6.766 kcal/mol, whereas the Zn-doped system gives −3.483 kcal/mol. For pristine BP-NT, the reported value is >0, and the Si-doped system also reports>1.324 kcal/mol.

These values indicate that energetic and thermodynamic descriptions are not interchangeable. Although the doped systems exhibit substantially stronger electronic interactions with thiophene, the calculated free-energy values are also affected by the thermodynamic treatment. Therefore, adsorption and interaction energies provide the clearest direct comparison of molecule–surface binding strength, whereas the reported Gibbs free energies should be interpreted in the context of the study's computational thermodynamic convention.

Electronic Properties and Quantum Molecular Descriptors

To determine the electrical and electronic properties of BP-NTs /doped-BPNTs and the Thiophene/BP-NTs- doped-BPNTs complexes, and the sensing capabilities of BP-NTs for thiophene, the Molecular Orbital Energies of HOMO and LUMO, the HOMO–LUMO energy band gap (Eg), Fermi level energy EF, work function Φ, hardness (η), and electrophilicity (ω) have been calculated and tabulated in Table 2. The pristine BP-NT has an Eg of 2.54 eV and a work function of 4.02 eV. Substituting a carbon atom with M=Al, Si, or Zn alters both quantities, indicating that the M-BPNT framework's electronic structure is sensitive to dopant type.

Table 2. HOMO energy (HOMO) in eV, LUMO energy (LUMO) in eV, HOMO/LUMO energy gap (Eg), work function (Φ), hardness (η), and electrophilicity (ω) of the complexes. %Δ Eg and %ΔΦ indicate the percentage change in bandgap and work function (Each complex was compared with its corresponding nanotube reference: pristine BPNT for complex 1, Al–BPNT for complex 2, Si–BPNT for complex 3, and Zn–BPNT for complex 4)

	BPNT	Al–BPNT	Si–BPNT	Zn–BPNT	complex1	complex2	complex3	complex4
HOMO	-5.29	-5.23	-5.35	-5.03	-5.31	-4.89	-5.06	-4.84
LUMO	-2.76	-2.49	-2.85	-2.58	-2.79	-2.18	-2.42	-2.35
Eg	2.54	2.74	2.50	2.45	2.52	2.71	2.63	2.48
%ΔEg					-0.79	1.09	5.20	1.22
Φ	4.02	3.86	4.10	3.81	4.05	3.53	3.74	3.59
%ΔΦ	-	-	-	-	0.75	-8.55	-8.78	-5.77
η	1.27	1.37	1.25	1.22	1.26	1.35	1.32	1.24
ω	6.39	5.44	6.72	5.93	6.52	4.61	5.31	5.20
EF	-4.02	-3.86	-4.10	-3.81	-4.05	-3.53	-3.74	-3.59
μ (-X)	-4.02	-3.86	-4.10	-3.81	-4.05	-3.53	-3.74	-3.59

In Table 2, Pristine BP-NT exhibits an Eg of 2.54 eV and a work function of 4.02 eV, while Al–BPNT, Si–BPNT, and Zn–BPNT exhibit Eg values of 2.74, 2.50, and 2.45 eV, respectively. Their corresponding work functions are 3.86, 4.10, and 3.81 eV. For Al–BPNT, the HOMO–LUMO gap increases to 2.74 eV (a 7.87% rise relative to pristine BPNT), while the work

function decreases from 4.02 to 3.86 eV (−3.98%). Si substitution slightly decreases Eg from 2.54 to 2.50 eV (−1.57%) and increases Φ to 4.10 eV (+1.99%). In the Zn-doped system, the HOMO–LUMO gap decreases to 2.45 eV (−3.54%), while the work function decreases to 3.81 eV (−5.22%).

The calculated HOMO–LUMO gaps for Complexes 1–4 are 2.52, 2.71, 2.63, and 2.48 eV, respectively. For Complex 1, the Eg decreases from 2.54 eV for pristine BPNT to 2.52 eV after complex formation, a reduction of 0.02 eV (0.79%). In contrast, Complex 2 shows a decrease in Eg from 2.74 eV for Al–BPNT to 2.71 eV, a reduction of 0.03 eV (1.09%). Complex 3 shows an increase in Eg from 2.50 eV for Si–BPNT to 2.63 eV, an increase of 0.13 eV (5.20%). Finally, Complex 4 exhibits a slight decrease in Eg from 2.45 eV for Zn–BPNT to 2.48 eV, corresponding to an increase of 0.03 eV (1.22%).

The work function provides complementary information on the electronic response. Complex 1 exhibits an increase in Φ from 4.02 eV for pristine BPNT to 4.05 eV, corresponding to a 0.75% increase. For Complex 2, the work function increases from 3.86 eV for Al–BPNT to 3.53 eV, corresponding to an 8.55% decrease. Complex 3 shows a decrease in Φ from 4.10 eV for Si–BPNT to 3.74 eV, corresponding to an 8.78% decrease. For Complex 4, the work function decreases from 3.81 eV for Zn–BPNT to 3.59 eV, corresponding to a 5.77% decrease.

These results indicate that the dopant's electronic influence is not uniform. Al substitution primarily increases frontier-orbital separation, whereas Zn substitution simultaneously decreases both Eg and Φ. Si–BPNT remains close to pristine BPNT in energy gap but exhibits the highest work function among the four isolated nanotube systems. Thus, the dopants establish distinct electronic environments prior to molecular adsorption, which must be considered when interpreting subsequent adsorption-induced changes.

To evaluate the electronic effect of adsorption, each complex was compared with its own corresponding nanotube reference. Complex 1 is associated with pristine BPNT, Complex 2 with Al–BPNT, Complex 3 with Si–BPNT, and Complex 4 with Zn–BPNT. This reference scheme allows the changes induced by molecular adsorption to be evaluated independently for each system.

These results demonstrate that adsorption does not produce a uniform change in the HOMO–LUMO gap. Complexes 1 and 2 show slight reductions in Eg relative to their corresponding nanotube references, whereas Complexes 3 and 4 show increases. The magnitude of these changes is relatively small, with the largest variation observed for Complex 3. This indicates that the effect of adsorption on the frontier-orbital separation depends on the electronic structure of the underlying nanotube and the specific adsorption configuration. The work-function results indicate that molecular adsorption produces a more pronounced response in Φ than in Eg for several of the systems. In particular, Complexes 2 and 3 exhibit substantial reductions in work function relative to their corresponding nanotube references, whereas the change for Complex 1 is small. Complex 4 also shows a noticeable reduction in Φ. These changes indicate modifications of the surface electronic potential associated with molecular adsorption.

The results therefore demonstrate that the electronic response of BPNT to molecular adsorption is strongly dependent on both the dopant and the adsorption environment. In particular, the pronounced work-function changes observed for the Si-containing and pristine BPNT complexes indicate substantial modifications of the surface electronic potential, whereas the Zn-containing system shows that adsorption can partially modify the electronic characteristics

introduced by metal substitution. These findings provide a consistent electronic-structure basis for further investigation of metal-doped BPNTs as adsorption-responsive nanomaterials.

Density of States (DOS) Analyses

From a materials perspective, the calculated above results indicate that pristine and doped BP-NTs should not be expected to respond identically to thiophene. The relatively weak interaction calculated for pristine BP-NT contrasts with the considerably stronger interactions obtained following Al, Si, and Zn substitution. In addition, adsorption modifies the electronic structure of the doped nanotubes, as demonstrated by the frontier-orbital and DOS analyses. Figure 5 compares the gas DOS spectra of Al-BPNT and Thiophene/Al-BPNT. Figure 6, presented the gas DOS spectra of Thiophene/Zn-BPNT.

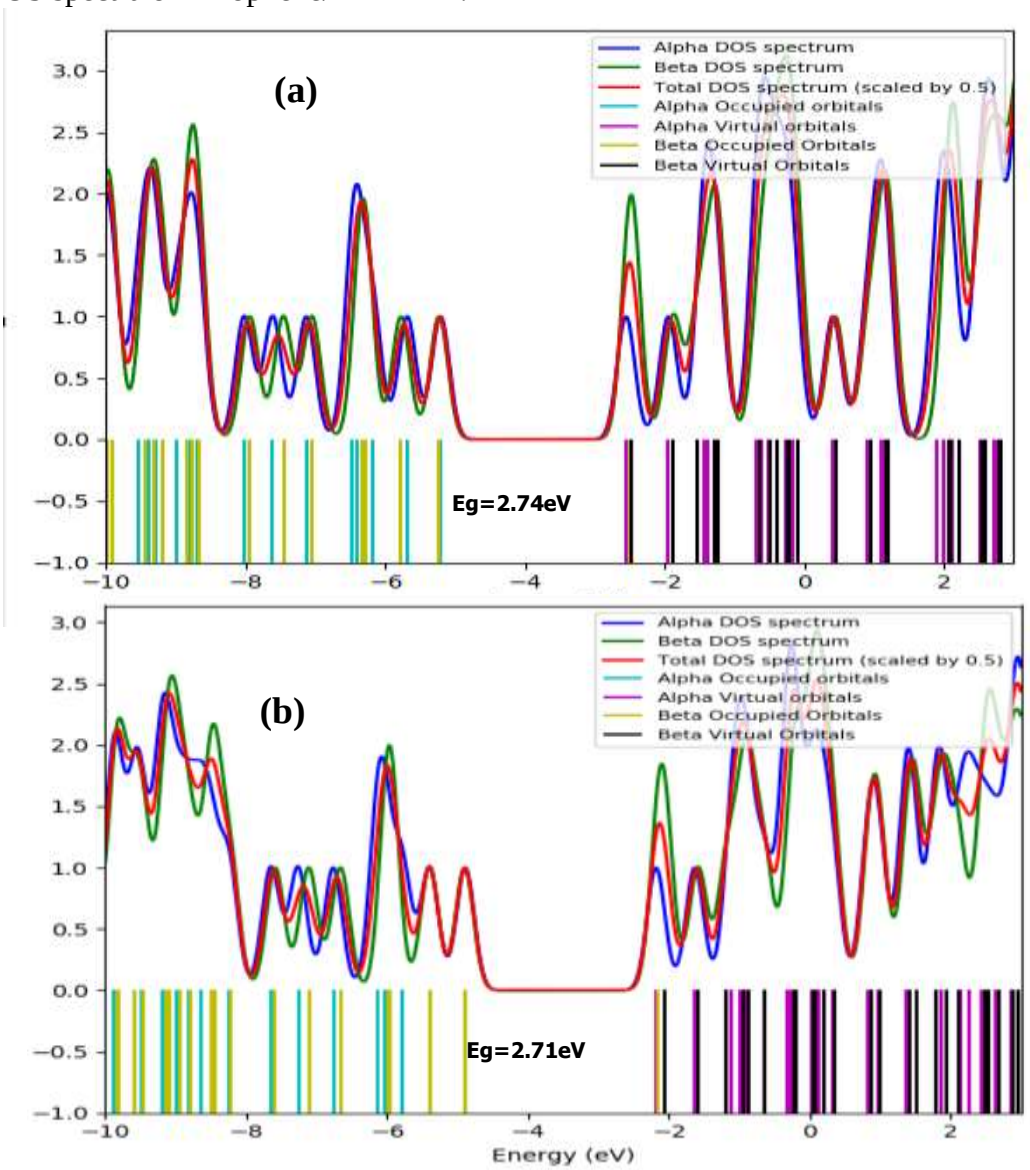

Figure. 5: DOS spectra of (a) Al-BPNT. The red Al curve is 0.5(DOS_{α} + DOS_{β}); the marked gap is the beta gap. (b) Thiophene/Al-BPNT (complex2)

For the Al-BPNT system, the DOS spectrum of the isolated Al-BPNT shows a distinct distribution of occupied and virtual electronic states, with a calculated energy gap of 2.74 eV. After thiophene adsorption, forming complex 2 (Thiophene/Al-BPNT), the DOS profile changes, and the energy gap decreases slightly to 2.71 eV. This relatively small reduction

indicates that thiophene adsorption perturbs the electronic structure of Al-BPNT without causing a dramatic collapse of the electronic gap. The change is consistent with electronic interaction between the adsorbed thiophene molecule and the doped nanotube. Thus, the Al dopant provides an electronically active adsorption environment in which thiophene adsorption produces a measurable redistribution of the available electronic states. The DOS spectra also preserve distinguishable contributions associated with the spin channels in the Al-containing system. The Al-BPNT DOS was therefore treated by considering the alpha and beta contributions, with the reported Al curve corresponding to 0.5(DOSα + DOSβ), while the indicated gap corresponds to the beta channel. This feature is important when interpreting the electronic response because the interaction cannot be described solely by the total density of states without considering the individual electronic contributions.

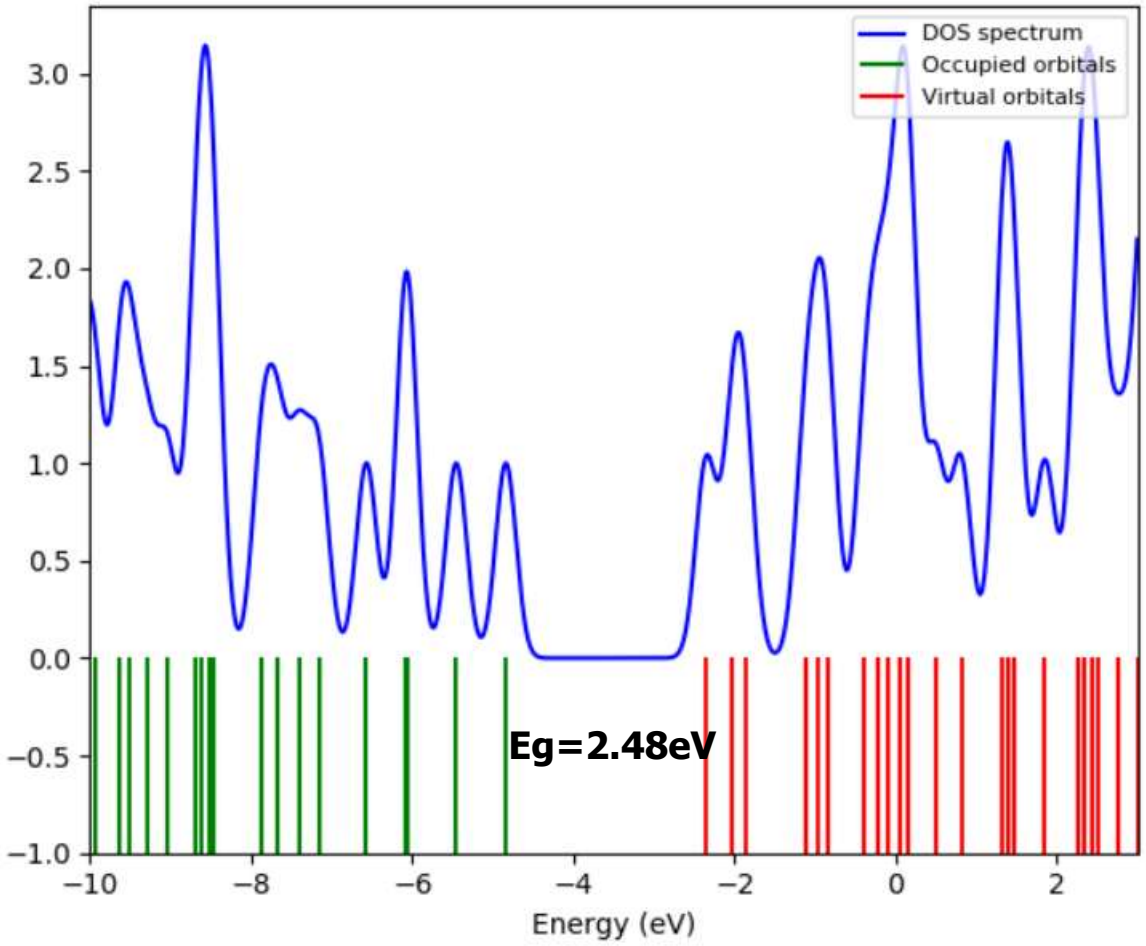

Figure. 6: DOS spectra of Thiophene/Zn-BPNT.

A similar electronic perturbation is observed in the Zn-doped system. The DOS spectrum of Thiophene/Zn-BPNT shows an energy gap of 2.48 eV. This substantially smaller gap than in isolated Al-BPNT indicates that Zn substitution creates a different electronic environment around the adsorption site.

The DOS distribution of the Zn-containing complex therefore shows that Zn incorporation modifies the electronic states available near the frontier region and that these states contribute to the electronic response to thiophene adsorption.

The DOS results should be interpreted alongside the calculated adsorption energies and charge-transfer characteristics. The stronger interactions observed for the metal-doped BP-NTs indicate that metal substitution introduces electronically active sites that interact more effectively with thiophene than the pristine nanotube. The DOS analysis provides an electronic-structure explanation for this behaviour: adsorption is accompanied by changes in the distribution and separation of occupied and unoccupied states. These changes are particularly relevant for understanding the response of the doped nanotubes, as the electronic structure near the frontier region determines how sensitively the material responds to molecular adsorption.

CONCLUSIONS

This work investigated thiophene adsorption on pristine and doped biphenylene nanotubes. Table I indicates that thiophene is physically adsorbed onto biphenylene nanotube surfaces. Thus, Al-biphenylene nanotubes and Zn-biphenylene nanotubes are candidates for use as electrochemical sensors for thiophene, and others are suitable for detection.

The DFT results demonstrate that substitutional Al, Si, and Zn doping significantly modifies thiophene adsorption on BP-NTs. The calculated adsorption energies, interaction energies, deformation energies, frontier-orbital properties, and DOS changes collectively show that the dopant atom plays an important role in determining the strength and electronic consequences of thiophene adsorption. The results thus provide a computational foundation for further investigation of doped BP-NTs in applications involving sulfur-containing molecular detection. The original paper likewise identifies the doped BP-NT systems as candidates for thiophene detection.

The DOS analysis demonstrates that **metal substitution and thiophene adsorption act cooperatively to modify the electronic structure of BP-NTs.** For Al-BPNT, thiophene adsorption changes the calculated gap from 2.74 to 2.71 eV, whereas the Thiophene/Zn-BPNT system exhibits a gap of 2.48 eV. These changes, together with the stronger adsorption calculated for the doped systems, support the conclusion that Al, Si, and Zn substitution creates electronically differentiated adsorption environments.

These results provide a theoretical basis for considering metal-doped BP-NTs as candidate materials for thiophene detection. However, the present calculations describe molecular adsorption on finite BP-NT models and therefore primarily establish the interaction and electronic-response characteristics of the systems. Experimental sensor performance, selectivity, response time, regeneration under operating conditions, and long-term stability would require separate investigation.

ABSTRACT

Soil structure is the most dynamic physical factor directly governing atmospheric carbon dioxide (CO_2) emissions through aggregate development, pore size distribution, and gas diffusion capacity. The CO_2 released from the soil is essentially a product of microbial decomposition (heterotrophic respiration) and root respiration (autotrophic respiration). Soil structure controls this release with two basic protective barriers consisting of aggregation and porosity. In aggregation or physical conservation, the stable structure of micro aggregates (<250 µm) in particular stabilizes organic carbon by trapping it in narrow pores inaccessible to microbial enzymes and oxygen. Mechanical interventions, such as intensive tillage, break down these aggregates, releasing carbon and causing sudden bursts of CO_2. The macro and micro-pore network of the soil determines the rate of gas exchange through the regulation of gas diffusion. In conclusion, sustainable agricultural practices that preserve soil structure, such as no-till cropping, cover crop use, and organic fertilization, enhance the soil's capacity to act as a carbon sink by increasing bio-glucosides like glomalin and aggregate stability, thereby minimizing CO_2 emissions that contribute to global warming.

Key words: Soil, structure, porosity, carbon dioxide, emission.

INTRODUCTION

Mitigating global climate change and reducing greenhouse gas emissions constitute one of the most critical focal points of modern environmental and agricultural sciences. As frequently emphasized in the reports of the Intergovernmental Panel on Climate Change (IPCC), terrestrial ecosystems play a dual role in the global carbon (C) cycle, acting both as a massive sink and a potential source (IPCC, 2023).

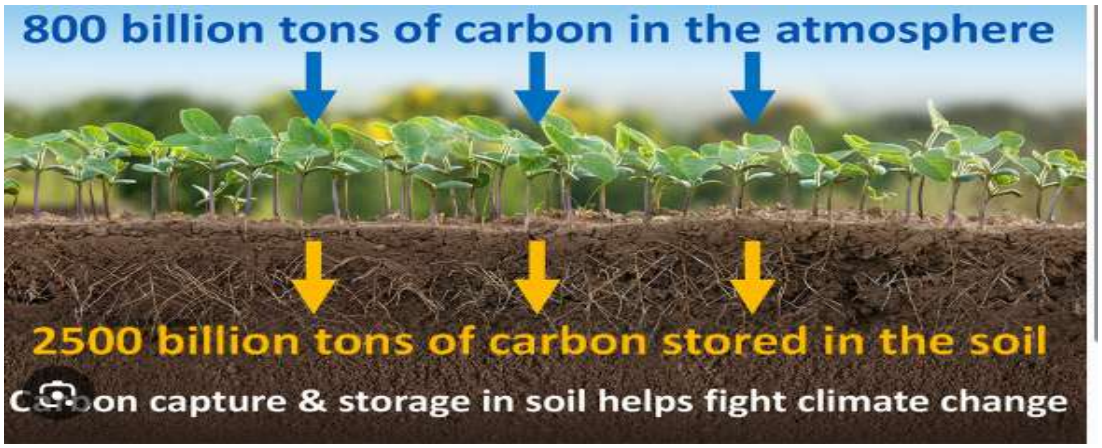

Fig. 1. Carbon in the soil plays a huge role in combating climate change
https://drearth.com/resources/article/fertilizer-nutrient-information-copy/

Global soils represent the largest dynamic terrestrial carbon pool, storing approximately three times the amount of carbon found in the atmosphere and four times that of aboveground biomass (around 1500–2400 Pg C) (Lal, 2004; Batjes, 2016). Consequently, even minor percentage fluctuations within the soil carbon pool possess the potential to exert a multiplier effect on atmospheric carbon dioxide (CO_2) concentrations and global warming trends. The relationship between soil structure and CO2 emissions is a critical issue regarding the global carbon cycle and sustainable agriculture.

Fig. 2. Soil Carbon Sequestration https://www.azocleantech.com/article.aspx?ArticleID=1655

Physical properties such as soil aggregates, porosity, and gas diffusion directly govern the respiration activities of microorganisms and roots. Soil structure consists of the arrangement of aggregates formed by the combination of primary mineral particles (sand, silt, clay) with organic binding agents, fungal hyphae, and root exudates and the pore network situated between these arrangements (Tisdall and Oades, 1982). On the other hand, CO_2 emission is a result of root respiration (autotrophic) and microbial decomposition (heterotrophic) (Schlesinger ve

Andrews, 2000). The rate and magnitude of these processes are directly controlled by soil structure which the most dynamic physical property of soil as well as by climatic factors such as soil temperature and moisture (Six et al., 2004). This review discusses how soil structure shapes CO_2 emissions through aggregation dynamics and pore-size distribution mechanisms, the effects of anthropogenic structural degradation on emission kinetics, and the potential of sustainable soil management strategies to transform soil from a carbon source into a stable carbon sink.

The Role And Mechanisms of Soil Structure on CO_2 Emissions

Soil structure influences CO_2 emissions through aggregate stability and pore size distribution**.** Aggregates are classified into macro aggregates (>250 µm) which are generally held together by roots and fungal hyphae and are more sensitive to management and micro aggregates (<250 µm) which are more persistent and responsible for the long-term stabilization of soil organic carbon (SOC) (Tisdall and Oades, 1982). The narrow pore structure of micro aggregates entraps organic matter, making it inaccessible to microbial enzymes and oxygen (O_2). This physical barrier prevents heterotrophic microorganisms from utilizing carbon as a substrate, consequently minimizing CO_2 production (Lal, 2004). The macro pore and micro pore network of the soil governs the rate of gas exchange (gas permeability). In loose and well-aggregated soils, O_2 influx and CO_2 diffusion are rapid, thereby supporting aerobic respiration (Smith et al., 2003). However, when soil becomes severely compacted or water-saturated, gas diffusion is virtually halted. In these anoxic environments, while aerobic CO_2 production is suppressed, anaerobic processes are activated, leading to the emission of greenhouse gases with much higher global warming potentials, such as methane (CH_4) and nitrous oxide (N_2O) (Davidson and Janssens, 2006, Ball, 2013).

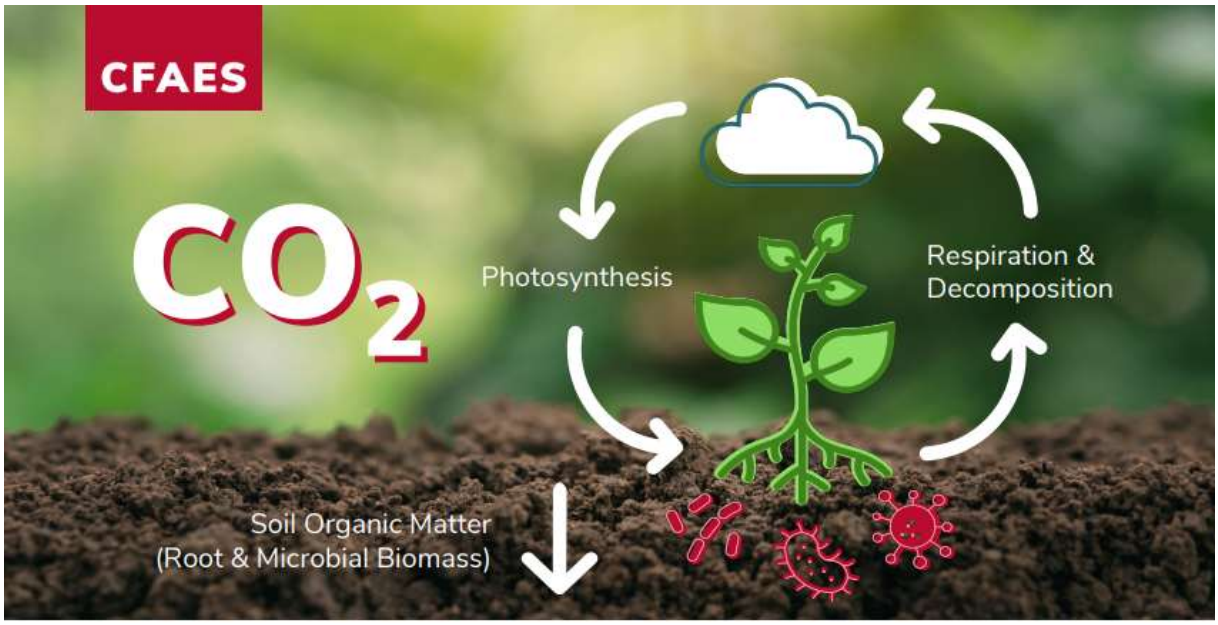

Fig. 3. The soil carbon cycle and the role of soil organic matter in carbon (https://carbon.osu.edu)

The Effect of Tillage on Aggregate Breakdown and CO2 Emission

Anthropogenic interventions such as intensive tillage, overgrazing, and monoculture production lead to the structural degradation of aggregate stability (Reicosky, 1997). The mechanical shear forces applied to the soil by tillage implements lead to the direct disruption of macro aggregates (>250 µm), which are particularly unstable (Beare et al., 1994), and result in the release of carbon-rich micro aggregates and free light fraction organic matter. Since vegetation and the

stubble layer are removed in tilled soils, the direct impact of raindrops on the bare soil (splash effect) physically disperses the aggregate structure (Al-Kaisi & Licht, 2005). Furthermore, as tilled dry soil rapidly becomes saturated with water, the compression of air within aggregate pores causes micro-explosions (slaking) and the disintegration of aggregates (Zaher et al., 2005). Fungi play a crucial role in binding aggregates together through their hyphae and glomalin, a stable glycoprotein they secrete (Wright & Upadhyaya, 1998). Intensive tillage physically disrupts fungal (Arbuscular Mycorrhizal Fungi - AMF) networks, significantly reducing new aggregate formation and aggregate stability (Helgason et al., 1998). When soil aggregates break down, stable organic carbon fractions, which have long been protected inside the aggregates, are suddenly exposed to a macroscopic influx of oxygen and thus become readily consumable substrates for heterotrophic microorganisms (Balesdent et al., 2000). This leads to massive emission waves from agricultural soils into the atmosphere, referred to as CO_2 bursts (Ellert and Janzen, 1999).

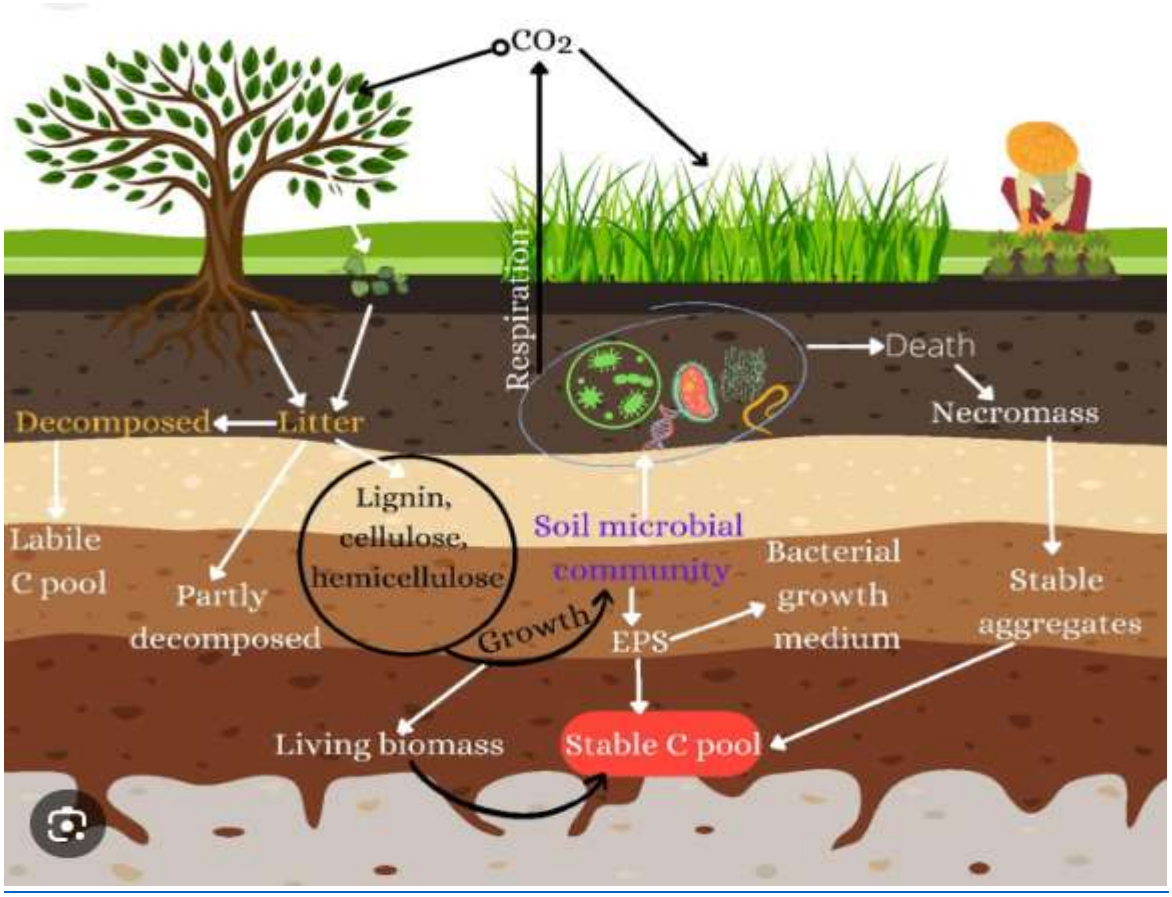

Fig. 4. Conceptual diagram of soil organic carbon formation and stabilization through plant residues and microbial processes. https://www.sciencedirect.com/science/article/pii/S0048969722000171

Sustainable Soil Management and Increasing Carbon Sinks

It has been reported that if global soil carbon stocks were increased by 0.4% annually, total human-induced annual CO2 emissions could be offset (Rodrigues et al., 2017). Achieving this goal depends on the global adoption of sustainable management practices. Sustainable agricultural practices that preserve and improve soil structure are the most effective tools for increasing the soil's carbon sequestration capacity. Conventional tillage mechanically disrupts macro aggregates, making carbon-rich micro aggregates vulnerable to microbial decomposition

(Beare et al., 1994). In contrast, conservation or no-till practices maintain aggregate stability and prevent mechanical fragmentation. Since the soil structure remains undisturbed, fungal hyphae and organic binding agents such as glomalin are preserved (Wright and Upadhyaya, 1998). This ensures the physical protection of carbon within the soil matrix and allows carbon to remain locked in the soil for extended periods, thereby minimizing CO_2 emissions (Six et al., 2002). Cover crops promote macro aggregate formation through their root systems and fungal hyphae. By blocking the physical impact of raindrops (splash effect) and wind erosion, they prevent the transport and loss of carbon-rich topsoil (Al-Kaisi & Licht, 2005). They stabilize microbial activity and prevent carbon loss through erosion. Keeping the soil covered with vegetation throughout the year ensures a continuous input of carbon. Furthermore, they contribute directly to microbial biomass and stable carbon fractions via root exudates (Paustian et al., 2016). Organic fertilizers such as compost and farm yard manure introduces humic substances and glomalin that a biotic glue produced by arbuscular mycorrhizal fungi into the soil and suppresses carbon emissions by maximizing aggregate stability (Wright and Upadhyaya, 1998). For example compost accelerates the formation of humic substances (humification) by supporting soil microbial activity and aggregation. Biochar obtained through the pyrolysis of biomass in an environment without oxygen consists of highly stable carbon that can remain in the soil without decomposing for hundreds or even thousands of years (Lehmann, 2007). When perennial plants and deep-rooted species are incorporated into the system instead of monoculture farming, deep-rooted plants transport carbon to the subsoil layers. Due to microbial activity and low oxygen levels, carbon in these subsoil layers is sequestered for a much longer period (centuries) compared to surface layers (Lorenz & Lal, 2005). Integrating trees into agricultural lands maximizes both above-ground (woody biomass) and below-ground carbon stocks simultaneously (Nair et al., 2009).

CONCLUSIONS

Soil structure is not just a mechanical support unit, but a biophysical filter that balances the global carbon budget. It plays a central role in regulating soil carbon dynamics and CO_2 emissions by mediating the accessibility of soil organic carbon (SOC) to microbial decomposers, the diffusion and transport of CO_2 and other gases within the soil, and the distribution and cycling of root and microbial respiration. Enhancing aggregate stability and optimizing porosity are highly effective in reducing CO_2 emissions by keeping the heterotrophic respiration rate under control. Sustainable agricultural management strategies directly contribute to the fight against global warming by transforming the soil from a carbon source into an active carbon sink.

ABSTRACT

This study was conducted to investigate the effects of potassium solubilizing bacteria (KSB) and different doses of biochar applications on growth parameters of wheat (*Triticum aestivum* L.), plant potassium content, and soil pH and electrical conductivity (EC). The experiment was carried out in a controlled climate chamber for 45 days under a photoperiod of 16 hours light (25°C) and 8 hours dark (20°C) with 60-70% relative humidity. The experiment was arranged in a completely randomized factorial design with three replications, consisting of two main factors: KSB application (non-inoculated control and KSB-inoculated) and four different biochar doses (0%, 1%, 2%, and 4%). Seeds were inoculated by immersion in bacterial suspension at approximately 10^8 CFU mL^{-1} for 30 minutes, while control seeds were treated with sterile distilled water. Each pot contained 2 kg of air-dry soil, and all pots received basal fertilization of 200 mg N kg^{-1} as ammonium sulfate and 80 mg P_2O_5 kg^{-1} as triple superphosphate, with no additional potassium fertilizer applied. At the end of the experiment, plant height (PH), plant fresh weight (PFW), plant dry weight (PDW), dry leaf weight (DLW), dry root weight (DRW), number of spikes (NS), plant potassium content, and soil pH and EC values were determined. the findings showed that KSB application significantly increased plant height by 6.2%, plant fresh weight by 15.8%, plant dry weight by 16.0%, and plant potassium content by 7.9%. Biochar application, particularly at the 4% dose, provided increases of 20.3% in plant height, 43.1% in dry leaf weight, and 43.2% in dry root weight, while causing a 23.7% decrease in plant potassium content. Analysis of variance results revealed that KSB × biochar interaction had highly significant ($p<0.01$; $p<0.001$) effects on plant fresh weight, plant dry weight, number of spikes, dry leaf weight, and dry root weight. While both KSB and biochar applications individually and in interaction had significant effects on soil pH, only KSB × biochar interaction was found to be significant for EC. In conclusion, it was determined that optimum dose ratios that would minimize potassium adsorption need to be determined in the combined application of biochar and KSB, and that long-term field trials using different biochar types and different KSB species are needed.

Keywords: Biochar, potassium solubilizing bacteria, *Triticum aestivum*, plant development

INTRODUCTION

Wheat (*Triticum aestivum* L.) is one of the staple food sources for the world's population and ranks among the strategic crops with the largest cultivation area in global cereal production. Sustainable increase in wheat production is of great importance to meet the food needs of the growing population. However, intensive agricultural practices lead to problems such as imbalanced use of nutrients in soils, loss of organic matter, and deterioration of soil quality. In

this context, developing alternative methods that reduce chemical fertilizer use while preserving soil health and improving plant nutrition has become a critical necessity for sustainable agriculture.

Potassium (K) is one of the three essential macro-nutrients required for healthy plant development. Potassium, which plays vital roles in physiological processes such as enzyme activation, protein synthesis, photosynthesis, water regulation, and osmotic control in plants, also directly determines product quality and yield (Marschner, 2012). Although total potassium content in soils is generally high, most of this potassium is trapped in the crystal structure of primary minerals such as feldspar and mica and is not in a soluble form directly available to plants (Sparks, 1987). Only 1-2% of soil potassium exists in plant-available forms (soluble and exchangeable K). This situation necessitates the development of alternative strategies to make potassium available to plants.

In recent years, the use of organic soil amendments has become increasingly widespread to enhance soil fertility and improve plant nutrition. Biochar, one of these amendments, is a carbon-rich, porous material produced through pyrolysis of organic materials under oxygen-limited or oxygen-free conditions (Lehmann, 2007). Biochar has the potential to improve physical, chemical, and biological properties of soils due to its high surface area, porous structure, high cation exchange capacity, and chemical functional groups (Lehmann et al., 2011). Numerous studies have reported that biochar applications increase soil water holding capacity, improve aeration, raise pH in acidic soils, and enhance nutrient retention (Chan et al., 2007; Atkinson et al., 2010). However, the effects of biochar on nutrients may vary significantly depending on application dose, feedstock type, pyrolysis temperature, and soil properties. Notably, findings also suggest that high-dose biochar applications may reduce nutrient availability to plants by adsorbing some nutrients through cation exchange capacity (Glaser et al., 2002; Bruun et al., 2012).

Potassium solubilizing bacteria (KSB) are microorganisms that live in the rhizosphere and can convert insoluble potassium minerals in soil into soluble forms available to plants. These bacteria belong to various genera, primarily *Bacillus*, *Pseudomonas*, *Paenibacillus*, *Rhizobacter*, and *Agrobacterium*, and their potassium solubilization mechanisms include production of organic acids (citric acid, malic acid, oxalic acid, gluconic acid, etc.), exopolysaccharide synthesis, and siderophore production (Sheng and He, 2006; Zhang and Kong, 2014). These microorganisms facilitate the release of potassium from mineral structures through acidification and chelation in the root zone. Research has shown that KSB inoculation significantly increases dry matter production and potassium uptake in wheat (Zahedi, 2016; Etesami et al., 2017). Furthermore, KSB applications are known to contribute directly to plant growth not only by enhancing potassium availability but also by producing plant growth-promoting hormones (indole-3-acetic acid, gibberellins) and activating biocontrol mechanisms against pathogens (Meena et al., 2014).

The combined use of biochar and KSB applications has the potential to create synergistic effects for sustainable agriculture. The porous structure of biochar can provide a protected habitat for microorganisms, facilitating their long-term survival and maintenance of metabolic activities in soil (Quilliam et al., 2013; Thies and Rillig, 2009). Additionally, biochar's surface chemistry and nutrient supply capacity can directly or indirectly influence microbial activity. However, current knowledge regarding biochar-KSB interactions is limited, and studies examining the effects of different biochar doses on KSB efficacy in wheat are needed.

The primary objective of this study is to investigate the effects of different doses of biochar and potassium solubilizing bacteria applications on wheat growth parameters, plant potassium content, and soil pH and EC values. Specifically, the study aims to: (i) determine the effect of KSB inoculation on wheat growth and potassium nutrition, (ii) evaluate the effects of increasing biochar doses on wheat growth and potassium dynamics, (iii) examine KSB × biochar interactions, and (iv) assess changes in soil pH and EC resulting from the applications. The

findings are expected to contribute to the development of optimal strategies for the combined use of biochar and KSB applications in wheat cultivation.

MATERIALS AND METHODS

Experimental Site and Conditions

The experiment was conducted in a controlled climate chamber for 45 days. The climate chamber was maintained at a photoperiod of 16 hours light (25°C) and 8 hours dark (20°C) with 60-70% relative humidity. Temperature, humidity, and lighting were regularly monitored and kept constant throughout the experiment.

Plant Material

Wheat (*Triticum aestivum* L.) seeds were used as plant material. Seeds were subjected to surface sterilization before applications, and healthy, uniformly sized seeds were selected for use in the experiment. Twenty wheat seeds were sown in each pot, and no thinning was performed following germination.

Experimental Design

The experiment was arranged in a completely randomized factorial design with three replications in a controlled climate chamber. The study included two main factors. The first factor was potassium solubilizing bacteria (KSB) application at two levels: non-inoculated control group [KSB(-)] and potassium solubilizing bacteria inoculated group [KSB(+)]. The second factor was biochar application consisting of four different doses: 0% (control), 1%, 2%, and 4%. Each treatment combination was tested in three pots. Accordingly, the total number of experimental units was 2 (KSB level) × 4 (biochar dose) × 3 (replication) = 24 pots. Pots were randomly positioned within the climate chamber to minimize variation caused by environmental conditions, and pot positions were periodically changed throughout the experiment. This approach aimed to reliably test differences among treatments while minimizing experimental errors.

Potassium Solubilizing Bacterial Culture and Seed Inoculation

For inoculation, wheat seeds were first surface sterilized by treatment with 70% ethanol (2 minutes) and 0.1% sodium hypochlorite (1 minute) solutions. Subsequently, seeds were rinsed three times with sterile distilled water. For KSB(+) application, seeds were immersed in prepared bacterial suspension (10^8 CFU mL^{-1}) for 30 minutes. For KSB(-) control application, seeds were kept in sterile distilled water for the same duration. Following inoculation, all seeds were air-dried under sterile conditions and sown immediately after drying.

Soil Preparation and Fertilization

The soil used in the experiment was air-dried, passed through a 2 mm sieve, and homogenized. Each pot was filled with 2 kg of air-dry soil. Soil samples were analysed prior to the experiment to determine certain physical and chemical properties.

All pots received basal fertilization of 200 mg N kg^{-1} soil as ammonium sulfate ($(NH_4)_2SO_4$) and 80 mg P_2O_5 kg^{-1} as triple superphosphate (TSP, 44% P_2O_5). No additional potassium fertilizer was applied. Fertilizers were homogeneously mixed with the soil.

Irrigation and Experimental Maintenance

Throughout the experiment, pots were regularly irrigated with distilled water to maintain 70% of field capacity, determined by gravimetric method. Irrigation was controlled by weighing, and leaching from pots was prevented. Pot positions were regularly changed throughout the experiment to minimize variation from environmental conditions.

Harvest and Measurements

Harvest was performed on day 45 of the experiment. Various morphological and physiological parameters were measured to evaluate plant development during harvest. Plant height was measured with a ruler from the soil surface to the plant tip, determined individually for all plants in each pot, and averaged. For plant fresh weight determination, harvested plants were cleaned of soil residues and weighed on a precision balance, with total fresh weight recorded per pot. For plant dry weight determination, fresh plant samples were dried in an oven at 65°C until constant weight and subsequently weighed on a precision balance to obtain dry weight values. For dry leaf weight and dry root weight determination, dried plants were separated into leaves and roots, and these parts were weighed separately and recorded in grams. For plant count per pot, the total number of emerged plants in each pot was counted and expressed as number. All measurements were performed in triplicate, and averages of the obtained data were calculated and used in statistical analyses.
Potassium analysis of plant samples was performed according to the method described by Kacar and İnal (2008). Dried plant samples were subjected to dry ashing, dissolved in appropriate acid solution, and potassium concentrations were determined using ICP-OES (Inductively Coupled Plasma Optical Emission Spectrometry). Results were expressed as percentage (based on dry weight).

Soil pH and Electrical Conductivity (EC) Analyses

Soil samples were collected from each pot after harvest. Soil pH was determined in soil-water suspension prepared at 1:2.5 (soil: distilled water) ratio using a pH meter. Electrical conductivity (EC) measurements were performed in the same suspension using an EC meter according to the method described by Kacar (1994). Both analyses were conducted in triplicate, and average values were calculated.

Statistical Analysis

Obtained data were subjected to analysis of variance (ANOVA) using SPSS (Statistical Package for Social Sciences) software. Differences among treatments were compared using LSD (Least Significant Difference) test at $\alpha=0.05$ significance level. ANOVA results were evaluated according to significance levels of $p<0.05$, $p<0.01$, and $p<0.001$.

RESULTS

ANOVA results for all parameters examined in the study are presented in Tables 1 and 2, while means and Duncan grouping for treatment effects on growth criteria, plant potassium content, and growing medium pH and EC contents are presented in Table 3.

As shown in Table 1, potassium solubilizing bacteria application had statistically significant effects on plant height ($p<0.05$), plant fresh weight ($p<0.05$), plant dry weight ($p<0.05$), and root fresh weight ($p<0.05$). In contrast, the effect of KSB application on root dry weight was found to be non-significant.

Table 1. Analysis of variance values for effects of potassium solubilizing bacteria (KSB) and biochar applications on plant growth criteria

Source	df	PH	PFW	PDW	RL	RFW	RDW
KSB	1	4.60 *	5.35 *	8.04 *	25.00 **	4.87 *	3.07 ns
Biochar	3	8.03 **	13.02**	11.26**	4.41 *	9.06 **	7.98 **
KSB × Biochar	3	2.42 ns	1.90 ns	3.00 öd	14.44 **	6.57 **	4.94 **

* ,**: Significant at $p<0.05$, $p<0.01$ respectively; ns: Non-significant. PH: Plant Height, PFW: Plant Fresh Weight, PDW: Plant Dry Weight, RL: Root Length, RFW: Root Fresh Weight, RDW: Root Dry Weight.,

As shown in Table 1, biochar application had statistically significant effects on plant height ($p<0.01$), plant fresh weight ($p<0.05$), plant dry weight ($p<0.01$), root fresh weight ($p<0.01$), and root dry weight ($p<0.01$). The KSB × biochar interaction showed highly significant effects on root length ($p<0.001$), root fresh weight ($p<0.01$), and root dry weight ($p<0.01$). The interaction effect was found to be non-significant for plant height, plant fresh weight, and plant dry weight.

Table 2. Analysis of variance values for effects of potassium solubilizing bacteria (KSB) and biochar applications on plant potassium, soil pH, and EC values

Source	**Df**	**Potassium**	**pH**	**EC**
KSB	1	6.25 **	129.39 **	0.49 ns
Biochar	3	14.36 **	21.18 **	7.62**
KSB × Biochar	3	1.06 ns	0.30 ns	1.13 ns

*, **: Significant at $p<0.05$, $p<0.01$ respectively; ns: Non-significant

When Table 2 is examined, it is seen that KSB application had highly significant effects on plant potassium content ($p<0.05$) and soil pH ($p<0.001$), whereas its effect on soil EC was non-significant. Biochar application created significant effects on plant potassium content ($p<0.001$), soil pH ($p<0.01$), and EC ($p<0.01$). The KSB × biochar interaction was found to be non-significant for plant potassium content, soil pH, and EC.

As shown in Table 3, potassium solubilizing bacteria application generally provided positive and statistically significant increases in the examined growth parameters of wheat. With KSB application, plant height increased by 6.2% from 31.08 cm to 33.00 cm compared to the control group. Plant fresh weight increased by 15.8% from 4.152 g to 4.808 g compared to the control group. Similarly, plant dry weight increased by 16.0% from 0.419 g to 0.486 g with KSB application. Root fresh weight increased by 13.0% with KSB inoculation, rising from 1.540 g to 1.740 g. The increase in root dry weight was determined to be statistically non-significant. KSB application also had a positive effect on plant potassium content, increasing it by 7.9% from 1.825% to 1.970%. In contrast, the effect of KSB application on root dry weight was not found to be statistically significant. Root dry weight was recorded as 0.138 g in the control group and 0.152 g in the KSB application. These findings reveal that potassium solubilizing bacteria significantly promotes vegetative growth and potassium nutrition of wheat, but this effect does not occur at the same level in all plant organs. The fact that KSB application provided particularly pronounced increases in above-ground parts suggests that in addition to the bacteria's potassium solubilizing capacity, other plant growth-promoting mechanisms (hormone production, nutrient solubilization, etc.) are also effective.

Table 3. Means and Duncan grouping for effects of potassium solubilizing bacteria (KSB) and biochar applications on plant growth criteria, plant potassium content, soil pH, and EC

Treatments	PH	RL	PFW	PDW	RFW	RDW	Potassium	pH	EC

A, B, C: Means followed by the same letters are not statistically different. PH: Plant Height, RL: Root Length, PFW: Plant Fresh Weight, PDW: Plant Dry Weight, RFW: Root Fresh Weight, RDW: Root Dry Weight.

Soil pH value increased from 7.12 to 7.27 with KSB application (2.1% increase), while EC decreased from 570 µS cm⁻¹ to 558 µS cm⁻¹ (2.1% decrease). Soil pH varied with biochar applications, with the highest pH value of 7.28 measured in the 4% biochar application, corresponding to a 1.8% increase compared to the control group. The 1% and 2% biochar applications did not cause significant changes in pH. Soil EC values showed a notable increase parallel to increasing biochar doses. Compared to the control group (0% biochar, 508 µS cm⁻¹), EC increased by 7.7% to 547 µS cm⁻¹ with 1% biochar, by 13.4% to 576 µS cm⁻¹ with 2% biochar, and by 23.0% to 625 µS cm⁻¹ with 4% biochar. These findings demonstrate that increasing biochar doses linearly increase soil EC values (Table 3).

As biochar application doses increased, different trends in parameter changes were determined depending on the dose. A regular increase in plant height was observed with increasing biochar dose. Plant height, which was 28.67 cm in the control group (0% biochar), reached 31.67 cm with 1% biochar, 33.33 cm with 2% biochar, and 34.50 cm with 4% biochar application. The 4% biochar application provided a 20.3% increase compared to the control group. The highest value was obtained from the 4% biochar application.

When biochar applications were examined, significant changes in plant fresh weight were observed depending on increasing biochar doses. Plant fresh weight was measured as 3.474 g in the control group (0% biochar), while it was determined as 4.113 g (18.4% increase) with 1% biochar, 4.438 g (27.7% increase) with 2% biochar, and 5.896 g (69.7% increase) with 4% biochar. The highest plant fresh weight was obtained with 4% biochar application. A similar trend was observed for plant dry weight. Plant dry weight, which was 0.397 g in the control group, was measured as 0.411 g (3.5% increase) with 1% biochar, 0.434 g (9.3% increase) with 2% biochar, and 0.568 g (43.1% increase) with 4% biochar. The highest plant dry weight was determined with 4% biochar application, while no statistically significant difference was found between the control group and 1% and 2% biochar applications. However, the 4% biochar application was statistically superior to all other doses (Table 3).

Biochar application caused significant increases in root fresh weight. The lowest value was determined in the control group (1.385 g), while it increased to 1.982 g with a 43.1% increase in the 4% biochar application. The 1% biochar application (1.462 g) was similar to the control, while 2% biochar (1.731 g) and 4% biochar applications gave significantly higher values (Table 3).

As shown in Table 3, root dry weight significantly increased with increasing biochar doses. Root weight, which was 0.118 g in the control group, increased to 0.134 g with 1% biochar, 0.157 g with 2% biochar, and 0.169 g with 4% biochar. A 43.2% increase was determined in the 4% biochar application compared to the control group. A significant increase in plant potassium content was observed with increasing biochar dose. Potassium content, which was 1.611% in the control group, increased to 1.860% with 1% biochar, 2.007% with 2% biochar, and 2.112% with 4% biochar. A 23.7% increase occurred in the 4% biochar application compared to the control group.

As indicated in the ANOVA table (Table 1), KSB × biochar interaction had highly significant effects on root length ($p<0.001$), root fresh weight ($p<0.01$), and root dry weight ($p<0.01$). This indicates that the effect of KSB application varies depending on biochar dose and that the combinations of the two applications should be evaluated together. The interaction effect on plant height was found to be non-significant.

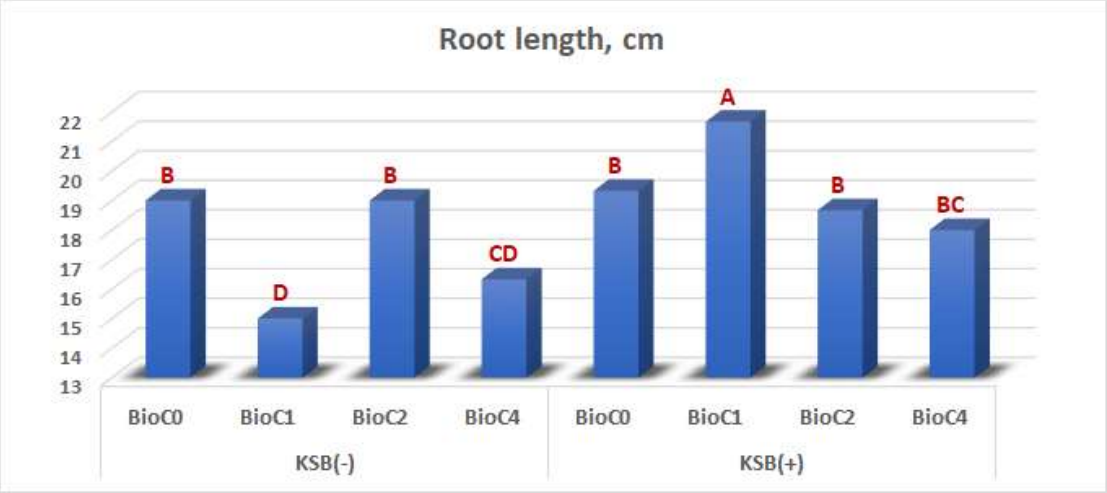

Fig. 1. Effect of potassium solubilizing bacteria (KSB) and biochar interaction on root length, BioC0, 0% Biochar; BioC1, 1% Biochar; BioC2, 2% Biochar; BioC4, 4% Biochar.

The KSB × biochar interaction was found to be statistically significant for root length ($p<0.001$). The highest root length was observed as 21.67 cm in the KSB(+) × BioC1 treatment, while the lowest value was determined as 15.00 cm in the KSB(-) × BioC1 treatment. KSB(+) application increased root length by 44.4% at the BioC1 dose, while in the KSB(-) group, BioC1 application showed a 21.1% decrease compared to the control. At high biochar doses (BioC4), root length showed a decreasing trend in both KSB applications.

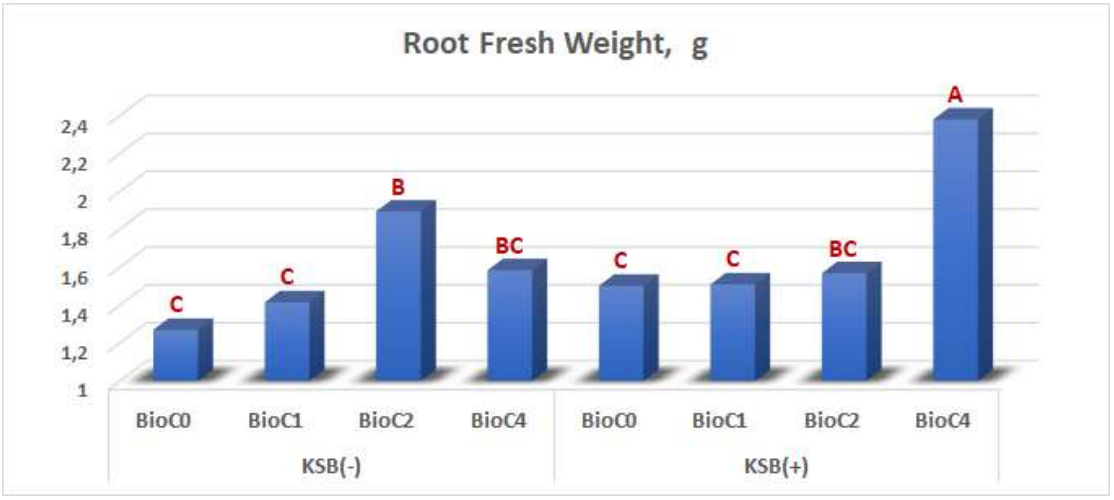

Fig. 2. Effect of potassium solubilizing bacteria (KSB) and biochar interaction on root fresh weight, BioC0, 0% Biochar; BioC1, 1% Biochar; BioC2, 2% Biochar; BioC4, 4% Biochar.

As shown in Figure 2, The KSB × biochar interaction was found to be statistically significant for root fresh weight ($p<0.01$). The highest root fresh weight was measured as 2.380 g in the KSB(+) × BioC4 treatment, while the lowest value was determined as 1.269 g in the KSB(-) × BioC0 treatment. KSB(+) application at the BioC4 dose increased root fresh weight by 87.5% compared to the KSB(-) × BioC0 control group. While increasing biochar dose showed an increasing effect on root fresh weight in KSB(-) applications, the highest increase was obtained in the KSB(+) × BioC4 treatment.

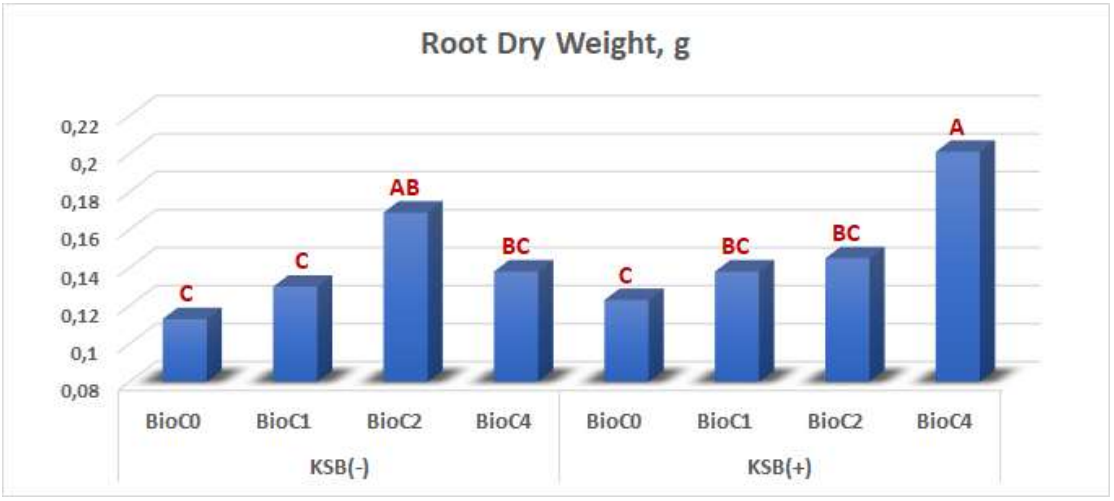

Fig. 3. Effect of potassium solubilizing bacteria (KSB) and biochar interaction on root dry weight, BioC0, 0% Biochar; BioC1, 1% Biochar; BioC2, 2% Biochar; BioC4, 4% Biochar.

The KSB × biochar interaction was found to be statistically significant for root dry weight ($p<0.01$). The highest root dry weight was obtained as 0.201 g in the KSB(+) × BioC4 treatment, while the lowest value was measured as 0.113 g in the KSB(-) × BioC0 treatment. The KSB(+) × BioC4 treatment provided a 77.9% increase compared to the control group, while the highest value in the KSB(-) group was observed as 0.169 g in the BioC2 treatment. The use of KSB application with 4% biochar caused significant increases in root dry weight.

DISCUSSION

Effects of Potassium Solubilizing Bacteria Application on Plant Growth and Potassium Uptake

In this study, potassium solubilizing bacteria (KSB) application was determined to have significant and positive effects on plant height, fresh and dry weight, dry leaf weight, and plant potassium content in wheat. The fact that KSB application provided increases of 6.2% in plant height, 15.8% in plant fresh weight, and 16.0% in plant dry weight is consistent with the plant growth-promoting effects of these microorganisms.@

The findings obtained are consistent with previous studies in this field. Zahedi (2016) reported that *Bacillus* species potassium solubilizing bacteria increased dry matter yield in wheat by up to 20%. Similarly, Sheng and He (2006) reported that potassium solubilizing bacteria solubilize fixed potassium by secreting organic acids (primarily citric, malic, and oxalic acids) in the rhizosphere, thereby significantly increasing potassium uptake by plants. This mechanism explains the 7.9% increase in plant potassium content observed with KSB application.

The positive effects of KSB application on plant growth are not limited to potassium solubilization activity. These bacteria can also contribute to plant growth through multiple mechanisms including production of plant growth-promoting hormones (particularly indole-3-acetic acid - IAA), reduction of ethylene stress through 1-aminocyclopropane-1-carboxylate (ACC) deaminase activity, improvement of iron uptake through siderophore production, and phosphate solubilization (Meena et al., 2014; Etesami et al., 2017). Therefore, the growth increases observed with KSB application may be a result of both direct improvement in potassium nutrition and other plant growth-promoting properties of the bacteria.

However, KSB application was determined not to have a statistically significant effect on root dry weight and spike number. This suggests that the effect of KSB does not occur at the same level in different plant organs, and that the application period (45 days) may have been insufficient to create significant differences in parameters such as root development and generative organ formation. In particular, differences in carbon and nutrient distribution between vegetative and generative growth may cause bacterial effects to manifest at different levels in different organs.

Effects of Biochar Application on Plant Growth, Potassium Uptake, and Soil Properties

In our study, biochar application, particularly at the 4% dose, provided significant increases of 20.3% in plant height, 43.1% in dry leaf weight, and 43.2% in dry root weight. These plant growth-promoting effects of biochar applications are consistent with findings widely reported in the literature.

Lehmann et al. (2011) stated that biochar increases soil water holding capacity, improves aeration, and creates a more suitable environment for root development due to its porous structure. The significant increase in root weight observed with 4% biochar application in this study is an important finding supporting this mechanism. The surface area and porosity of biochar may allow roots to spread over a larger area within the soil and access a greater volume for nutrient uptake.

Chan et al. (2007) expressed that biochar increases the nutrient retention capacity of soils through cation exchange capacity (CEC), thereby improving plant nutrition by reducing nutrient losses, especially in systems where leaching is intensive. Atkinson et al. (2010) also reported that biochar application increases soil aggregate stability and improves soil structure, emphasizing that these physical improvements contribute positively to plant root development and consequently plant growth.

However, the 23.7% decrease in plant potassium content with increasing biochar dose is a quite remarkable and unexpected finding in this study. High-dose biochar application may have reduced potassium availability to plants by adsorbing potassium ions from the soil solution onto its surface. Biochar, especially when pyrolyzed at high temperatures, can have high cation exchange capacity, and this increases the retention of cations such as K^+, Ca^{2+}, and Mg^{2+} (Glaser et al., 2002; Mukherjee et al., 2011). Negatively charged functional groups on the biochar surface (carboxyl, phenolic hydroxyl, carbonyl, etc.) can electrostatically attract and retain potassium ions. At high doses, biochar can limit potassium uptake by plants by increasing this adsorption effect. Bruun et al. (2012) also stated that biochar application may reduce the uptake of some nutrients by plants and that this may be related to the adsorption mechanism.

The high rate of increase in plant biomass with biochar application may have remained behind the increase in potassium uptake, leading to a relative decrease in potassium concentration in tissues. This is known as the "dilution effect," commonly encountered in plant nutrition. For example, while dry leaf weight increased by 43.1% and dry root weight by 43.2% with 4% biochar application, the increase in potassium uptake did not reach these rates, resulting in a decrease in potassium concentration in tissues. The dilution effect occurs particularly during rapid growth periods when nutrients are diluted within cell walls and protoplasm, and it is also one of the main reasons for the decrease in nutrient concentrations as plants age (Marschner, 2012).

According to ANOVA results, biochar application has a highly significant effect on soil pH ($p<0.01$). Considering that the biochar used in this study is alkaline in character, it can be assumed that it increased soil pH. Changes in soil pH can indirectly affect potassium availability to plants. At high pH values, the surface charges of soil colloids may change, and the amount of potassium in exchangeable form may decrease. Additionally, pH increase may affect microbial activity and organic matter mineralization, thereby altering potassium cycling. However, since potassium availability is generally influenced more by soil mineralogy and cation exchange systems than by pH, this effect may be less determining compared to adsorption and dilution.

In the study, biochar application alone was determined not to have a statistically significant effect on soil EC. This finding indicates that biochar does not directly change soil salinity as an inert material, but when applied together with KSB, it affects EC through interaction. This suggests that the effects of biochar on salinity occur largely indirectly through microbial activity and changes in soil chemistry.

KSB × Biochar Interaction

The fact that KSB × biochar interaction was found to be highly significant for plant fresh weight ($p<0.001$), plant dry weight ($p<0.01$), number of plants per pot ($p<0.001$), root fresh weight ($p<0.01$), and root dry weight ($p<0.01$) in the ANOVA reveals that the effects of the combined use of the two applications differ from their simple sums and indicates the presence of synergistic or antagonistic interactions.

Interactions between biochar and KSB can be explained by various mechanisms:

1. **Habitat Provision:** The porous structure of biochar can serve as a protected habitat for microorganisms, allowing KSB populations to survive longer in soil and maintain their metabolic activities (Quilliam et al., 2013; Thies and Rillig, 2009). This may lead to increased effectiveness of KSB and greater contribution to plant growth. Biochar pores help maintain population densities by protecting bacteria from predators (protozoa, nematodes) and adverse environmental conditions (drought, extreme temperatures).
2. **Nutrient Supply:** Biochar may contain carbon sources and mineral nutrients that microorganisms can utilize. This may increase the metabolic activity and potassium

solubilization capacity of KSB (Liang et al., 2010). Labile carbon fractions on the biochar surface can provide energy sources for microorganisms, positively affecting population dynamics and enzymatic activities.

3. **Chemical Environment Modification:** Biochar can affect the working environment of KSB by changing soil pH, ionic strength, and forms of nutrients. For example, changes in soil pH with biochar application may affect bacteria's organic acid production and potassium solubilization efficiency. Additionally, the amount of potassium adsorbed by biochar may determine whether the potassium solubilized by bacteria can be taken up by plants.
4. **Root Development Modulation:** Root development promoted by biochar can increase bacterial-plant interactions by expanding the colonization area of KSB in the rhizosphere. A more developed root system provides a larger colonization surface for KSB, and this may increase the amount of root exudates, thereby promoting bacterial activity.

However, the non-significant KSB × biochar interaction on plant potassium content ($p>0.05$) suggests that biochar's potassium adsorption may be more dominant than bacteria's potassium solubilization activity. In other words, biochar's potassium retention capacity may have limited KSB's potassium solubilization effect, and changes in plant potassium content occurred largely depending on biochar dose.

Quilliam et al. (2013) reported that biochar application significantly changes rhizosphere microbial community structure and can promote the activity of some bacterial groups while suppressing others. This finding indicates that biochar may have strain-specific effects on KSB and that interactions may occur at different levels in studies with different strains.

Effects on Soil pH and EC

In the study, KSB and biochar were found to have highly significant effects on soil pH both individually and in interaction. The decrease in soil pH with KSB application can be evaluated in relation to organic acid production by bacteria. Similarly, the effect of biochar application on pH varies depending on biochar's specific chemical structure and alkaline or acidic character. While the biochar used in this study was expected to show a pH-increasing (alkaline) effect, absolute measurement of soil pH values is necessary to determine exactly in which direction it causes change.

The significant effect of KSB × biochar interaction on soil EC ($p<0.01$) reveals that combined applications may produce unpredictable results on salinity and therefore caution should be exercised in practical applications. Electrical conductivity is an indicator of total ion concentration in soil solution, and excessive salinity is an important factor negatively affecting plant development. Biochar and KSB applications may cause increases or decreases in EC by changing ion balance. Detailed analysis of soil solution ion composition is needed to better understand the mechanisms underlying these effects.

CONCLUSION

In this study, the effects of potassium solubilizing bacteria (KSB) and different doses of biochar applications on wheat growth parameters, plant potassium content, and soil pH and electrical conductivity (EC) were investigated. The findings obtained showed that both applications significantly promoted plant growth, but biochar application in particular may cause unexpected negative effects on potassium nutrition.

Potassium solubilizing bacteria application provided statistically significant increases in plant height, fresh and dry weight, and plant potassium content in wheat. These findings are consistent with the study by El-Egami et al. (2024), who reported that potassium uptake

significantly increased in wheat plants inoculated with *Bacillus circulans* and yield increases were achieved even under saline soil conditions. Similarly, Chen et al. (2018) reported that biochar application promotes the development of potassium solubilizing bacteria populations in soils and this accelerates the decomposition of especially 2:1 type potassium-containing minerals, thereby increasing plant potassium uptake. Furthermore, Jiang et al. (2024) showed that bacterial strains applied together with biochar significantly increased plant biomass and nutrient uptake and increased the diversity and abundance of beneficial bacterial groups belonging to the families Bacillaceae and Paenibacillaceae in the rhizosphere. This supports that the positive effects of KSB application on plant growth are not limited to potassium solubilization activity but also contribute to plant nutrition by positively shaping rhizosphere microbial communities. However, the fact that KSB application did not create a statistically significant effect on root dry weight and spike number in this study suggests that bacterial effects do not occur at the same level in different plant organs and that the 45-day experimental period may have been insufficient to create significant differences in these parameters.

Biochar application, particularly at the 4% dose, provided significant increases in parameters such as plant height, dry leaf weight, and dry root weight. These findings are partially consistent with the review study by Bilias et al. (2023), who stated that biochar application may promote plant potassium uptake through indirect mechanisms by increasing potassium retention capacity through properties such as cation exchange capacity, porosity, and specific surface area in soil. It is thought that biochar promotes root development and increases water holding capacity by improving the physical properties of soil through its porous structure and high surface area. However, a serious decrease of 23.7% occurred in plant potassium content at the same dose. This unexpected finding can be explained by factors such as high-dose biochar application reducing potassium availability to plants by adsorbing potassium ions from the soil solution onto its surface, the high rate of increase in plant biomass with biochar application remaining behind the increase in potassium uptake, leading to dilution of potassium concentration in tissues (dilution effect), and/or biochar indirectly affecting potassium uptake mechanisms by changing soil pH. On this subject, Bilias et al. (2023) emphasized that the effects of biochar applications on soil potassium availability show significant differences depending on the type of feedstock from which biochar is produced, pyrolysis temperature, and soil properties, and that biochar produced at low pyrolysis temperatures (<500°C) has higher water-soluble and exchangeable potassium fractions. This suggests that the properties of the biochar used in our study may have led to potassium adsorption. Additionally, the significant effect of biochar application on soil pH ($p<0.01$) indicates that this change may indirectly affect potassium uptake mechanisms.

ANOVA results showed that KSB × biochar interaction had highly significant effects on plant fresh weight, plant dry weight, spike number, dry leaf weight, and dry root weight. This indicates that the effects of the combined use of the two applications differ from their simple sums and that biochar modulates the living environment and metabolic activity of KSB by changing rhizosphere conditions. Chen et al. (2018) reported that biochar application promotes potassium solubilizing bacteria development in both soil types and this is associated with changes in soil pH and water-soluble potassium. Furthermore, in the study by Li et al. (2025) examining the effects of different fertilizer regimes and biochar applications on rhizosphere microbial communities, it was emphasized that biochar application promotes specific microbial communities and offers a promising option for sustainable agricultural practices. However, the non-significant interaction effect on plant potassium content suggests that biochar's potassium adsorption may be more dominant than bacteria's potassium solubilization activity.

While KSB and biochar applications were found to have highly significant effects on soil pH both individually and in interaction, only KSB × biochar interaction was found to be significant for EC value. This finding reveals that the effects of biochar and KSB applications on soil

salinity are not independent of each other and may produce unpredictable results when applied together.

Based on the results obtained from this study, it is of great importance to determine optimum dose ratios in field conditions that will minimize potassium adsorption and maximize KSB efficacy in cases where biochar and KSB will be used together. Since the 4% biochar dose in this study provided high biomass production but caused significant decrease in potassium content, it is recommended to try lower doses (e.g., 1-2%) or biochar types produced from different feedstocks. As stated by Bilias et al. (2023), the potassium supply potential of biochar largely depends on feedstock type and pyrolysis conditions. Additionally, detailed analysis of potassium fractions (soluble, exchangeable, mineral) before and after application in soils treated with biochar will enable better understanding of biochar's effects on potassium dynamics. KSB application should be considered as part of an integrated nutrient management strategy to reduce chemical fertilizer use, especially in soils where potassium is present at sufficient levels but not in available form. Previous studies have shown that KSB application can provide similar yield increases when used with half the dose of chemical potassium fertilizers. Practitioners should consider the initial potassium status of soils, physicochemical properties of biochar, and local climatic conditions when recommending biochar and KSB combinations.

For future research, these findings obtained under controlled climate chamber conditions need to be verified with long-term field trials under different soil, climate, and agricultural practices. Chen et al. (2018) stated that the effects of biochar applications on plant potassium uptake vary depending on soil type, and that biochar effects last longer especially in soils rich in 2:1 type potassium-containing minerals. Comparative investigation of the effects of biochar types produced from different feedstocks (wood, agricultural wastes, animal manure, grape pomace, coffee husk, hazelnut shell, etc.) and at different pyrolysis temperatures is recommended. Bilias et al. (2023) emphasized that potassium-rich biomasses are promising resources for biochar production but are not yet widely used. Detailed investigation of the interactions of potassium solubilizing bacteria belonging to different species and strains with different biochar types will allow identification of the most successful combinations. Mechanistic studies such as biochar's potassium adsorption kinetics, KSB's organic acid production profile, and effects on root exudation will enable better understanding of the physiological and chemical processes underlying the observed effects. Investigation of the effects of biochar application on rhizosphere microbial community structure and functional gene activity using metagenomics, metatranscriptomics, and other advanced molecular methods will make significant contributions to elucidating biochar-KSB-plant triple interactions at the molecular level. Investigation of the persistent effects of biochar and KSB applications in different growing periods and different crop rotation systems is of critical importance for long-term sustainability. Furthermore, cost-effectiveness analyses of biochar and KSB applications and economic feasibility studies at different farm scales will be a critical evaluation criterion for the adoption and dissemination of these practices by farmers in practice. Finally, modeling the effectiveness of biochar and KSB applications under climate change scenarios can guide the determination of future agricultural production strategies.

In conclusion, although the combined use of biochar and potassium solubilizing bacteria in wheat cultivation is a promising approach within the scope of sustainable agricultural practices, optimum dose, application time, and methods need to be studied in detail under field conditions. This study makes significant contributions to the knowledge in this field and provides a valuable foundation for future research.

ABSTRACT

Phosphorus fixation influences both fertilizers use efficiency and the potential transfer of phosphorus from soil to surface waters. However, phosphorus-fixation behavior in Albanian river basin soils remains poorly documented. This study assessed phosphorus fixation in topsoil (0–30 cm) from the Ishëm River Basin and examined its relationship with selected soil properties. Two grams of soil were equilibrated in duplicate with 20 mL of KH_2PO_4 solution prepared in 0.01 M $CaCl_2$, supplying 0, 25, 50, 100, 200 and 500 mg P kg^{-1} soil. Samples were shaken for 24 h at approximately 24 °C, and phosphorus remaining in solution was measured colorimetrically by the Murphy–Riley method. The selected soils exhibited total phosphorus levels ranging from 182.81 to 662.65 mg P kg^{-1}, organic matter contents from 0.94% to 4.66%, and clay contents from 5.16% to 62.48%. Fixed phosphorus was calculated as added phosphorus minus phosphorus remaining at equilibrium. Across all P additions, adsorption ranged from 38.31% to 98.99%. Soils with higher clay and organic matter contents retained a greater proportion of added phosphorus, following logarithmic relationships with clay content ($R^2 = 0.962$) and organic matter content ($R^2 = 0.622$). These patterns indicate that total P content alone does not dictate fixation behavior, which is strongly governed by soil texture and organic matter content. These preliminary findings provide an essential baseline for improving phosphorus-fertilizer management and assessing phosphorus mobility in the Ishëm River Basin.

Keywords: Phosphorus fixation, Ishëm River Basin, soil texture, organic matter, adsorption capacity

INTRODUCTION

Phosphorus (P) is an essential macronutrient that supports plant growth, energy transfer and crop production. Although soils may contain considerable amounts of total P, only a small proportion is present in the soil solution and immediately available for plant uptake. When mineral fertilizers or organic materials are added to the soil, the soluble phosphate they release reacts with soil constituents, reducing its concentration and mobility. These reactions affect fertilizer-use efficiency and can promote the long-term accumulation of P in agricultural soils (Asomaning, 2020; Ning et al., 2022).

The removal of phosphate from the soil solution is commonly described as P fixation or sorption. Sorption initially involves the adsorption of phosphate onto reactive mineral surfaces, whereas subsequent reactions can convert adsorbed P into more stable or precipitated forms. Phosphorus retention therefore has a dual agronomic and environmental role. Strong fixation can reduce P availability to crops and increase fertilizer requirements. In contrast, soils with low retention capacity, or soils in which sorption sites have become progressively saturated,

may be more susceptible to P mobilisation and transfer through runoff, erosion or drainage (Ning et al., 2022; Kamali et al., 2023). Understanding soil P-retention capacity is consequently important for both fertilizer management and the control of nutrient losses to surface waters.

Phosphorus-fixation capacity varies considerably among soils because it is controlled by interacting physical and chemical properties. Clay minerals and iron and aluminium oxides provide reactive surfaces for phosphate adsorption, particularly in acidic and highly weathered soils. In neutral and alkaline soils, reactions involving calcium and carbonate minerals may become increasingly important. Soil pH, texture, organic matter, parent material and previous P inputs can therefore influence both the amount and strength of P retention (Asomaning, 2020; Oyebanjo et al., 2022; Kamali et al., 2023). The role of organic matter is particularly complex. Organic compounds can compete with phosphate for sorption sites or block reactive mineral surfaces, but they can also influence P retention indirectly through interactions with metal oxides, soil aggregation and organo-mineral complexes. Consequently, neither total P nor an individual soil property can independently describe P-fixation behaviour.

Previous studies in Albania have shown considerable variation in P fixation among soils with contrasting physicochemical properties. Huqi et al. (2021) examined selected soils from different regions of Albania and found differences in the retention of added P, which were related to clay content, organic matter, and soil pH. A subsequent study of greenhouse soils with contrasting cultivation histories and initial P contents also revealed substantial variation in P retention. In that study, the proportion of added P that was fixed generally decreased as the amount of P applied increased, whereas soils with lower initial P contents tended to retain a greater proportion of the applied phosphorus (Huqi et al., 2023). Together, these studies provided an initial basis for understanding P-fixation behaviour in Albanian soils; however, they focused on individual soils and agricultural production systems rather than examining soils within a river-basin context.

This approach is particularly relevant to the Ishëm River Basin, where agriculture, dense settlements and other human activities affect a connected soil–water system. Recent monitoring across five tributaries in the basin reported elevated TP concentrations (Huqi et al., 2025). Topsoil P can reach rivers attached to eroded particles or dissolved in surface runoff, depending on soil properties, land use, hydrology and topography (Dong et al., 2021). Strong P retention may reduce P-use efficiency and promote soil P accumulation, requiring careful fertilizer management. Assessing P retention can therefore support soil-fertility management and help identify potential nutrient pressures on surface waters.

Despite earlier studies of selected Albanian soils, information on P-fixation behaviour in the Ishëm River Basin remains limited. This study provides a preliminary assessment of selected topsoils differing in clay, organic matter and total P content. Soils richer in clay and organic matter were expected to retain more of the added P, while total P alone was not expected to explain differences in P fixation among soils. The study therefore quantified the fixation of added P in selected topsoils (0–30 cm) and examined its relationship with key soil properties. The findings provide an initial basis for assessing P availability and mobility and supporting integrated soil and water management in the basin.

MATERIALS AND METHODS

Soil sampling and preparation

Three topsoil samples were collected from selected locations within the Ishëm River Basin, Central Albania. The samples were identified as Soil A (Krujë), Soil B (Larushk), and Soil C (Lanabregas). All samples were collected from the 0–30 cm soil layer. Following collection, the samples were air-dried at room temperature, gently disaggregated, homogenized, and passed through a 2-mm sieve before laboratory analysis.

Physicochemical soil analyses

Physicochemical characterization of the prepared soil samples was conducted in the laboratory of the Faculty of Agriculture and Environment, Agricultural University of Tirana, Tirana, Albania. Soil pH was measured in a 1:5 soil-to-water suspension according to ISO 10390:2021, while electrical conductivity (EC) was determined in a 1:5 aqueous soil extract according to ISO 11265:2025. Soil organic matter was determined by the potassium dichromate oxidation method described by Walkley and Black (1934). Total nitrogen (TN) was determined using the modified Kjeldahl method according to ISO 11261:1995. Following sample digestion, total phosphorus (P-tot) in the resulting solution was determined using the ammonium molybdate spectrometric method according to ISO 6878:2004. Soil particle-size distribution was determined by the hydrometer method following the principles of ISO 11277:2020.

Phosphorus-fixation experiment

The phosphorus-fixation experiment was performed using a modified batch-equilibration procedure adapted from Ahmed et al. (2008). Two grams of each soil sample were placed in 50-mL centrifuge tubes, and each treatment was prepared in duplicate. Phosphorus solutions containing 0, 2.5, 5, 10, 20, and 50 mg P L^{-1} were prepared by dissolving potassium dihydrogen phosphate (KH_2PO_4) in 0.01 M $CaCl_2$. A 20-mL aliquot of each solution was added to the soil samples, resulting in a soil-to-solution ratio of 1:10 and corresponding P additions of 0, 25, 50, 100, 200, and 500 mg P kg^{-1} soil.

The soil suspensions were shaken for 24 h at approximately 24 °C and 144 rpm. After equilibration, the samples were centrifuged at 5,000 rpm for 15 min, and the resulting supernatants were passed through 0.45-µm syringe membrane filters. Phosphorus remaining in the equilibrium solution was measured colorimetrically at 880 nm using the molybdenum-blue method of Murphy and Riley (1962). A zero-P treatment containing soil and 0.01 M $CaCl_2$ without added phosphorus was included for each soil to account for phosphorus released naturally during equilibration.

The amount of P adsorbed by each soil was calculated as the difference between the amount of P added and the amount remaining in the equilibrium solution, after correction for P measured in the zero-P treatment. Adsorbed P was expressed as mg P kg^{-1} soil, while percentage P adsorption was calculated relative to the amount of P added.

RESULTS AND DISCUSSION

Physicochemical properties of the selected soils

Selected physicochemical properties of the three studied soils are presented in Table 1.

Table 1. Physicochemical properties of the selected soils.

Code	pH	EC µS cm^{-1}	Organic Matter %	Total Phosphorus mg kg^{-1}	Total Nitrogen mg kg^{-1}	Clay %	Silt %	Sand %
Soil A	7.70	83.20	1.90	182.81	2010.04	62.48	27.16	10.36
Soil B	6.81	26.20	0.94	265.15	1020.33	5.16	20.64	74.20
Soil C	7.59	110.95	4.66	662.65	2953.05	31.62	23.72	44.66

The selected soils differed mainly in texture, organic matter and total P content. Soil A had the highest clay content (62.48%) and the lowest total P content (182.81 mg P kg^{-1}), whereas Soil B was predominantly sandy (74.20%) and had the lowest organic matter content (0.94%). Soil C had the highest organic matter (4.66%) and total P contents (662.65 mg P kg^{-1}). These contrasting properties may influence P fixation because clay minerals and associated Fe and Al oxides provide reactive sites for phosphate retention, while organic matter may modify this process through interactions with mineral surfaces (Asomaning, 2020; Kamali et al., 2023).

Phosphorus remaining after equilibration

The amount of P remaining in the equilibrium solution after the 24-h equilibration period is presented in Table 2.

Table 2. Phosphorus remaining after equilibration in the selected soils at different P-addition levels.

Added P (mg P kg^{-1} soil)	P remaining after equilibration (mg P kg^{-1} soil)		
	Soil A	**Soil B**	**Soil C**
25	0.759	1.453	0.326
50	0.683	3.580	0.503
100	1.270	16.639	1.613
200	2.703	69.045	6.6387
500	23.340	308.442	49.089

Phosphorus remaining in solution generally increased with increasing P addition, although the response differed among the soils (Table 2). Differences were relatively small at the lower P additions but became more pronounced at higher levels. At 500 mg P kg^{-1}, the equilibrium solution of Soil B contained 308.44 mg P kg^{-1}, compared with 23.34 mg P kg^{-1} for Soil A and 49.09 mg P kg^{-1} for Soil C. This indicates that Soil B had a substantially lower P-retention capacity under high P loading. A similar increase in equilibrium-solution P with increasing P addition has been associated with the progressive occupation and reduced availability of soil P-binding sites (Ahmed et al., 2008).

The relationship between added P and P remaining after equilibration was further evaluated using linear regression (Table 3).

Table 3. Linear regression equations relating added P to P remaining after equilibration.

Soil	Regression equation	R^2 Value
Soil A	y = 0.0491x - 2.8334	0.9272

Soil B	y = 0.667x - 36.9	0.9768
Soil C	y = 0.1059x - 6.9008	0.9453

Linear regression showed strong positive relationships between added P and P remaining after equilibration (R^2 = 0.927–0.977). The higher slope observed for Soil B suggests that a greater proportion of the added P remained in solution as P addition increased, indicating lower P retention compared with the other soils.

Phosphorus adsorbed to soil after treatment with added P

The amounts of P adsorbed by the selected soils at different P-addition levels are presented in Table 4.

Table 4. The amount of Adsorbed – P to soil after treatment with Added – P in solution

Added P (mg P kg^{-1} soil)	Adsorbed P (mg P kg^{-1} soil)		
	Soil A	**Soil B**	**Soil C**
25	24.241	23.546	24.674
50	49.316	46.419	49.496
100	98.730	83.360	98.386
200	197.297	130.954	193.361
500	476.660	191.557	450.910
Mean	**169.25**	**95.17**	**163.37**

Adsorbed P increased with increasing P addition in all three soils (Table 4). Differences among the soils were relatively small at the two lowest addition levels but became more pronounced as P addition increased. At 500 mg P kg^{-1}, Soil A adsorbed 476.660 mg P kg^{-1} and Soil C adsorbed 450.910 mg P kg^{-1}, compared with only 191.557 mg P kg^{-1} in Soil B. Across all P-addition levels, mean adsorbed P followed the order Soil A (169.25 mg P kg^{-1}) > Soil C (163.37 mg P kg^{-1}) > Soil B (95.17 mg P kg^{-1}). The lower adsorption by Soil B is consistent with its sandy texture and low clay and organic matter contents, whereas the greater adsorption by Soils A and C may be associated mainly with their higher clay contents and differences in organic matter (Asomaning, 2020; Kamali et al., 2023).

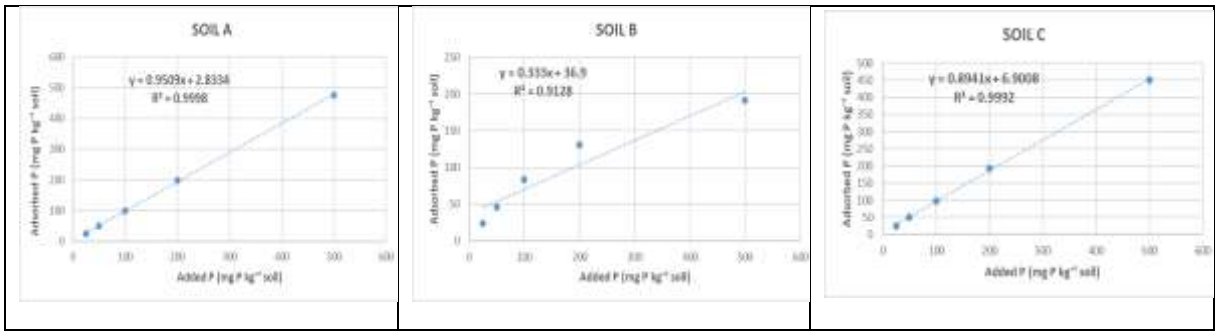

Figure 1. Relationships between added P and adsorbed P in the selected soils. Linear regression equations and R^2 values are shown in each panel.

Changes in the amount of P adsorbed with added P were examined for each soil. The regression analysis showed that there is a linear relationship between the amount of P added

to the solution and the amount of P adsorbed from soil at the time of equilibrium in all studies soils.

The relationships between Added – P and percentage of Adsorbed – P in selected soils.

The percentage of the added P adsorbed to the soil is shown in Table 5.

Table 5. Adsorbed P as a percentage of the added P in solution

Added P (mg P kg^{-1} soil)	Adsorbed – P as % of Added – P in solution		
	Soil A	**Soil B**	**Soil C**
25	96.96	94.184	98.696
50	98.63	92.838	98.992
100	98.73	83.360	98.386
200	98.65	65.477	96.681
500	95.33	38.311	90.182
Average	**97.66**	**74.834**	**96.587**

The percentage of added P adsorbed remained high in Soil A and Soil C, averaging 97.66% and 96.59%, respectively. In contrast, adsorption in Soil B decreased from 94.18% to 38.31% as P addition increased, resulting in a lower mean adsorption of 74.83%.

Relationships between mean adsorbed phosphorus and selected soil properties

The relationships between mean adsorbed P and selected properties of the three soils were examined. Mean adsorbed P was calculated as the average amount adsorbed by each soil across the five P-addition levels, ranging from 25 to 500 mg P kg^{-1} soil. Soil organic matter and clay content were considered, and their relationships with mean adsorbed P are presented in Figure 2.

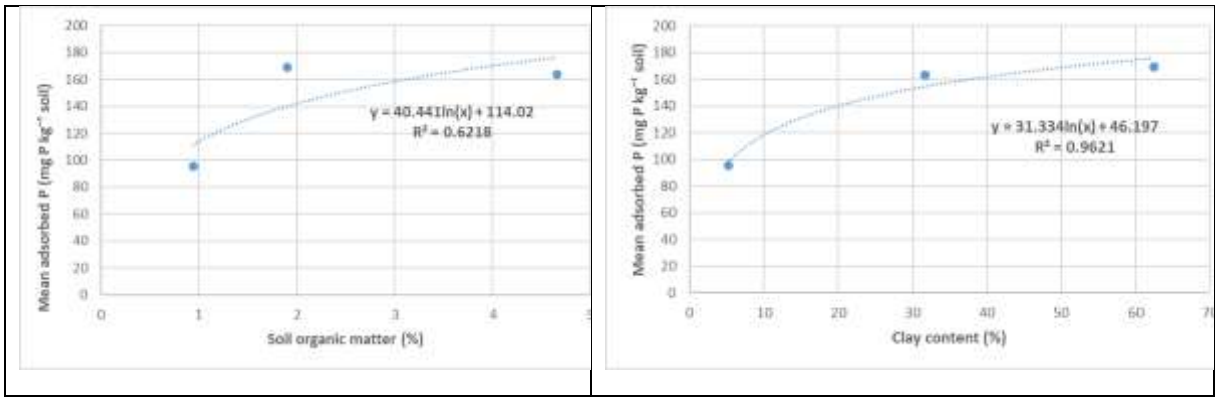

Figure 2. Relationships between mean adsorbed P and (a) soil organic matter and (b) clay content in the selected soils.

CONCLUSIONS

The selected soils exhibited substantial differences in P adsorption, with 38.31–98.99% of added P adsorbed after 24 h of equilibration. Although the amount of adsorbed P increased with increasing P addition in all soils, the proportion adsorbed varied considerably. Soils A and C maintained high mean adsorption percentages of 97.66% and 96.59%, respectively. In contrast, Soil B had a lower mean adsorption of 74.83%, which decreased to 38.31% at the highest P-addition level. This indicates that Soils A and C retained added P more effectively, whereas Soil B showed lower retention under high P loading.

Mean adsorbed P showed a stronger relationship with clay content ($R^2 = 0.962$) than with organic matter ($R^2 = 0.622$). Within the three studied soils, mean adsorbed P showed a stronger descriptive association with clay content than with organic matter; however, additional soils are required to confirm this pattern. The results also indicate that total P content alone cannot adequately explain soil P-retention behaviour. Although these findings are based on only three soils and should be considered preliminary, further studies involving additional soils are needed to better understand P adsorption. Nevertheless, the present results provide a useful baseline for developing soil-specific phosphorus-fertilizer strategies that balance fertilizer-use efficiency with the potential risk of P mobility in the Ishëm River Basin.

Acknowledgments

This research was carried out within the framework of the AMORE AL project. The project is funded by Austrian Partnership Programme in Higher Education and Research for Development (APPEAR) and supported by BOKU University, TU Wien and Karlsruhe Institute of Technology. The authors would like to express their sincere gratitude to all project partners and associated institutions for their valuable support, data provision and technical contributions.

ABSTRACT

The occurrence of mycotoxins in rye, barley, and wheat bran in Albania was investigated. Twenty-four mycotoxins—including aflatoxins (B1, B2, G1, and G2), deoxynivalenol (DON), 15-acetyl DON, 3-acetyl DON, mycophenolic acid, penicillic acid, zearalenone (ZEA), fumonisins (FB1, FB2), ochratoxin A (OTA), roquefortine C, HT-2, T-2, gliotoxin, neosolaniol, cyclopiazonic acid, diacetoxyscirpenol (DAS), tenuazonic acid, tentoxin, alternariol, and alternariol methyl ether—were analyzed using liquid chromatography-tandem mass spectrometry. Samples were collected from feed-producing facilities. At least one mycotoxin was detected in 75.0% of analyzed samples (9/12), with barley exhibiting the highest incidence (71.4%), followed by rye and wheat bran. Toxins produced by the Alternaria genus were most prevalent, while Fusarium toxins were less common; only DON was identified in one sample. Alternaria toxins—tenuazonic acid (75.0%), tentoxin (22.5%), alternariol (8.33%), and alternariol methyl ether (8.33%)—were the most abundant among analyzed mycotoxins. Deoxynivalenol (DON) was the only Fusarium toxins detected in wheat bran (33.3%), while mycotoxins from the genera Aspergillus and Penicillium were not detected. The occurrence of mycotoxins in feed ingredients was lower than previously reported for maize grown in Albania, with concentrations remaining below maximum levels where applicable. However, the presence of Alternaria toxins highlights the necessity for enhanced monitoring of raw materials, and preventive measures throughout the cereal supply chain.

Keywords: feed, rye, barley, wheat bran, mycotoxins, aflatoxin, deoxynivalenol, fumonisins, LC-MS/MS, Albania

INTRODUCTION

Mycotoxins are low-molecular-weight secondary metabolites produced by filamentous fungi (Costa et al., 2019; Gurikar *et al.*, 2023). Fungal spoilage of agricultural commodities can contaminate food and feed (Stroka and Gonçalves, 2019). The main producing fungal genera are Aspergillus, Penicillium, Fusarium, and Alternaria (Pinton et al., 2025), which grow in the field and during storage under inappropriate conditions (Kępińska-Pacelik & Biel, 2021).

Mycotoxin contamination is a global threat and will become more significant due to climate change and the globalization of the food and feed market (Altomare, Logrieco, Gallo, 2021). All over the world, more than 1000 mycotoxins have been identified, yet less than 20 are regulated (Pinton et al., 2025). Market globalization of agricultural commodities has increased awareness of mycotoxin contamination, with AFs being most distinguished for their public health implications and agro-economic significance (Altomare, Logrieco, Gallo, 2021).

European Commission has established maximum levels (ML) in food (European Commission, 2023; European Commission, 2024), where, for unprocessed cereals intended for human consumption or as an ingredient in foodstuffs other than maize, the ML is 2 µg/kg for AFB1 and 4 µg/kg for the sum of AFs, while in maize the ML is 5.0 µg/kg for AFB1 and 10.0 µg/kg for the sum of AFs. The ML of AFB1 is 0.02 mg/kg in feed, 0.01 mg/kg in complementary and complete feed, except feed for dairy animals, piglets and young poultry animals where ML is 0.005 mg/kg (European Commission, 2011).

Tabela 1. EU Maximum Levels in feed materials for main mycotoxins

Mycotoxin	Feed material (mg/kg)	Compound feed	Notes
Aflatoxin B1	0.02	(Cereal, oilseed, maize)	Strictet for dairy animals (carry over into milk)
Deoynivaleno (DON)	8-12	Cereal, maize, soybeans	Horses highly sensitive
Zearalenone	2-3	Maize, cereals	Pigs most sensitive
Ochratoxin A	0.25	Cereals, cereal products	Cats extremely sensitive
Fumonisins (B1 and B2)	60	Maize, maize products	Horses most sensitive
T-2 and HT-2- toxin	0.25-0.5	Cereals, cereal products	Cats excluded due to extreme sensitivity

Aflatoxins (AFs) are produced mainly by *A. flavus* and *A. parasiticus* (Cary et al., 2018; El-Sayed et al., 2022). The growth of aflatoxigenic-producing fungi depends on crop and soil types, as well as climate conditions (Sudan et al., 2026). Aflatoxin contamination of cereals is associated with poor storage conditions and field contamination. Post-harvest spoilage may occur due to inappropriate moisture content and storage temperatures. Natural aflatoxins include aflatoxin B1 (AFB1), aflatoxin B2 (AFB2), aflatoxin G1 (AFG1), aflatoxin G2 (AFG2) (CAST, 2003). AF contamination of foods and feedstuffs is global, but groundnuts, maize, and cottonseeds are reported to be at higher risk of contamination and, consequently, a major source of exposure (Akpoghelie et al., 2025).

Fusarium species are among the most well-known toxigenic fungi, particularly in temperate regions, and can cause severe reductions in crop yield through various plant diseases (Munkvold et al., 2019). The most distinguished Fusarium mycotoxins are zearalenone (ZEA), fumonisins (FBs), T-2 toxin, HT-2 toxin, neosolaniol (NEO), diacetoxyscirpenol (DAS), deoxynivalenol

(DON), and its 3-acetyl (3-AcDON) and 15-acetyl (15-AcDON) derivatives (Leite et al., 2021; El-Sayed et al., 2022).

Alternaria toxins naturally occur on food and feed that are contaminated with Alternaria species, and alternariol, alternariol monomethyl ether, tenuazonic acid, altertoxins, and tentoxin are the most present. Some of these mycotoxins are carcinogenic, toxic, and mutagenic. The limited evidence on toxigenic effects has dictated no established maximum levels for this group of mycotoxins (Nagda & Meena, 2024).

The fate of different mycotoxins during cereal treatment processes, such as sorting, cleaning, debranning, and thermal processing, can significantly reduce mycotoxin concentrations (Bullerman and Bianchini, 2007). In contrast, milling processes result in repartitioning of mycotoxins in different milling fractions (Tibola et al., 2015).

Exposure to these compounds is a major threat to human and animal health and is associated with different acute or chronic mycotoxicoses (Awuchi et al., 2022).

Mycotoxin occurrence in barley and rye

Among cereals, maize and wheat are the most important in terms of production quantity and are consequently the most studied for mycotoxin contamination. Occurrence of aflatoxins in barley was mainly reported from Europe and the Mediterranean region (Binder et al., 2007), Spain (Ibanez-Vea et al., 2012), Serbia (Kos et al., 2014) and Slovenia (Babič et al., 2021), occurrence of aflatoxins in rye was reported from Europe during the period 2007–2012 (EFSA, 2013), Serbia (Kos et al., 2014) and Poland (Kosicki et al., 2020)

This study aimed to provide insight into the presence of twenty-four mycotoxins produced by four fungal genera: Alternaria (tenuazonic acid, tentoxin, alternariol, alternariol methyl ether), Fusarium (DON, 3-acetyl-DON, 15-acetyl-DON, ZEA, FB1, FB2, T-2, HT-2, DAS, and NEO), Aspergillus (aflatoxins B1, B2, G1, and G2), and Penicillium (mycophenolic acid, cyclopiazonic acid, roquefortine C) in two main cereal commodities produced in Albania, maize and wheat, both used as food and feed. This study represents the first report on the presence of these mycotoxins in crop commodities from Albania.

MATERIALS AND METHODS

Sample characterization

Barley, rye, and wheat bran were sampled from local feed distributors in Albania. The sampling procedure was carried out in accordance with Commission Regulation (EC) No 401/2006 (European Commission, 2006) on sample collection.

Standards and Chemicals

Single standards of ZEA, FB1 and FB2 (Romer Labs, Tulln, Austria) mixed with trichothecene standard solution in acetonitrile (DON, 3-AcDON, 15-AcDON, T-2, HT-2, DAS and NEO) produced by Trilogy (Washington, MO, USA); both stock standard solutions and the mixed

working standard solutions were prepared in acetonitrile and stored in amber glass vials at –20°C. Aflatoxin standards (AFB1, AFB2, AFG1 and AFG2) were purchased from Romer (Union, MO, USA). Stock standard solutions were prepared in acetonitrile, and the mixed working standard solution was prepared with acetonitrile, methanol, acetic acid (Sigma-Aldrich, Steinheim, Germany), and ammonium acetate (Merck, Darmstadt, Germany), all of p.a. or LC-MS grade purity. Deionized water was prepared using a Milli-Q system (Millipore, Bedford, MA, USA).

Deionized water was prepared using a Milli-Q system (Millipore, Bedford, MA, USA). The extraction solution was a mixture of acetonitrile and deionized water in an 84:16 (v/v) ratio. For the final sample solution, a mixture of deionized water and methanol in an 80:20 (v/v) ratio was used. Mobile phase components A and B were deionized water and methanol, both containing 0.2 g of ammonium acetate and 5 mL of acetic acid per liter.

Aflatoxin extraction

For simultaneous determination of aflatoxins (AFB1, AFB2, AFG1 and AFG2), a procedure consisting of the extraction of mycotoxins from ground cereal samples with the acetonitrile-deionized water mixture and liquid chromatography-tandem mass spectrometry (LC-MS/MS) was used. Sample preparation and mycotoxin determination were performed according to analytical procedures described elsewhere (Driehuis, Spanjer, Scholten, & Te Geffel, 2008; Lattanzio, Della Gatta, Suman, & Visconti, 2011; Rasmussen, Storm, Rasmussen, Smedsgaard, & Nielsen, 2010). 10 g of a sample was shaken with 100 mL of an acetonitrile-deionized water mixture (84+16) for 1 hour using a linear shaker IKA HS 501 digital (IKA Labortechnik, Staufen, Germany). 4 mL of the filtered extract was evaporated under vacuum to dryness using the system Syncore Polyvap (Büchi, Flawil, Switzerland). The dry residue was reconstituted with 0.5 mL of a methanol-deionized water mixture (80+20). 10 µl of the solution was injected into the LC-MS/MS system (Acquity UPLC H Class system coupled with a triple-quadrupole instrument, Waters).

Fusarium and Alternaria toxins extraction procedure

For the simultaneous determination of mycotoxins (DON, 3-AcDON, 15-AcDON, ZEA, FB1, FB2, T-2, HT-2, DAS, and NEO), a procedure described in detail by Topi et al. (60) was applied. The procedure consisted of extracting mycotoxins from ground cereal samples and determining them by LC-MS/MS. Specific MS/MS parameters related to the determined mycotoxins (retention times, ionization mode, and monitored transitions) are given in Table 7.

Table 1. Retention times of Fusarium toxins, ionization mode, and monitored transitions.

Analyte	Ionization mode	Retention time (min)	Precursor ion (m/z)	Quantifier ion (m/z)	Qualifier ion (m/z)
DON	ESI+	3.14	297.3	203.1	249.1
3-AcDON	ESI+	5.00	339.1	203.1	137.0

15-AcDON	ESI+	5.00	339.1	136.9	261.1
DAS	ESI+	7.06	384.3	307.2	247.2
HT-2	ESI+	8.91	442.4	215.1	263.2
T-2	ESI+	10.27	484.4	185.1	215.2
ZEA	ESI-	11.30	317.2	131.0	174.9
FB1	ESI+	10.20	722.4	334.2	352.2
FB2	ESI+	12.70	706.4	318.2	336.2

LC-MS/MS analysis

The chromatographic separation was performed on a Zorbax Eclipse Plus C18 Rapid Resolution HD column (2.1 x 100 mm, 1.8 µm; Agilent). The mobile phase consisted of two components mixed in gradient mode. Component A consisted of deionized water (995 ml), acetic acid (5 ml), and ammonium acetate (0.2 g), and component B consisted of methanol (995 ml), acetic acid (5 ml), and ammonium acetate (0.2 g). The initial eluent composition was 95% A and 5% B. The proportion of component B was linearly increased to 40% within 4 min and further to 70% within the next 8 min. The composition was held for 4 min, and then component B was increased to 90% in 1.5 min. The proportion of component B was held at 90% for 2.5 min, then returned to 5% over 1 min. The composition was held for 4 min. The mobile phase flow rate was 300 µL/min, and the chromatography column temperature was 40 °C. MS/MS analysis was carried out using electrospray ionization (ESI), and the triple-quadrupole mass spectrometer was operated in multiple reaction monitoring (MRM) mode. The capillary voltage was 3,4 kV, desolvation temperature 500 ºC, ion source temperature 150 ºC, and collision cell voltage 20 V. Other LC-MS/MS parameters as well as the limits of detection (LOD), limits of quantification (LOQ), and recoveries obtained within the validation process for single mycotoxins are given in Table 2. The Limit of detection (LOD) of single analytes was determined based on the signal-to-noise ratio of 3:1. As LOQ, a value of 2.5 times LOD was selected. LOD and LOQ were 0.20 µg/kg and 0.40 µg/kg, respectively, for every single aflatoxin.

Table 2. Retention times, the m/z precursor ion, the m/z monitored product ions, LOD, LOQ, and the recovery of aflatoxins (AFB1, AFB2, AFG1 and AFG2).

Analyte	Retention time (min)	Precursor ion (m/z)	Quantifier ion (m/z)	Qualifier ion (m/z)	LOD (µg/kg)	LOQ (µg/kg)
AFB1	5.25	313.2	213.2	241.1	0.6	2.0
AFB2	4.75	215.2	243.2	259.1	0.6	2.0
AFG1	2.92	329.1	214.8	199.9	0.6	2.0

AFG2	5.33	331.1	189.0	285.1	0.6	2.0

Method Validation

The Limit of detection (LOD) of single analytes was determined at a signal-to-noise ratio of 3:1. A value 3.3 times the LOD was selected as the Limit of quantification (LOQ). The recoveries and precision were tested using maize and wheat samples spiked with *Fusarium* toxins at the concentration levels of 50, 100 and 500 μg/kg.

The linearity of the method was tested in the concentration range 50–500 μg/kg using matrix-matched standard solutions analyzed in triplicate. Good linearity was demonstrated for all analytes, with correlation coefficients exceeding 0.997. The accepted LOD and LOQ for all single Fusarium toxins were 15 (g/kg) and 50 (g/kg), respectively. The mean recoveries of single toxins in maize at the tested concentration levels ranged from 90% to 117%. In wheat, recoveries ranged from 87% to 112%, except for DON, which was 124%. The reproducibility expressed as RSD_R was less than 16% for all *Fusarium* toxins in maize and ≤30% for all *Fusarium* toxins in wheat. The reproducibility and mean recoveries of the toxins were in line with the criteria set out in Commission Regulation (EC) No 401/2006 and its amendments, except for DON, which slightly exceeded the required value.

RESULTS AND DISCUSSIONS

Contamination of barley and rye

In the investigated barley samples, no aflatoxin contamination was detected (Table 3). Aflatoxin G2 was detected in one barley sample. Aflatoxin occurrence in barley has been reported mainly in European countries (Kow et al., 2025). AFB1 in barley from the Czech Republic was reported in 87% of samples, with mean and maximum values of 2.1 and 4.0 μg/kg, respectively (Sedmikova *et al*., 2001). The AFB1 incidence in barley samples from northern regions of Spain during 2007-2008 was found in 100%, and the mean value was 0.11 μg/kg, while the mean value of the sum of AFs was 0.12 μg/kg (Ibanez-Vea *et al*., 2012). In conclusion, our findings on AFB1 contamination are in accord with reports from Europe and the Mediterranean region (Pleadin *et al*., 2024).

Table 3: Occurrence of mycotoxin contamination in rye and barley samples

	Parameter	**Sum of AFs**	**AFB1**	**AFB2**	**AFG1**	**AFG2**
Barley	No. positive/Total samples	0/5	0/5	0/5	0/5	0/5
Rye	No. positive/Total samples	1/2	0/2	0/2	0/2	1/2
Rye	% of positive samples	50.0	0.0	0.0	0.0	50.0
Rye	Min-Max (□g/kg)	0.61	n.d	n.d	n.d	0.61
Rye	No. samples above 2 □g/kg		0			

Rye	No. samples above 4 □g/kg	0				

N.B. Results expressed for 12% moisture content.

Occurrence of aflatoxin G2 in one barley sample with an uncommon presence of 0.61 μg/kg. This situation was similar to that of wheat samples from the same region of Korça. Rye is cultivated and used in modest amounts in Albania compared to other cereal grains. Data on AFB1 Occurrence reported in rye samples come mainly from Europe. In the EFSA report, during the period 2007–2012 was not found AF contamination in a total of 57 analyzed samples (EFSA, 2013). Occurrence of aflatoxins in rye from the region indicates that they were not found in rye samples from Serbia (Kos *et al*., 2014), while they were found at elevated levels (4.56 μg/kg) in samples from Romania (Gagiu *et al*., 2018).

Results indicate the presence of four Alternaria toxins in barley samples: tenuazonic acid, tentoxin, alternariol and alternariol methyl ether, while in rye and wheat bran two toxins were detected: tenuazonic acid and tentoxin. The most prevalent was tenuazonic acid, with an incidence of 71.4% and a maximum value of 0.22 mg/kg.

The highest incidence (100%) was observed in wheat bran, while occurrence was the second-most-contaminated feed commodity, with a maximum of 0.088 mg/kg.

The rye commodity presented an incidence of 50%, and a maximum occurrence of 0.022 mg/kg. Based on the dataset for the Occurrence of Alternaria toxins in barley, rye, and wheat bran feed commodities, both the variability of contamination and the potential risk to animal exposure are evident.

Barley crop showed the highest contamination frequency, with 71.4% of samples positive for tenuazonic acid (TeA) and the same proportion positive for the sum of Alternaria toxins. The mean TeA concentration (0.1458 mg/kg) was notably higher than in rye and wheat bran, with values ranging from 0.0832 to 0.227 mg/kg. Tentoxin, alternariol, and alternariol methyl ether were each detected in only one sample (14.3%), but their presence indicates a broader spectrum of Alternaria metabolites. The relatively high median values suggest that barley is a significant contributor to Alternaria toxin exposure in feed.

Rye crop exhibited lower contamination levels, with only 50% of samples positive for TeA and tentoxin, and no alternariol or alternariol methyl ether detected. Concentrations were minimal (mean TeA 0.022 mg/kg; tentoxin 0.006 mg/kg), reflecting limited fungal activity or effective post-harvest handling. The absence of alternariol derivatives may indicate either lower fungal colonization or differences in substrate susceptibility compared to barley and wheat bran.

Wheat bran resulted contaminated with TeA, with all samples positive (100%). The mean concentration (0.061 mg/kg) was lower than in barley but higher than in rye. Tentoxin was detected in two-thirds of samples (66.7%), though alternariol and its methyl ether were absent. The average sum of Alternaria toxins was 0.0693 mg/kg, with a maximum of 0.092 mg/kg. This suggests that wheat bran is a consistent carrier of TeA, possibly due to its high nutrient content and surface area that favor fungal growth.

Comparative Insights

Tenuazonic acid was the most prevalent toxin across all commodities, confirming its dominance among Alternaria metabolites in feed.

Barley seed showed the broadest toxin profile, with occasional detection of alternariol and alternariol methyl ether, while wheat bran was consistently contaminated but with a narrower spectrum. Rye appeared least affected, both in frequency and concentration, suggesting species-specific resistance or lower fungal colonization.

Implications

The findings emphasize the need for routine monitoring of Alternaria toxins in feed, particularly in barley and wheat bran, which demonstrated higher contamination rates. Although concentrations were relatively low compared to regulated mycotoxins (e.g., aflatoxins, DON), the co-occurrence of multiple Alternaria metabolites raises concerns about additive or synergistic toxic effects (Lin, Jia, Wu, 2023). Given the absence of EU maximum levels for Alternaria toxins in feed, these results contribute valuable baseline data for risk assessment and may support future regulatory considerations.

The Occurrence of Fusarium toxins and other metabolites produced by Aspergillus and Penicillium species was also investigated in the analyzed feed samples. Target compounds included DON, 15-acetyl-DON, 3-acetyl-DON, mycophenolic acid, penicillic acid, zearalenone (ZEA), fumonisins (FB1, FB2), ochratoxin A (OTA), roquefortine C, HT-2, T-2, gliotoxin, neosolaniol, cyclopiazonic acid, and diacetoxyscirpenol (DAS). Among all these toxins, contamination was evidenced only in a single sample for DON, while the remaining analytes were not detected. This finding is in accordande with previous publication on mycotoxin occurrence (Topi et al., 2023).

Conclusions

This study provides new insights into the occurrence of twenty-four mycotoxins, analyzed by liquid chromatography coupled with tandem mass spectrometry, in selected feed commodities (barley, rye, and wheat bran) cultivated and used in Albania.

Alternaria toxins revealed the highest incidence, with tenuazonic acid (TeA) as the most prevalent metabolite, detected in all wheat bran samples and in the majority of barley samples, while rye showed lower contamination levels. These findings confirm that TeA is the dominant Alternaria toxin in feed, with barley and wheat bran representing consistent sources of contamination.

No aflatoxin B1 contamination was detected in the barley samples analyzed, although aflatoxin G2 was found in one barley sample at 0.61 μg/kg. This uncommon occurrence is consistent with sporadic findings reported in wheat from the same region. Rye samples analyzed in this study did not show aflatoxin contamination, in agreement with international reports.

Screening for Fusarium toxins (DON, 15-acetyl-DON, 3-acetyl-DON, zearalenone, fumonisins FB1 and FB2, HT-2, T-2) and for metabolites of Aspergillus and Penicillium (ochratoxin A, mycophenolic acid, penicillic acid, roquefortine C, gliotoxin, cyclopiazonic acid, diacetoxyscirpenol, neosolaniol) revealed contamination only in a single sample for DON. The

low incidence of these regulated mycotoxins indicates that, under the conditions studied, Alternaria toxins are the primary concern for contamination.

Overall, the results highlight the importance of monitoring non-regulated mycotoxins such as Alternaria metabolites, which were consistently present in barley and wheat bran. Although aflatoxin contamination was limited in this dataset, its occurrence in barley confirms the need for vigilance, given the established risk in European contexts. The absence of significant Fusarium and Aspergillus toxins suggests that contamination pressure in the studied region is currently low. Nevertheless, continued surveillance is essential to ensure feed safety and to support future regulatory considerations for Alternaria toxins.

ABSTRACT

Reliable soil moisture monitoring is essential for precision agriculture and irrigation management, but long-term sensor deployment often introduces faults such as disconnection, signal saturation, drift, and noise, which conventional threshold-based systems struggle to distinguish from genuine soil moisture changes. This study proposes a hybrid framework combining Long Short-Term Memory (LSTM) prediction, Autoencoder (AE) reconstruction, and Isolation Forest (IF) validation, evaluated on a synthetic multivariate time-series dataset representing normal and faulty sensor conditions. The LSTM and Autoencoder jointly produce a Composite Error score, checked against a statistical threshold and cross-validated by an Isolation Forest; however, this error-based pathway alone under-detects fault types that are locally smooth, namely signal saturation and gradual drift, despite being physically implausible. Adding a lightweight raw-value validation layer, which checks readings against the sensor's normal operating range and trailing variance, raised recall from 0.097 to 0.854 and F1-score from 0.154 to 0.724, while the Isolation Forest added no measurable benefit. These results indicate that reliable soil moisture fault detection requires combining learned temporal error signals with simple, physically-grounded validation rather than relying on deep learning error metrics alone, offering a foundation for future validation on real-world data and deployment on low-power IoT platforms.

Keywords: Soil Moisture, Sensor Fault Detection, LSTM, Autoencoder, Isolation Forest, Precision Agriculture

INTRODUCTION

Soil moisture is one of the most critical variables in precision agriculture: it directly governs irrigation scheduling, crop yield, and water-resource efficiency. Continuous field-scale monitoring has become a cornerstone of modern decision-support tools for farmers (Bandaru et al., 2024). As agricultural operations increasingly adopt Internet of Things (IoT)-based sensing to automate irrigation decisions, the reliability of the underlying soil moisture measurements becomes a precondition for the reliability of the irrigation system itself. Unlike a delayed dashboard reading, an undetected sensor fault in an automated irrigation pipeline can directly cause over-watering, crop stress from under-watering, or unnecessary maintenance visits. Each of these carries a real economic and environmental cost (Zou et al., 2023). In practice, soil moisture sensors deployed in the field for extended periods are subject to a range of degradation mechanisms: physical disconnection or cable damage, signal saturation caused by sensor-soil contact issues or hardware limits, gradual calibration drift due to corrosion or biofouling, and transient noise from electrical interference or power instability (Zou et al., 2023). These fault modes do not announce themselves: a drifting or saturated sensor keeps producing plausible-

looking, or a

simple static threshold, to distinguish a genuine change in soil conditions from a slowly failing sensor. Traditional threshold-based monitoring systems, which flag a reading only when it exceeds a fixed operational range, are structurally poorly suited to this problem: a slowly drifting sensor may remain within the "normal" range for a long period before crossing the threshold, by which point substantial irrigation decisions have already been made on faulty data. This is not merely a theoretical concern. An evaluation of the International Soil Moisture Network's threshold- and spectrum-based Flagit module against manually labeled field data found that it correctly identified only about half of true anomalies, and its performance degraded further as anomaly prevalence increased (Bandaru et al., 2024). Conversely, overly sensitive thresholds generate frequent false alarms, leading to alarm fatigue and reduced trust in the monitoring system. Deep learning-based anomaly detection offers a data-driven alternative, capable of learning the temporal and multivariate structure of normal sensor behavior rather than relying on a single static bound. However, as this study's own experimental findings later demonstrate, learned temporal-error metrics are not uniformly effective across fault types. Fault modes that manifest as smooth, slowly-varying signals, such as gradual drift or a sensor stuck at a fixed value, can counter-intuitively be *easier* for a sequence model to predict or reconstruct than genuine normal variation. This weakens the very error signal such models rely on for detection. This motivates the central premise of this work: a robust soil moisture fault-detection system should combine learned, model-based anomaly scoring with complementary, domain-grounded validation, rather than relying on any single detection signal alone. Building on a hybrid LSTM-Autoencoder-Isolation Forest architecture previously validated by the authors for industrial gas-leakage detection (Tezcan and Kursun, 2025), this study tests whether the same architecture transfers to the agricultural soil moisture domain. Where it does not transfer well, we propose a targeted extension to close the gap.

LITERATURE REVIEW

Sensor reliability has become a central concern as the Agricultural Internet of Things (Ag-IoT) has expanded from research prototypes to field-scale deployments. A recent comprehensive survey categorizes the root causes of agricultural sensor faults, including hardware degradation, environmental interference, and calibration decay, and traces the progression of fault-diagnosis strategies from statistical models to deep learning-based approaches. It notes that robust, generalizable fault detection for agricultural sensors remains an open area of active development (Zou et al., 2023). Rule- and threshold-based quality control remains the de facto standard in operational soil moisture networks. The International Soil Moisture Network's Flagit module, for instance, flags observations using fixed geophysical ranges, constant-value checks, and derivative-based spike/break detection. Evaluated against manually labeled field data from the Precision Sustainable Agriculture network, Flagit correctly identified roughly 95% of valid readings but only about half of true anomalies, and its performance degraded further at sites with higher anomaly prevalence. This is a direct illustration of the static-threshold limitation that motivates learned, data-driven alternatives. A bidirectional LSTM-based quality-control model (DeepQC) trained on the same network's soil moisture time series substantially outperformed Flagit on anomaly recall while requiring no ancillary meteorological inputs (Bandaru et al., 2024). The specific combination of an LSTM Autoencoder with an Isolation Forest, the architecture adopted in this study, has direct precedent in the literature. Tran, Heuchenne, and Thomassey (2020) proposed a hybrid LSTM Autoencoder-Isolation Forest framework for multivariate industrial time series and reported improved performance over a One-Class SVM

baseline. Closer to the present application domain, Priyanto, Hendry, and Purnomo (2021) applied an Isolation Forest to pseudo-label raw land-monitoring sensor data before training an LSTM Autoencoder for agricultural anomaly detection, reporting high precision and recall on their dataset. To the authors' knowledge, this is the most directly comparable prior application of this architecture family to agricultural sensor monitoring. Fault detection for precision-agriculture wireless sensor networks has also been addressed with lightweight, transfer-learning-based LSTM models designed for the limited-labeled-data conditions typical of agricultural deployments (Aitamar and Abbadi, 2025). A related line of work applies LSTM-based pipelines to synthetically injected faults in vineyard meteorological sensor networks, an experimental design methodologically close to the fault-injection approach used here (Costanti et al., 2024).

Beyond the choice of architecture, two further strands of related work motivate design decisions made in this study. First, several works highlight that fixed statistical thresholds are a persistent limitation of hybrid deep-learning fault detectors. A dynamic thresholding mechanism combined with an LSTM-Attention Autoencoder adapts more robustly to noisy or drifting sensor conditions than static thresholds in wireless sensor networks (Ijaz, Jan, and Koo, 2025). Multi-step-ahead LSTM Autoencoder prediction, rather than single next-step prediction, has also been proposed specifically to improve sensitivity to gradually developing faults (Hasan, Jan, and Koo, 2024). Second, and most directly relevant to this study's own findings, standard data-driven LSTM Autoencoders have been reported to struggle with incipient, gradual drift faults under noisy conditions, precisely because purely error-based reconstruction metrics ignore the physical plausibility of the underlying signal. This has motivated physics-coupled loss formulations that explicitly constrain reconstructions to respect known physical relationships among sensor variables (Jia et al., 2026).

Across this body of work, two gaps remain. First, existing agricultural applications of the LSTM-Autoencoder-Isolation Forest architecture (Priyanto et al., 2021) have not, to the authors' knowledge, been evaluated against ground-truth fault labels using standard precision/recall/F1 metrics, nor benchmarked against single-model configurations under a pre-registered, non-post-hoc-tuned evaluation protocol. This study adopts that protocol, extending the authors' prior hybrid LSTM-Autoencoder-Isolation Forest work on industrial gas-leakage detection (Tezcan and Kursun, 2025) to soil moisture sensing. Second, consistent with the drift-detection weakness documented by Jia et al. (2026) in an industrial setting, this study's own experiments confirm that purely error-based deep learning detection struggles with slowly-varying, locally smooth fault types, specifically drift and signal saturation, in the soil moisture domain. This motivates the lightweight raw-value validation layer introduced in the proposed framework, which complements rather than replaces the learned error-based detection pathway.

METHODOLOGY

The study utilizes a synthetic multivariate time-series dataset consisting of four sensor features relevant to precision agriculture: Soil Moisture, Ambient Temperature, Relative Humidity, and Light Intensity, sampled hourly. A 60-day (1,440-hour) normal-operation dataset was generated to represent typical field conditions, incorporating diurnal temperature and light cycles, humidity inversely coupled to temperature, and irrigation-driven soil moisture spikes followed by exponential drydown. This normal dataset was used exclusively for model training and threshold calibration. A held-out validation split (15% of the normal data) was reserved solely for calibrating the anomaly threshold, so it was never exposed to the test set.

A separate 300-hour test simulation was constructed by injecting four fault types into the soil moisture channel, consistent with categories established in the sensor fault-detection literature: (i) disconnection (flatline near zero), (ii) signal saturation (stuck-at-maximum), (iii)

gradual drift (a slow additive ramp representing calibration decay), and (iv) abnormal noise spikes (high-amplitude transient noise). Unlike the other three fault types, which affect every time step within their window, noise spikes were injected stochastically at each time step within the window (approximately 50% probability per step), so only the affected time steps carry a positive ground-truth label while the remaining time steps within that window retain genuinely normal readings. Each fault segment was assigned a ground-truth binary label accordingly, yielding 103 anomalous and 197 normal time steps in the test set. All features were normalized using a MinMax scaler fitted exclusively on the normal training data, and 20-step sliding windows (TIME_STEPS = 20) were constructed for both model families, mirroring the windowing strategy of the authors' prior gas-leakage detection study.

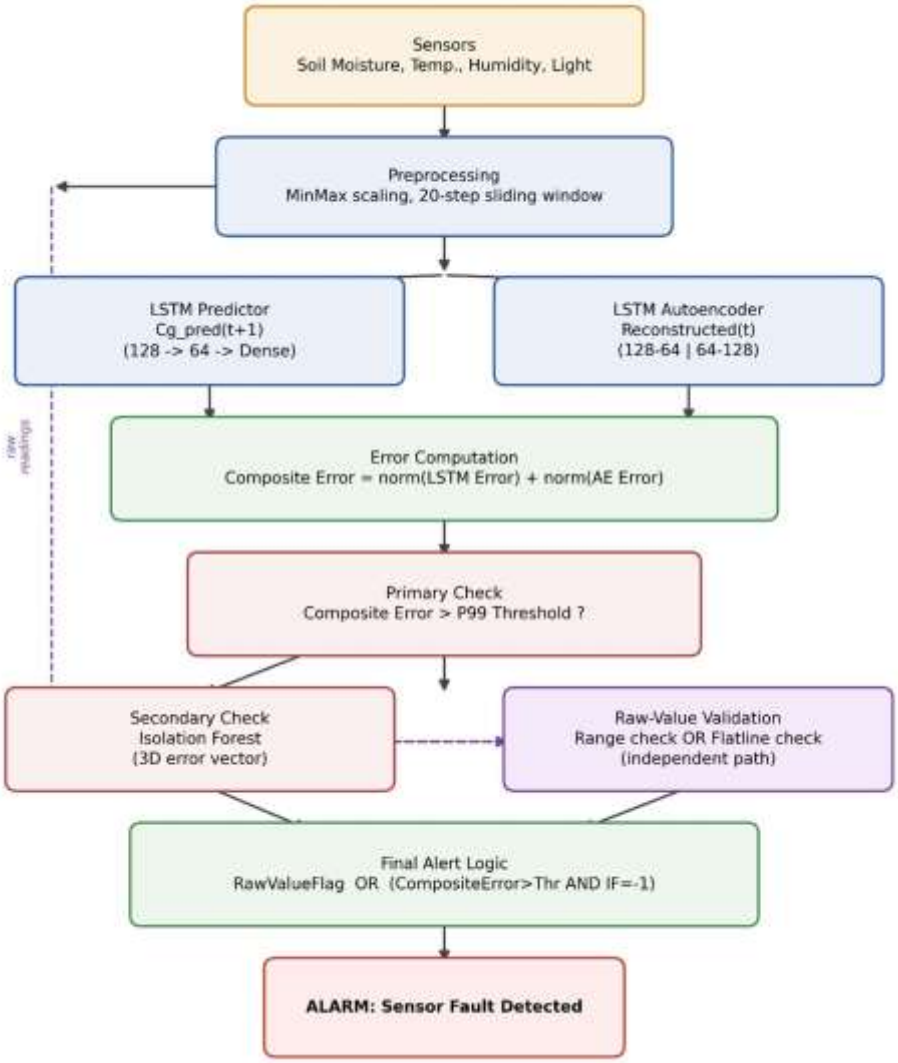
The proposed framework consists of two independent deep learning components and two complementary validation layers.

A. LSTM Prediction Model. A two-layer LSTM network (128 and 64 units) followed by a single-unit Dense output layer forecasts the next soil moisture value from the preceding 20-step, 4-feature window.

B. LSTM Autoencoder Model. An encoder of two LSTM layers (128 and 64 units) compresses each 20-step, 4-feature window into a latent representation, which a symmetric decoder (64 and 128 units) reconstructs via a TimeDistributed Dense output layer.

C. Composite Error and Statistical Threshold. The LSTM prediction error and the Autoencoder's soil-moisture reconstruction error are each normalized by their respective standard deviations on the validation split, then averaged to form a Composite Error score. A statistical threshold is set at the 99th percentile of the Composite Error distribution on the (unseen-to-the-model) validation split.

D. Raw-Value Validation Layer. During preliminary evaluation, error-based detection was found to under-detect fault types that are locally smooth and therefore easy for a next-step predictor to track, namely signal saturation and gradual drift, even though the underlying raw values are physically implausible for the sensor's normal operating range. This is consistent with recent findings that standard LSTM Autoencoders struggle with incipient, gradual drift faults because purely error-based reconstruction metrics disregard the physical plausibility of the underlying signal (Jia et al., 2026). To address an analogous weakness in the soil moisture domain, we introduced a lightweight raw-value validation layer that flags readings which either (a) fall outside the normal operating range observed during training, with a small tolerance margin, or (b) show near-zero variance over a trailing 5-step window relative to the normal rate of change, a flatline or stuck-sensor signature. Unlike the physics-coupled loss formulation of Jia et al. (2026), which requires joint training with a correlation-aware objective, this layer needs no additional model training and operates directly on raw sensor readings. The trade-off is that it is specific to the soil moisture channel rather than general across all sensor variables.



E. Isolation Forest (IF) Filter. As in the authors' prior work, an Isolation Forest is trained on a 3-dimensional error vector (Composite Error, LSTM Error, AE Error) derived from the validation split, providing a contextual, non-parametric secondary check intended to reject Composite-Error-based alarms that do not correspond to a genuinely abnormal multidimensional error profile.

Two candidate detections are combined into the final alert logic:

1. **Model-based alert:** CompositeError > Threshold(P99), subject to confirmation by the Isolation Forest (IFPrediction = -1).
2. **Raw-value-based alert:** raised independently whenever the raw-value range or flatline condition is met, since such cases are physically self-evident and do not require probabilistic confirmation.

Final Alert = RawValueFlag ∪ (CompositeError > Threshold ∩ IFPrediction = -1)

Figure 1 summarizes the full detection pipeline described above, from raw sensor readings through the preprocessing, dual-model error computation, statistical/Isolation Forest validation pathway, and the independent raw-value validation pathway, into the final combined alert logic.
Figure 1. System architecture of the proposed framework, combining the statistical/Isolation

Forest error pathway with an independent raw-value validation pathway.
This two-track design combines the statistically-grounded, IF-validated detection pathway with an explicit compensation for its blind spot on smooth/slow-varying fault signatures, observed in this study's preliminary evaluation.

RESULTS AND DISCUSSION

The 300-hour test simulation contained four injected fault segments: disconnection (hours 40–62), signal saturation (hours 110–135), gradual drift (hours 175–215), and abnormal noise spikes (hours 245–270), yielding 103 of 280 evaluable windows labeled anomalous after windowing. All hyperparameters (the P99 threshold, the Isolation Forest contamination rate of 0.05, the Composite Error definition, and the raw-value validation layer's range/flatline criteria) were fixed prior to evaluation and were not adjusted based on test-set performance.

Table 1 summarizes the detection performance of all six evaluated configurations across Precision, Recall, F1-Score, and Accuracy.

Table 1. Detection performance of all six evaluated configurations on the 300-hour test set.

Model	Detected	False Positives	Precision	Recall	F1-Score	Accuracy
LSTM Only	30	15	0.500	0.146	0.226	0.632
Autoencoder Only	31	19	0.387	0.117	0.179	0.607
Hybrid (LSTM + AE)	27	17	0.370	0.097	0.154	0.607
Hybrid + Isolation Forest	27	17	0.370	0.097	0.154	0.607
Hybrid + Raw-Value Validation	140	52	0.629	0.854	0.724	0.761
Full System (Hybrid + Raw-Value Validation + IF)	140	52	0.629	0.854	0.724	0.761

In this experiment, the standalone LSTM and Autoencoder benchmarks achieved limited recall, no higher than 0.146. Segment-level analysis of the Composite Error revealed the underlying mechanism: for the disconnection and noise-spike faults, mean error rose to 3.5–3.7 (approaching the 4.39 threshold), but for signal saturation and gradual drift, mean error remained near 1.3–1.4, well below the threshold. Essentially none of the saturation or drift windows crossed it. Because next-step predictors and autoencoders are optimized to track locally smooth, low-complexity sequences, a sensor stuck at a constant value or drifting along a smooth ramp is, paradoxically, *easy* for these models to predict or reconstruct once the fault has been in effect for even a few steps, despite being physically anomalous. This is consistent with reconstruction-based anomaly detectors' known tendency to generalize to simple anomalies.

Combining LSTM and AE error signals did not yield a recall or F1 improvement here; LSTM Only achieved the highest recall (0.146) and F1 (0.226) among the three error-only configurations. The Isolation Forest filter, trained on the validation error distribution, produced identical predictions to the unfiltered Hybrid model (27 detections in both cases). In this specific experiment, with this specific error formulation (a 3-dimensional vector of Composite, LSTM, and AE error), the Isolation Forest did not provide additional detection value beyond the Composite Error threshold alone. This result is reported as observed, without adjustment to the pre-registered hyperparameters or error definition.

Adding the raw-value validation layer raised recall from 0.097 to 0.854 and F1 from 0.154 to 0.724, at the cost of increased false positives (17 → 52); precision counter-intuitively improved as well (0.370 → 0.629), because the additional true positives captured by the raw-value validation layer outnumbered the additional false positives it introduced. This confirms that the two fault types missed by error-based detection (saturation, drift) were recovered almost entirely by the raw-value validation check, while detection of disconnection and noise-spike faults, which were already partially captured by the Composite Error, was largely unchanged. The Isolation Forest again made no measurable difference when layered on top of the full system (140 detections in both configurations): in this specific experiment, with this specific error formulation, IF did not add detection value at either stage of the pipeline.

These results suggest that prediction- and reconstruction-error-based deep learning models alone are insufficient for soil moisture sensor fault detection. This is not because the

hybrid combination itself is flawed, but because two of the four canonical fault types (saturation, drift) are inherently difficult for temporally-smooth error metrics to flag. A lightweight, physically-grounded raw-value check is a necessary complement rather than an optional add-on in this experiment. The finding that Isolation Forest did not add measurable value here is specific to this dataset and this 3-dimensional error formulation, and should not be read as a general statement about Isolation Forest's usefulness elsewhere; it is reported as an observed outcome of this particular configuration.

Figure 2 shows the Composite Error time series against the P99 threshold, with the four injected fault windows shaded, illustrating directly why saturation and drift remain undetected by the error-based pathway.

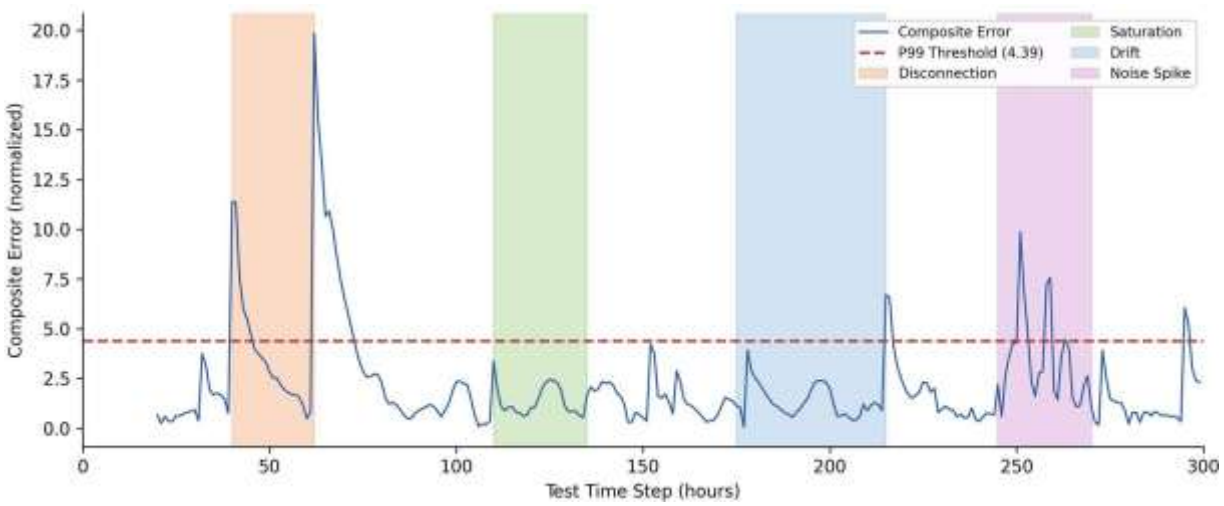


Figure 2. Composite Error over the 300-hour test window, with the P99 threshold and the four injected fault windows shown.

Figure 3 compares all six evaluated configurations across Precision, Recall, F1-Score, and Accuracy.

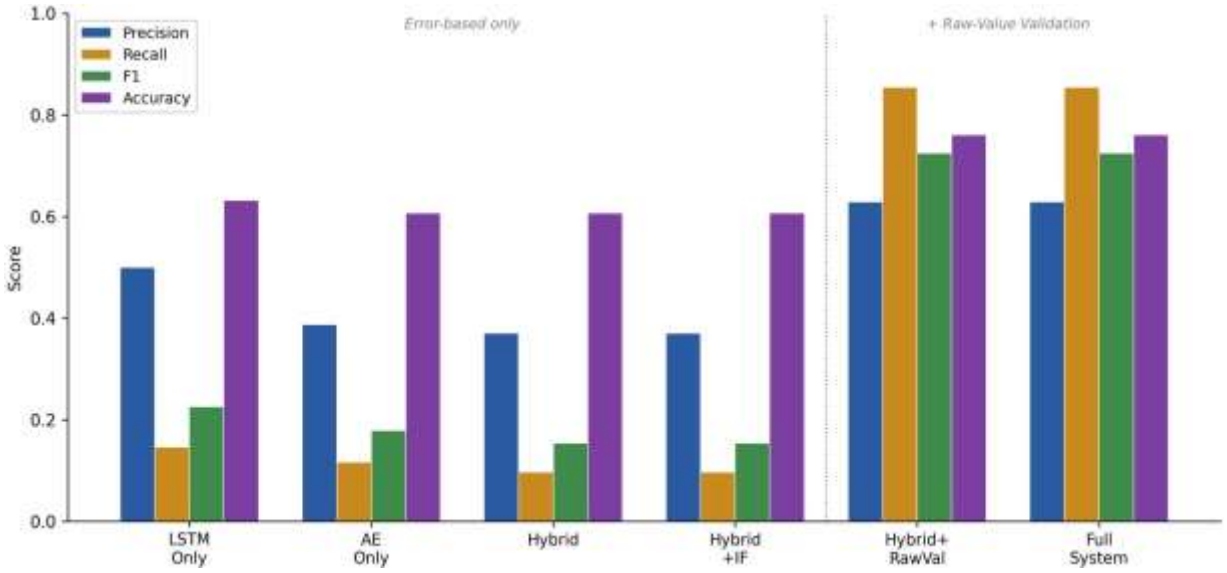

Figure 3. Precision, Recall, F1-Score, and Accuracy for all six evaluated configurations.

Figure 4 shows the raw soil moisture signal itself, with fault windows shaded and points flagged by the Full System overlaid, illustrating which fault types are caught by the raw-value pathway versus the error-based pathway.

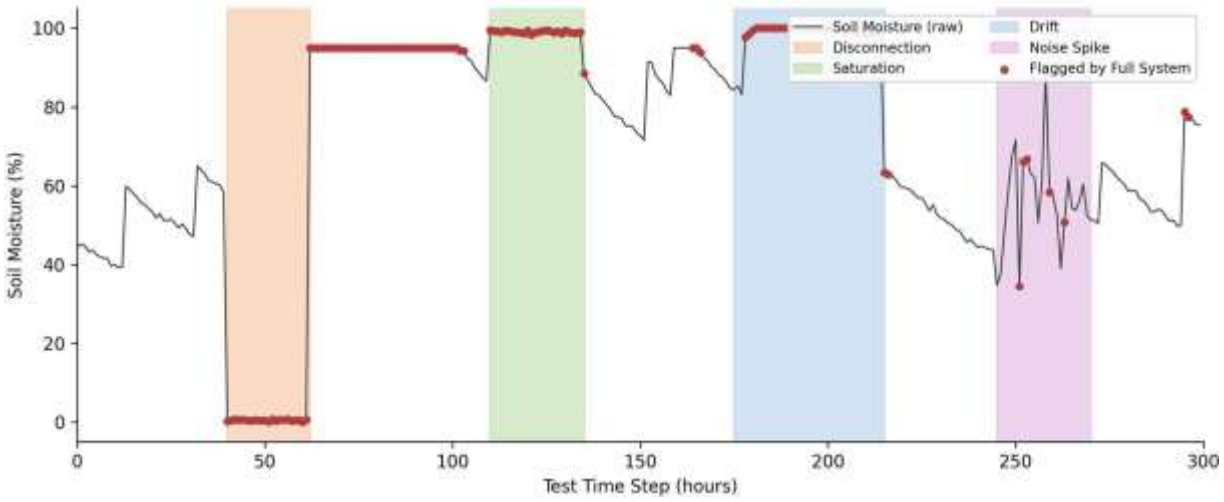

Figure 4. Raw soil moisture signal over the test period, with fault windows and Full System detections marked.

Figure 5 summarizes the Composite Error distribution grouped by fault type, quantifying the segment-level pattern described above across the full window population rather than a single mean value per segment.

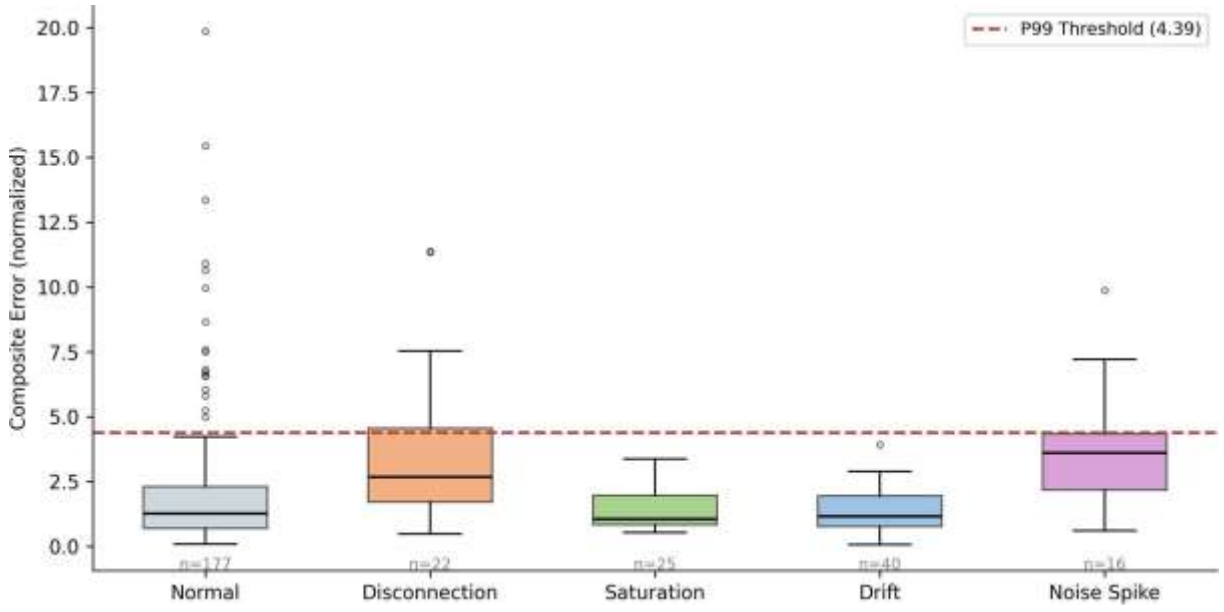

Figure 5. Distribution of per-window Composite Error by fault type, with the P99 threshold overlaid.

CONCLUSION

This study evaluated a multi-layered LSTM-Autoencoder-Isolation Forest framework for early detection of soil moisture sensor faults. Under hyperparameters fixed prior to evaluation, the error-based LSTM, Autoencoder, and Hybrid configurations achieved limited recall (0.097–0.146), as two of the four injected fault types, signal saturation and gradual drift, proved locally smooth enough for next-step prediction and reconstruction models to track without triggering a large error, despite being physically implausible. In this specific experiment, with this specific 3-dimensional error formulation, the Isolation Forest filter produced no measurable change in detection outcomes. A lightweight raw-value validation layer, checking raw sensor readings against the normal operating range and trailing variance observed during training, recovered the majority of missed detections, raising the Full System's recall to 0.854 and F1-score to 0.724. This indicates that, in this experiment, reliable soil moisture fault detection required combining learned temporal error signals with simple, physically-grounded sanity checks, rather than relying on deep learning error metrics alone.

ABSTRACT

Dairy goat farming is a significant sector of modern animal husbandry, and methods to enhance productive performance are a current priority in the context of optimizing resource use and increasing sustainability in the industry. Saanen dairy goats are distinguished by their high production potential and adaptability to various farming systems. This study analyses the milk production of two Saanen goat farms involved in purebred improvement programs over a three-year period, comparing two farming systems: traditional (pasture-based) and intensive (permanent housing). Milk yield was estimated using the Fleischmann formula (accounting for the kid-rearing period), and statistical analysis was performed using a paired two-sample t-test for means. Significant differences ($p<0.001$) in average milk production were observed over the three years for the pasture-raised group; yields increased progressively from 737.31 ± 186.11 kg in the first lactation to 856.07 ± 180.90 kg in the second and 929.44 ± 224.89 kg in the third, while the average lactation length decreased from 315.6 days to 307.3 days. Consequently, total milk production was primarily driven by the goats' increasing productive capacity, with average daily yields of 2.34 kg/day in the first lactation, 2.79 kg/day in the second, and 3.02 kg/day in the third. Milk production in the intensively managed goat group increased significantly from one lactation to the next, alongside an extension of the lactation period and an increase in average daily yield. Goats raised under the intensive system achieved higher production levels than those in the traditional system starting from the very first lactation (836.4 kg vs. 737.3 kg), with the differences becoming even more pronounced in subsequent lactations (1,198.6 kg and 1,236.2 kg vs. 856.1 kg and 929.4 kg, respectively). These results suggest that intensive management, through the control of nutrition and husbandry conditions, facilitates a fuller expression of the genetic potential of Saanen goats.

INTRODUCTION

Goat farming is a livestock sector undergoing continuous development, driven by the species' adaptability, the nutritional value of its milk, and growing interest in efficient production systems. Population growth, urbanization, and rising incomes in certain regions of the world have led to an increasing demand for food sources, with animal-derived protein playing a key role—thereby boosting interest in the development and intensification of the livestock sector (Dida F.M. et al., 2025).

Amidst current concerns regarding resource optimization and increased sustainability in livestock farming, the choice of production system can significantly influence animal performance. Intensifying livestock production entails the construction of housing and facilities for storing feed and manure, as well as the acquisition of energy- or fuel-consuming machinery, factors viewed as contributing to a larger carbon footprint. Conversely, intensive livestock farming is considered more efficient in terms of emissions per unit of output, owing to improved feed conversion and animal productivity (Gerber et al., 2011). However, traditional systems are regarded as more eco-friendly and more effective at reducing greenhouse gas emissions (Parsad R et al., 2025; Kerven C, 2024). Furthermore, regarding grazing, goats offer the advantage of utilizing rugged, marginal land unsuitable for arable crops, thereby avoiding competition with land used for human food production (Van Zanten et al., 2018).

Milk is an excellent source of protein and other nutrients; goat milk, in particular, is preferred due to its favourable organoleptic and nutritional properties, making it suitable for sensitive consumers, including children and individuals with allergies or lactose intolerance (Castro N. et al., 2023). Goat milk is characterized by higher digestibility compared to milk from other animal species, owing to the smaller diameter of its fat globules (Zhao L. et al., 2022). Rich in medium-chain fatty acids, oligosaccharides, essential amino acids, and easily absorbable minerals (Verma A.K., 2025), goat milk is often considered a functional food.

Saanen goats are robust animals with a calm temperament that adapt very well to various rearing methods, particularly intensive systems. The Saanen breed is one of the most widespread breeds specialized for milk production, valued for its high productive potential, adaptability to diverse geographical regions and climates (E.B. Mawussi et al., 2024; O.T.L.F. Offoumon et al., 2023), and ability to thrive under different farming conditions. Consequently, a comparative analysis of productive performance based on the rearing system can provide valuable insights for optimizing management in dairy goat farms.

Against this background, this study aims to evaluate the productive performance of Saanen goats raised under traditional (extensive) and intensive systems, highlighting the specific characteristics and advantages of each system analysed.

MATERIAL AND METHOD

The study was conducted at two Saanen goat farms involved in milk production improvement programs and managed under two different systems: intensive and traditional. The herds at both farms originated from a core group of goats imported from the Poitiers region of France. Females in their first lactation were selected from the herds, and their milk production was monitored over the first three lactation years. Two groups were thus formed: the ST group (traditional system), consisting of 30 goats, and the SI group (intensive system), consisting of 40 goats.

The farm managed under the traditional system is located in the sub-mountainous zone of the Western Carpathians at an altitude of 700 m, an area characterized by productive pastures available for an extended period of the year. Vegetation growth is favoured by the cool, humid climate, which ensures a supply of lush, succulent grass. The local vegetation consists of a mixture of grasses (*Dactylis glomerata, Festuca pratensis, Lolium perenne*), legumes (*Medicago falcata, Trifolium repens*), and other medicinal plants (*Plantago lanceolata, Achillea millefolium, Taraxacum officinale*), as well as varied shrubby vegetation, such as bilberry, cowberry, and dwarf juniper, ensuring a diverse and substantial diet for 7–9 months of the year. During the winter, the goats are kept in loose housing and fed mountain hay, supplemented with 500 g of a barley, corn, and pea mixture. Reproduction in mountain farm

goats (traditional system) is influenced by climatic factors; it occurs earlier in years characterized by short, mild summers (temperatures of 17–20°C) and a cool, rainy autumn, compared to years with longer, hotter summers (22–28°C) and low precipitation.

The Saanen goats raised under an intensive farming system belong to a farm located in Dobrogea, a region characterized by a pronounced temperate-continental, semi-arid climate, with summer temperatures ranging from 26°C to 34°C. Under these conditions, the goats are kept exclusively in a permanent loose-housing system within shelters equipped with artificial ventilation. Feeding follows a strictly established schedule, with rations tailored to the animals' age, physiological status, and milk production levels. At this intensive-system farm, lactating goats are grouped according to lactation number (first-lactation vs. multiparous goats) and milk yield (1.5–2 kg, 2–3 kg, 3–4 kg, and over 4 kg/day). Specifically, lactating goats received 2.5 kg of alfalfa (split into two feedings) and a pelleted feed based on corn, barley, bran, and sunflower meal, containing 15.5% crude protein and fed in variable amounts (1.5–2.8 kg, depending on milk yield) split into three feedings, along with straw provided ”ad libitum”. Wheat straw was used for bedding in the pens due to its superior capacity for absorbing liquid manure. In this intensive system, manure removal was automated and performed every three weeks to maintain an optimal microclimate, specifically, keeping ammonia levels minimal and preventing overheating and excessive humidity. Goats in both farming systems (ST and SI) had access to fresh water ad libitum, provided via troughs in the traditional system and automatic drinkers in the intensive system. Salt licks and mineral blocks were also provided. (Molasses Licking Blocks, 5 kg, ROMVAC).

In both farms, reproduction was achieved through controlled mating during the breeding season (September–October). Concentrating matings within a short timeframe and stimulating fertile estrus were accomplished through herd management, specifically, by housing males separately from the does at a distance that prevented visual or olfactory contact. Each year, starting in early September, olfactory and visual stimulation was induced by keeping males in the presence of females for one to two hours daily, both morning and evening. In the traditional farm, teaser bucks wore protective aprons and were allowed to roam freely among the does, whereas in the intensive farm, bucks were led along the aisles between the female pens. In this way, the "male effect" triggered and relatively synchronized estrus in the females, resulting in a concentrated mating and, consequently, a concentrated kidding season.

Kidding was followed by a suckling period that varied from year to year depending on the kids' physical development and, above all, the farmer's priority regarding whether to retain the offspring for herd replacement or to market the milk. After weaning, the goats were milked mechanically, ensuring complete and hygienic milking twice daily, using mobile milking units equipped with ”Melasty milk meters” (SC Expert Moldova Trading SRL) for gravimetric milk measurement. Milk production monitoring, specifically, recording a goat's milk yield—was carried out on a scheduled control day by recording the quantity of milk obtained during the two daily milkings. The monitoring took place over five consecutive months, with an interval of 28–34 days between checks (official method A4) (ICAR, 2018; Sargent, 1968).

The total milk yield per goat was determined by applying the Fleischmann formula with the standard interval method:

$$MY = \frac{I_0M_1 + I_1*(M_1 + M_2) + I_2*(M_2 + M_3) + I_{n-1}*M_{n-1} + Mn + I_nM_n}{2 \qquad\qquad 2 \qquad\qquad 2}$$

where:

M_1, M_2, M_n are the weights in kilograms, given to one decimal place, of the milk yielded in the

24 hours of the recording day.
I_1, I_2, I_{n-1} are the intervals, in days, between recording dates.
I_0 is the interval, in days, between the lactation period start date and the first recording date. I_n is the interval, in days, between the last recording date and the end of the lactation period.

Correlations between the parameters monitored in the study (mean, standard deviation, minimum and maximum values) were calculated using Excel functions, and the statistical assessment of differences between parameters within each farming system was performed using the "t-Test: Paired Two-Sample for Means." Statistical differences regarding the monitored parameters, specifically gestation length, total milk yield, and average daily production, between the two farming systems were evaluated for each lactation rank using the "t-Test: Two-Sample Assuming Unequal Variances."

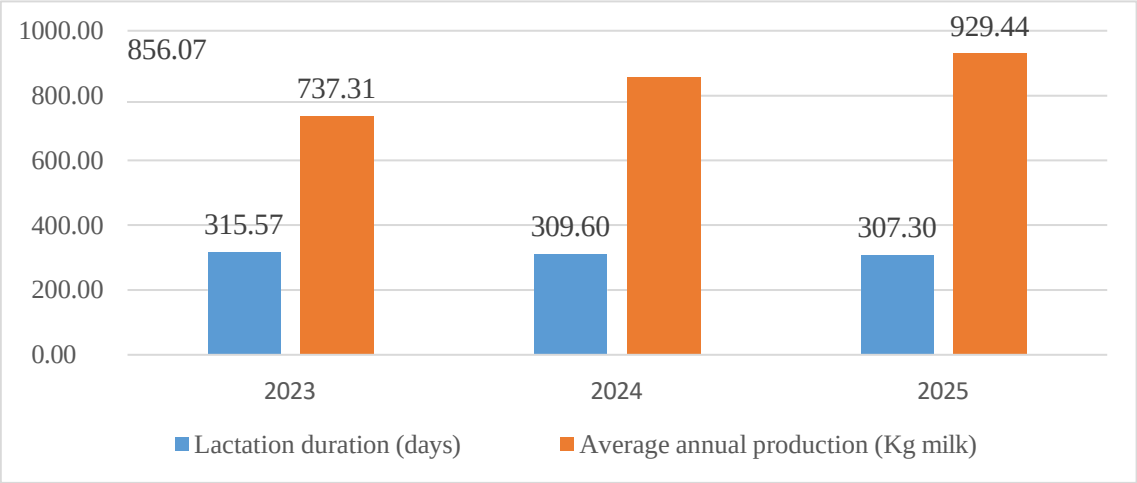
RESULTS AND DISCUSSION

The group of 30 Saanen goats, managed under a traditional system, showed a progressive increase in average milk yield: from 737.31 ± 186.11 kg in the first lactation to 856.07 ± 180.90 kg in the second, and to 929.44 ± 224.89 kg in the third (Table 1). A comparison of yields using the paired-sample t-test revealed statistically significant differences between all analysed lactations: lactation I vs. lactation II ($p = 0.00002$), lactation II vs. lactation III ($p = 0.00033$), and lactation I vs. lactation III ($p < 0.000001$). The results demonstrate a significant increase in milk yield as the animals age and reach productive maturity, with the yield in the third lactation being 26.05% higher than in the first.

Table 1

Evolution of milk production in Saanen goats raised under a traditional system during the first three years of lactation

Year	Specification	Average	STD DEV.	MIN.	MAX.
2023 L1	Lactation length (days)	315.57	15.06	279	333
	Total milk/lactation (kg)	737.31	186.11	466.23	1174.28
	Average kg/day	2.34	0.59	1.54	3.58
2024 L2	Lactation length (days)	309.60	28.16	286	448
	Total milk/lactation (kg)	856.07	180.90	613.47	1217.18
	Average kg/day	2.79	0.66	1.96	4.13
2025 L3	Lactation length (days)	307.30	19.29	266	330
	Total milk/lactation (kg)	929.44	224.89	535.35	1360.12
	Average kg/day	3.02	0.71	1.67	4.73



L1 – lactation in primiparous animals,
L2 – second year of lactation,
L3 – third year of lactation.

The average total milk yield and average daily yield obtained from Saanen goats raised in Romania's temperate zone exceed the yields obtained under grazing conditions in humid tropical regions, where reported yields for the first three lactations were 603.1 liters (primiparous goats), 626.6 liters (2nd lactation), and 648.5 liters (3rd lactation), with daily yields of 1.7 liters, 2.6 liters, and 2.7 liters, respectively (Offoumon et al., 2023).

Lactation duration (in days) showed no significant differences across the three consecutive years, although a slight decrease in the number of days was observed (Graph 1):
315.6 days for the first lactation, 309.6 days for the second, and 307.3 days for the third;

statistical comparison across the three lactation years yielded p-values > 0.05: p = 0.2842 (lactations 1 and 2), p = 0.6940 (lactations 2 and 3), and p = 0.0749 (lactations 1 and 3).

Graph 1
Correlation between lactation length and average annual milk production in Saanen goats raised under a traditional system

The long lactation period observed in this study, compared to the 266.8 days reported by Mioc et al. (2008), can be attributed to the quality of the alpine pasture and favoured by a long autumn with moderate rainfall. Lower lactation lengths have been reported for Saanen goats raised on pasture in tropical regions: 171.25 days for the first lactation, 193.18 days for the second, and 214.41 days for the third (E.B. Mawussi et al., 2024), highlighting the influence of environmental factors on milk production in traditional extensive farming systems.

Consequently, the increase in average annual production among goats in the traditional group was driven by the animals' enhanced productive capacity, linked to body growth and physiological and hormonal maturation—rather than by changes in the duration of lactation (A. Kasap et al., 2026).

Average daily milk production over the three consecutive years showed significant increases (p > 0.05), with values of 2.34 ± 0.59 kg/day for primiparous goats, 2.79 ± 0.66 kg/day for the second lactation, and 3.02 ± 0.71 kg/day for the third lactation.

In the intensive system, milk production among the 40 Saanen goats increased significantly from one lactation to the next, alongside an extension of the lactation period and an increase in average daily production (Table 2). Total milk production values were 836.36 ± 184.50 kg for primiparous goats, 1,198.63 ± 132.16 kg for the second lactation of the same goats, and 1,236.19 ± 142.13 kg for the third lactation. The paired-sample t-test revealed highly statistically significant differences: between the first and second lactations ($p < 0.000001$), between the second and third lactations ($p = 0.0062$), and between the first and third lactations ($p < 0.000001$). The results indicate a marked increase in production between the first and second lactations (+43.3%), followed by a smaller, weakly statistically significant increase ($p = 0.006$, $p < 0.05$) between the second and third lactations (+3.13%).

Milk production increased by approximately 47.8% between the first and third lactations, highlighting the superior capacity of Saanen goats to realize their productive potential under intensive farming conditions.

The results of the present study are superior in terms of total milk yield compared to a sample of 670 intensively farmed Saanen goats in Croatia, which showed a production of

697.59 kg for primiparous goats (K. Zeljić Stojiljković et al., 2025), and to a yield of 727.9 kg obtained in New Zealand (M. Scholtens et al., 2020). Higher values were reported for a herd of 3,434 intensively farmed Saanen goats in Canada, which recorded an average total milk yield of 921 kg during the first lactation (E. Massender et al., 2022), while M. Teissier et al. (2024) report an average total yield of 1,119 kg of milk.

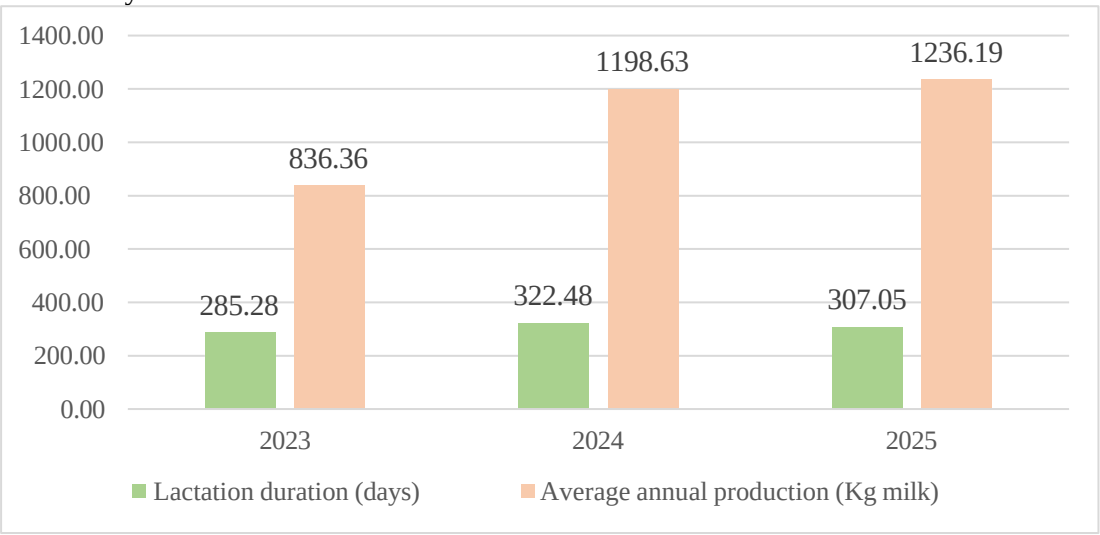


Table 2
Evolution of milk production in Saanen goats raised under an intensive system during the first three years of lactation

Year	Specification	Average	STD DEV.	MIN.	MAX.
2023 L1	Lactation length (days)	285.28	19.04	265	318
	Total milk/lactation (kg)	836.36	184.49	540.54	1195.91
	Average kg/day	2.93	0.62	1.86	4.48
2024 L2	Lactation length (days)	322.48	10.76	296	333
	Total milk/lactation (kg)	1198.63	131.71	931.62	1537.86
	Average kg/day	3.72	0.39	3.02	4.63
2025 L3	Lactation length (days)	307.05	13.37	293	337
	Total milk/lactation (kg)	1236.19	142.16	966.85	1555.00
	Average kg/day	4.03	0.47	3.22	5.15

L1 – lactation in primiparous animals,
L2 – second year of lactation,
L3 – third year of lactation.

Primiparous goats recorded the shortest average lactation duration (285.28 ± 19.04 days), while the longest duration was observed during the second lactation (322.48 ± 10.76 days); during the third lactation, the duration decreased slightly to 307.05 ± 13.37 days. Statistically significant differences ($p < 0.000001$) in average lactation duration were observed across the three years. Notably, although the average duration of the third lactation decreased compared to the second, milk yield increased by 3.13%, as illustrated in Graph 2.

Graph 2
Correlation between lactation length and average annual milk yield in Saanen goats raised under an intensive system

The controlled management conditions, specifically the microclimate and nutrition characteristic of the intensive system practiced at this farm, enabled a better expression of the productive potential inherent to the Saanen breed. This is further demonstrated by the evolution of average daily milk yield over the three-year period: it rose from 2.9 ± 0.62 kg/day for primiparous goats to 3.72 ± 0.39 kg/day in the second lactation and 4.03 ± 0.47 kg/day in the third lactation, with differences being highly statistically significant across all comparisons (L1/L2, L2/L3, L1/L3; $p < 0.000001$).

These results demonstrate, as was the case with the group managed under the traditional system, a continuous improvement in the animals' productive capacity as they reach physiological maturity.

To clearly highlight the influence of the two management systems used for Saanen goats at the two farms, the monitored parameters were compared, and performance differences were determined for each stage of lactation (Table 3).

Table 3
A summary overview of milk production indicators for Saanen goats raised under traditional and intensive systems.

Indicator	Traditional system	Intensive System	The Difference Intensive–Traditional	p
Average total production L1 (kg)	737.31	836.36	99.05 (13.43%)	0.0307
Average total production L2 (kg)	856.07	1198.63	342.56 (40.02%)	< 0,000001
Average total production L3 (kg)	929.44	1236.19	306.75 (33.01%)	< 0,000001
Lactation duration I (days)	315.57	285.28	-30.29 (9.59%)	< 0,000001
Lactation duration II (days)	309.60	322.48	12.88 (4.16%)	0.023
Lactation duration III (days)	307.30	307.05	-0.25 (0.08%)	0.9517
Average daily production L1 (kg)	2.34	2.93	0.59 (25.21%)	0.0001
Average daily production L2 (kg)	2.79	3.72	0.93 (33.33%)	< 0,000001
Average daily production L3 (kg)	3.02	4.03	1.01 (33.44%)	< 0,000001

A comparative analysis of the productive performance of Saanen goats from the two farms, managed under a traditional system (based on grazing) and an intensive system (permanent housing), categorized by lactation rank, reveals differences between the systems regarding total milk yield, average daily yield, and lactation length.

For primiparous goats, the average milk yield (per lactation) was 737.31 kg in the traditional system and 836.36 kg in the intensive system. The 99.05 kg difference, representing a 13.43% advantage for the intensive system, was statistically significant ($p = 0.0307$); this trend persisted through the subsequent two lactations, albeit with a smaller margin of difference.

Differences in total average yield (per lactation) between the management systems became more pronounced during the second lactation: the yield rose to 856.07 kg in the traditional system and to 1,198.63 kg in the intensive system, resulting in a highly statistically significant difference ($p < 0.000001$) of 342.56 kg (or 40.02%) in favour of the intensive system.

By the third lactation, average milk yield increases more significantly in goats raised under the intensive system, reaching 1,236.19 kg compared to 929.44 kg in the traditional system, with the difference of 306.75 kg (33.01%) being statistically highly significant ($p < 0.000001$).

In both farming systems, milk yield increases with successive lactations, though the magnitude of this increase is greater in the intensive system. This trend can be attributed to the physiological and, by extension, productive maturation of the goats; furthermore, the farming system, microclimate conditions, and nutrition allow for varying expressions of the Saanen breed's productive potential.

Regarding lactation duration, it is evident in both systems that a higher total milk yield is not solely the result of a greater number of milking days. Thus, the higher milk yield obtained from goats in the intensive system compared to the traditional system is not consistently associated with a longer lactation period. In the first lactation, the average duration was actually significantly shorter in the intensive system (285.28 days) than in the traditional system (315.57 days), a difference of 30.29 days ($p < 0.000001$). Consequently, the superior milk yield of primiparous goats in the intensive system, which was 13.43% higher than that of goats in the traditional system, cannot be attributed to a longer lactation duration. During the second lactation, the situation changes: the lactation period was 322.48 days in the intensive system compared to 309.60 days in the traditional system, with the difference of 12.88 days (4.16%) being statistically significant ($p = 0.023$). However, this difference is insufficient to explain the 40.02% higher total milk production in the intensive system, given that the lactation period is only 4.16% longer.

The fact that a longer milking period does not necessarily result in higher milk yield is evident during the third lactation; the average lactation duration for goats raised under the two systems was roughly equal, 307.30 days in the traditional system and 307.05 days in the intensive system, with a statistically insignificant difference ($p = 0.9517$) of only 0.25 days.

Under these conditions, the intensive system recorded a total yield 33.01% higher than that of the traditional system. The lack of a direct correlation between lactation duration and milk yield is clearly supported by the average daily yield, which was significantly higher in the intensive system across all three lactations. Primiparous goats in the intensive system recorded a daily yield of 2.93 kg/day, compared to 2.34 kg/day in the traditional system, representing a 25.21% advantage ($p = 0.0001$). During the second lactation, the values were 3.72 kg/day versus
2.79 kg/day, with the difference rising to 33.33% ($p < 0.000001$). In the third lactation, daily yield reached 4.03 kg/day in the intensive system compared to 3.02 kg/day in the traditional system, a superiority of 33.44% ($p < 0.000001$).

Average daily production is the indicator that best illustrates the advantage of raising Saanen goats under an intensive system; this is evident during the first lactation, where goats in the intensive system achieve higher total production despite a shorter lactation period, and during the third lactation, where production is 33.01% higher even though lactation duration is nearly equal between the two farming systems. In the current context, with increasing emphasis on reducing GHG emissions from livestock farming systems, the issue of pasture-based versus indoor (stabled) rearing continues to be a subject of research, yielding controversial results.

In the current context of increasing emphasis on reducing GHG emissions from livestock farming systems, the issue of pasture-based versus confinement-based systems remains a subject of ongoing research, with results proving controversial. For instance, Dida
F.M. et al. (2025) cite Flysjö et al. (2011), Belflower et al. (2012), and O'Brien et al. (2014), who reported that pasture-based and confinement systems have similar carbon footprints when grassland carbon sequestration is excluded from the analysis; conversely, Capper et al. (2009)

and Gerber et al. (2011, 2013) argue that intensive milk production systems generate lower greenhouse gas emissions per unit of milk produced, owing to superior feed efficiency and higher productivity.

CONCLUSIONS

Milk production performance, specifically total average production and average daily production, in Saanen goats is influenced by the farming system from the very first lactation; intensive systems yield higher production levels compared to traditional farming methods. Saanen goats, a breed specialized for milk production and highly adaptable to environmental conditions, effectively utilize natural resources (such as alpine pastures); however, they inevitably expend energy traversing greater distances to forage and adapt to the natural environment, which limits their productive performance. Under stabling conditions, characterized by limited movement, feeding tailored to physiological stage and production levels, and a controlled, optimal microclimate, Saanen goats raised in Romania are able to fully realize the breed's inherent productive potential.

[4]Institut Technique des Grandes Culture (ITGC Constantine)

ABSTRACT

Humic substances are known for their benefits to improve soil quality, and consequently improve plants' growth. A study was carried out at the Technical Institute of Vaste Cultures (ITGC El-Khroub) in Constantine, using Triticum Durum Wheat known as "Wahbi", of Algerian origin as a plant material. The experimental trial is a randomized complete block design with 4 replications, consisting of 5 treatments: (**T0**: Control soil with no treatment, **T1**: Urea 46% at a dose of 133kg/Ha, **T2**: Humic acid at a dose of 1 L/Ha, **T3**: Humic acid at a dose of 1.5 L/Ha and **T4**: Humic acid at a dose of 2 L/Ha).The use of humic acid has shown an efficiency on all the studied parameters: number of plants per square meter, number of grains per ear, length of ears with and without awns, plant height, thousand grain weight (tgw), number of ears per square meter and yield per hectare. The R software was used for statistical calculations. The optimum HA dose of T3 resulted in a 62.73% increase in yield over the control soil, with improvements in grain number, ear length and plant height. The use of humic acid shown better effect on the plant growth parameters compared to Urea 46%, even at low doses. Statistical analysis using ANOVA demonstrated significant differences among the treatments for most agronomic parameters ($p < 0.05$), confirming the robust impact of humic acid applications compared to the control and urea treatments across yield and growth-related traits.

INTRODUCTION

Durum wheat is the second most important crop of wheat and the tenth most important crop in the world. It has a crucial importance in ensuring food safety of populations (Mohammadi et al., 2023). Humic Acid is one of the most important organic acids, known for its benefits to plants growth (Sallume et al., 2023). It is resulting from the decomposition of the organic matter and contains a combination

(Al Fayyadh et al., 2020). The use of humic substances to enhance the yield of Durum wheat

production has made the subject of several recent studies around the world (see, for example, Pacuta, 2021; Mutlu & Tas, 2022; Sallume, 2023; Arambam, 2024).

Arambam. (2024) reported that humic acid has greater potential impacts on various agronomic parameters and soil properties, by increasing the intake of nutrients, strengthening the structure of the soil, reducing stress, and encouraging biological activity. The study carried out by Mutlu & Tas. (2022) revealed that foliar application of (1.5, 2.5, 3.5 and 4.5 L/Ha) humic acid at heading increased photosynthesis activity of plants. Sharma et al. (2023) mentioned that the addition of humic acid to the 100 percent recommended dose of fertilizers increases all the growth parameters of wheat significantly. The present work aims at studying the effect of humic acid at low doses (1, 1.5 and 2 L/Ha) on growth parameters of Triticum Durrum Wheat, known as "Wahbi", of Algerian origin, applied on an agricultural land in Constantine- Algeria.

MATERIALS AND METHODS

Site Localisation and Characteristics

The experiment was carried out during the 2023-2024 agricultural season at the Technical Institute of Vaste Cultures (ITGC) in El Khroub, Constantine, located at BP 35, El Baaraouia, El Khroub (7MCC+WWX). The station is located in the sub-humid bioclimatic zone with mild winters, characterised by a rainy season from October to May, followed by a dry season from June to September. This region also has a wide range of temperatures, with average values ranging from 0.45°C in March to 45.26°C in June, indicating a temperate climate with mild winters and warm summers, which favours resilient plant species such as cereals.

Figure 1. Site Location

Application of Humic Acid on Durum Wheat

The plant material used is a variety of durum wheat (Triticum durum) known as "Wahbi", of

Algerian origin, developed by the ITGC of Constantine in 1986. The experimental design is a randomised complete block design with 4 replications, consisting of 5 treatments. Each plot or block is 1.2m x 5m, which corresponds to a size of $6m^2$.The study focuses on a single variable, the "fertilisation element", with a series of treatments and doses applied to evaluate their effectiveness. T0: control with no treatment, T1: Urea 46% at a dose of 133kg/Ha, T2: HA at a dose of 1 L/Ha, T3: HA at a dose of 1.5 L/Ha and T4: HA at a dose of 2 L/Ha. These treatments were applied every fifteen days starting from 60 days after seeding with applications scheduled for days 60, 75, 90, 105, and 120.

The following parameters were studied to evaluate the effect of different doses of HA on DURRUM Wheat growth: number of plants per square meter, number of grains per spike, spike length, plant height, thousand grain weight (tgw), spike number per square meter and yield per hectare.

Data Analysis

Statistical analysis was performed on the original untransformed data. A two-way analysis of variance (ANOVA), including F-value and p-value for all parameters, was performed using R statistical software. The least significant difference (LSD) multiple comparison post hoc test was used to compare means when ANOVA indicated significant differences.

RESULTS AND DISCUSSION

Physicochemical Properties of Soil

Soil physicochemical properties are basic indicators of soil nutrient content and characteristics (Meena et al., 2020). Soil samples were analysed for their physicochemical properties, the results of which are presented in Table 1. As research has demonstrated that HA affects the physicochemical properties of soil (Zhao et al., 2022), analysis was conducted both before and after applying HA at different concentrations.

The soil pH values remained within the optimal range (6.5–8.5) both prior to and following humic acid (HA) application, indicating consistently slightly alkaline conditions (Dandwate,

2020). HA functioned as a buffering agent, effectively stabilizing soil pH by mitigating fluctuations in acidity, thereby enhancing nutrient availability in alkaline soils. Electrical conductivity (EC) values were stable and consistently below salinity thresholds, demonstrating that HA application did not adversely impact soil salinity (Dandwate., 2020).

Table 1. Physico-chemical Properties of Soil Samples

Parameter	T0	T1	T2	T3	T4
pH	8.34	8.28	8.42	8.32	8.45
EC (dS/m)	0.19	0.30	0.18	0.22	0.17
O.C%	1.53	1.48	1.60	1.67	1.75
O.M%	2.65	2.57	2.77	2.89	3.03

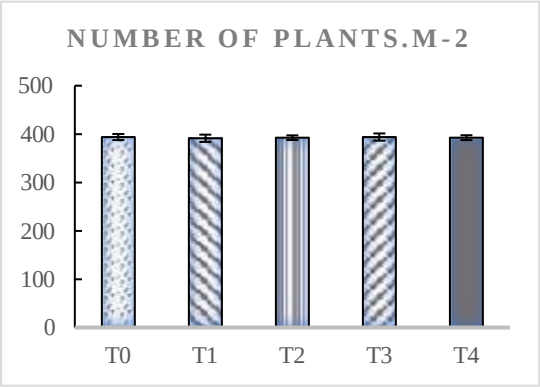
C/N	1.10	1.04	1.14	1.17	1.20

Significant increases in soil organic carbon (O.C%) and organic matter (OM) were observed with HA treatments, particularly at higher application rates (T3 and T4), elevating the soil fertility status to high and very high categories as per established classifications (Hazelton & Murphy, 2007; Addis & Abebaw, 2014). These findings suggest that HA contributes to enhanced carbon sequestration and improved soil quality, likely through the augmentation of humic substances (Pettit., 2015). Conversely, urea alone (T1) was associated with a slight reduction in organic carbon content, despite increasing nitrogen availability.

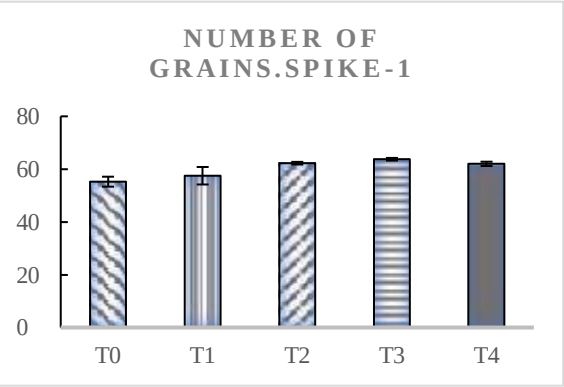
Nitrogen content exhibited a modest but consistent increase corresponding with HA application rate, reaching maximum levels at the highest HA dose, indicative of improved nitrogen retention or bioavailability. Additionally, the carbon-to-nitrogen (C/N) ratio displayed a progressive increase with HA treatment, underscoring the role of HA in promoting organic matter stabilization and long-term soil fertility by facilitating balanced nutrient cycling.

In summary, HA application exerted a beneficial influence on soil physicochemical properties by enhancing organic matter content, nutrient status, and pH buffering capacity without

detrimental effects on salinity. These improvements collectively support the establishment of healthier soil conditions conducive to sustainable crop productivity (Lato et al., 2023).



Soil texture was also studied, showing that the soil type is “Silty Clay” with 2.56% of sand, 46.15% of silt and 56.41% of clay.



Study of Growth Parameters

Parameters such as plant density, grain and spike numbers, spike length, plant height, thousand grain weight, and crop yield were compared in the diagrams below (Figure 2), and summarised in table 2. Statistical analysis was carried out on the raw data using two-way ANOVA (reporting F and p-values). Where significant differences were found, means were compared by the LSD post hoc test, following the approach of Mutlu & Tas (2022).

At the onset of treatment application, the number of wheat plants per square meter was uniform across all treatments, including the control group. Statistical analysis confirmed no significant differences in initial plant density ($p > 0.05$), as expected, since this measurement was taken before any treatments could exert their effects. This baseline uniformity validated the experimental design and ensured that subsequent variations in measured traits resulted from the treatments themselves, rather than pre-existing differences in plant establishment. The application of humic acid demonstrated a marked impact on the number of grains per spike. While the control (T0) and urea treatment (T1) produced similar results, treatments with humic acid (T2, T3, and T4) led to a substantial increase, with T2 and T3 showing the greatest enhancements. ANOVA results revealed statistically significant differences between treatments ($p < 0.05$), emphasizing the efficacy of humic acid, particularly at certain dosages, in promoting reproductive productivity in wheat.

Spike length, was positively influenced by humic acid application. The longest spikes were observed in T2 (1 L/Ha). The control and urea treatments lagged behind, indicating a clear benefit from humic acid supplementation. Statistical analyses highlighted significant inter-treatment differences ($p < 0.05$), reinforcing the role of humic acid particularly at moderate doses in stimulating spike elongation and potentially improving grain-setting capacity.

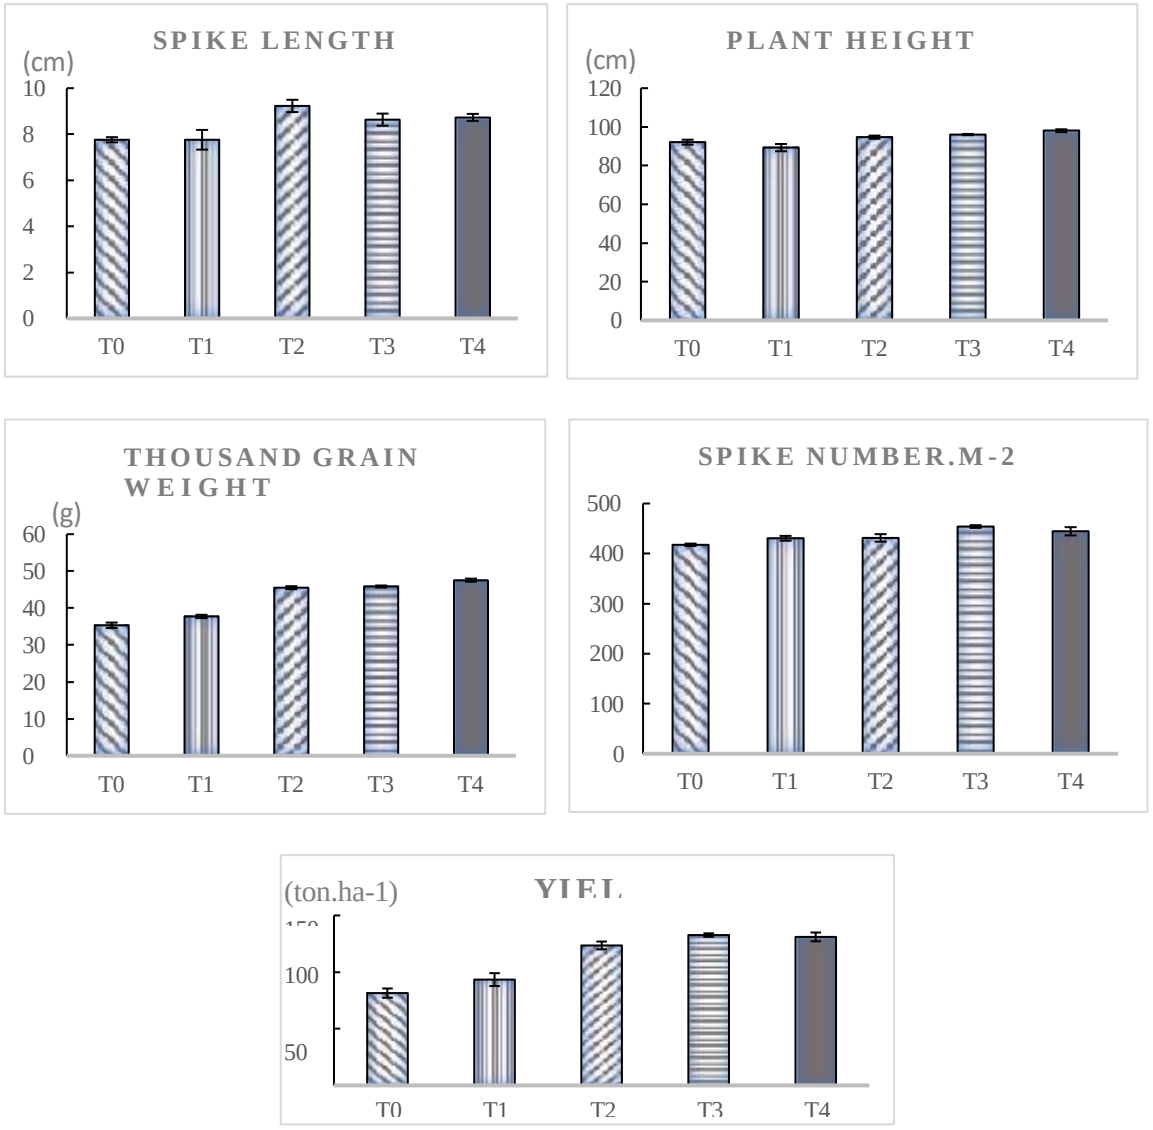


Figure 2. The Impact of Treatments on Major Yield and Growth Parameters in Wheat

Treatments incorporating humic acid resulted in increased plant height compared to both the control and urea-only applications. Whereas urea alone produced a slight reduction in stature relative to the control, the addition of humic acid (T2, T3, T4) promoted notable height gains. The most pronounced increase was recorded at the 2 L/ha application rate (T4). Statistical grouping further delineated the humic acid treatments as significantly superior in this trait ($p < 0.05$), demonstrating its role in enhancing vegetative growth.

Grain weight exhibited substantial improvement in response to humic acid treatments. The greatest thousand grain weights were recorded in T4, followed closely by T3 and T2, while T1 and T0 showed comparatively lower values. The statistical analysis ($p < 0.05$) confirmed the superiority

of humic acid treatments, suggesting that they effectively promote grain filling and improve overall grain quality.

The density of spikes per unit area, a key yield determinant, was most favourably impacted by the 1.5 L/ha humic acid treatment (T3), which yielded the highest spike number. T4 and T2 also facilitated notable increases, whereas T1 and the control (T0) showed significantly lower spike densities. The observed differences were statistically significant ($p < 0.05$), underscoring the ability of humic acid to enhance reproductive efficiency and maximize productive tillering. Yield comparisons revealed striking advantages conferred by the humic acid treatments. Treatments T3 and T4 achieved the highest yields, with T3 narrowly outperforming T4. Both were followed by T2, which also showed a marked improvement over the control and urea-only treatments. The differences in yield were highly significant ($p < 0.05$), and the application of humic acid, especially at 1.5–2 L/ha, resulted in yield increases of over 60%compared to the untreated control, highlighting its agronomic value.

Table 2. Comparative Analysis of Major Yield and Growth Parameters in Wheat Under Five Distinct Treatments: Means, Variance, and Statistical Significance

CONCLUSION

The comparative evaluation of different treatments across seven key growth parameters (number of plants per square meter, number of grains per spike, spike length, plant height, thousand grain weight (tgw), spike number per square meter and yield per hectare) in wheat demonstrates the pronounced and consistent benefits of humic acid applications. When applied at appropriate rates, humic acid significantly enhances plant growth, reproductive development, and final yield, outperforming both the control and urea-only treatments in every measured trait. These results strongly advocate for the integration of humic acid into wheat cultivation practices, as it offers a

promising strategy for unlocking higher productivity and improved crop performance under field conditions.

The humic acid treatment at 1.5 L/ha (T3) emerged as the most efficient approach for optimizing wheat growth and productivity across seven key agronomic parameters. Specifically, T3 achieved the highest number of grains per spike, averaging 63.75. Plant height was also significantly enhanced under T3, surpassing both the control and urea treatments. Furthermore, the thousand grain weight reached 45.84 grams, while the spike number per square meter peaked at 454, marking the densest spike population recorded. Most notably, T3 delivered the highest grain yield, producing 132.66 tons per hectare, which represents a substantial increase compared to all other treatments. Collectively, these findings underscore the superior efficacy of humic acid at 1.5 L/ha in promoting wheat development and yield, highlighting its potential as a valuable agronomic strategy for sustainable crop improvement.

ABSTRACT

The present study was conducted to evaluate the in vitro cytotoxic effect and wound healing potential of rose (*Rosa damascena*) oil on the human keratinocyte cell line (HaCaT).HaCaT cells were exposed to rose oil at concentrations ranging from 312.5 to 10,000 µg/mL, and cell viability was assessed using the MTT assay. Additionally, the wound healing capacity of the oil was determined through an in vitro scratch (wound closure) assay. The MTT assay results revealed that keratinocyte viability exhibited a concentration dependent response following oil treatment. Cell viability ranged from 18.32% at the highest tested concentration (10,000 µg/mL) to values exceeding 100% at concentrations of 2,500 µg/mL and lower, reaching a maximum of 120.30% at 312.5 µg/mL Notably, rose oil demonstrated a pronounced proliferative effect at lower and moderate concentrations, suggesting that it actively supports cell viability within this concentration range. In the scratch assay, the oil exhibited considerable wound healing activity, as evidenced by enhanced cell migration and closure of the denuded area. Given its capacity to promote cell regeneration and facilitate wound repair, this natural product holds promise for diverse therapeutic and industrial applications. In conclusion, rose oil may be regarded as a potential natural agent for wound healing, with possible utility in both medical and cosmetic formulations. Further investigations, including mechanistic studies and in vivo evaluations, are warranted to fully elucidate its bioactive potential and safety profile.

Keywords: Rose oil, HaCaT, cytotoxicity, wound healing, MTT

INTRODUCTION

The genus *Rosa* comprises over 200 species; however, only a limited number of these are utilized for commercial-scale essential oil production (Gudin, 2000). Among them, the Damask rose (*Rosa damascena* Mill.), a member of the Rosaceae family, stands out as a commercially significant and widely recognized aromatic plant. A variety of products derived from its flowers—including rose oil, rose concentrate, rose extract, and rose hydrosol—are extensively employed in the medical, dietary, cosmetic, and healthcare sectors (Umezu et al., 2002; Lohani et al., 2013).

The essential oil obtained from Damask rose flowers via steam distillation exhibits a remarkably rich chemical profile. Its principal constituents include monoterpene alcohols such as citronellol, geraniol, nerol, and phenylethyl alcohol, alongside various aliphatic hydrocarbons (Baydar & Baydar, 2005). The synergistic interaction among these components confers upon the oil a broad spectrum of biological activities, including anti-inflammatory, antimicrobial, antioxidant, and wound-healing properties (Boskabady et al., 2011; Mahboubi, 2015).

Re-epithelialization, a crucial phase in the wound healing process, involves the migration of keratinocytes from the wound margins to cover the injured area. Consequently, in vitro models that assess cell viability and migration using human keratinocyte cell lines, such as HaCaT, are widely employed in the development of novel therapeutic agents (Rheinwald & Green, 1975; Liang et al., 2007). In this regard, previous studies have reported that various extracts and fractions of *R. damascena* exert proliferative and anti-inflammatory effects on keratinocyte cells.

The present study was therefore designed to investigate the in vitro cytotoxic effects and wound healing potential of *R. damascena* (Isparta rose) oil on the HaCaT human keratinocyte cell line. The effects of different concentrations of rose oil on cell viability were assessed using the MTT assay, while its wound healing capacity was evaluated through an in vitro wound closure assay. It is anticipated that the findings will contribute to the understanding of this natural product's potential applications in medical and cosmetic fields and will provide a foundation for future mechanistic and in vivo investigations.

MATERIAL AND METHOD

Cell Line

The human keratinocyte cell line HaCaT used in this study was obtained from a commercial source.

Determination of Cytotoxic Activity

The cytotoxic activity of commercially available rose oil on HaCaT keratinocyte cells was assessed using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) colorimetric assay (Mossman, 1983). Cells were counted using the trypan blue exclusion method and seeded into 96-well microplates at a density of 1×10^4 cells per well in 200 µL of Dulbecco's Modified Eagle Medium (DMEM). The plates were incubated at 37°C for 24 hours in a humidified atmosphere containing 5% CO_2 to allow cell attachment. Following incubation, the culture medium was removed, and the cells were treated with rose oil at various concentrations (10,000–312.5 µg/mL) dissolved in dimethyl sulfoxide (DMSO) for 24 hours. At the end of the treatment period, the wells were emptied, washed with 100 µL of Dulbecco's Phosphate-Buffered Saline (D-PBS), and then 100 µL of fresh DMEM containing 10 µL of MTT solution (5 mg/mL in PBS, final concentration 0.5 mg/mL) was added to each well. The plates were further incubated for 3 hours at 37°C under 5% CO_2 and 98% humidity. After this incubation, the medium was removed, 100 µL of DMSO was added to each well, and the plates were shaken at room temperature for 25 minutes. Absorbance was then measured at 540 nm (Abdul Ghafoor et al., 2022; Yeniocak et al., 2025). The percentage of inhibition was calculated using the following equation:

$$\% \text{ Inhibition} = 100 - [100 \times (\text{Sample}_{abs}) / (\text{Control}_{abs})]$$

Determination of Wound Closure Effect

The wound closure effect of rose oil was evaluated using the scratch (wound closure) assay method (Justus et al., 2014). HaCaT cells (5×10^5) were seeded into 6-well plates and cultured in DMEM supplemented with 10% fetal bovine serum (FBS) and 1% antibiotic

solution under standard conditions. Once the cells reached an appropriate confluency, a linear scratch was created in each well using a 10-µL pipette tip. The wells were then washed with D-PBS to remove cellular debris. Subsequently, the cells were treated with rose oil at the IC_{30} concentration. DMSO (the solvent for rose oil) and cells cultured in DMEM alone (cell control) served as control groups. Images of the scratched areas were captured using a Leica IL microscope to monitor and estimate cell migration.

Statistical Analysis

Data are expressed as mean ± standard deviation (SD) from at least three independent experiments. Concentration-inhibition data were analyzed using R software (version 4.5.2) (R Core Team, 2024). A four-parameter logistic model (LL.4) was fitted to the data using the "drc" package (Ritz et al., 2015), and IC_{30} values were subsequently calculated. Model fitting and visualization were performed using the "ggplot2" package (Wickham, 2011).

RESULTS AND DISCUSSION

The concentration-inhibitory graph of rose oil on human keratinocyte cells is shown in Figure 1.

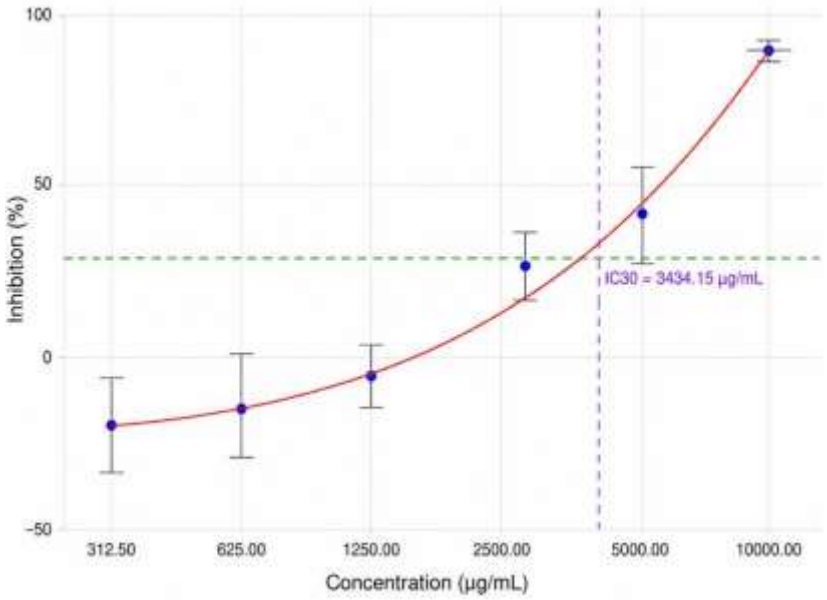

Figure 1. The inhibitory effect of rose oil on HaCaT cells. Data points represent mean inhibition percentages. Error bars would mean ±SD from three independent experiments.

The lowest inhibitory effect of rose oil on HaCaT cells was observed at 312.50 µg/mL, whereas the highest inhibition was detected at 10000 µg/mL.

The wound closure effect of rose oil at the IC_{30} concentration on HaCaT cell migration is presented in Figure 2. Images were captured at 0, 4, and 24 hours, and the wound closures were compared with those of the control group.

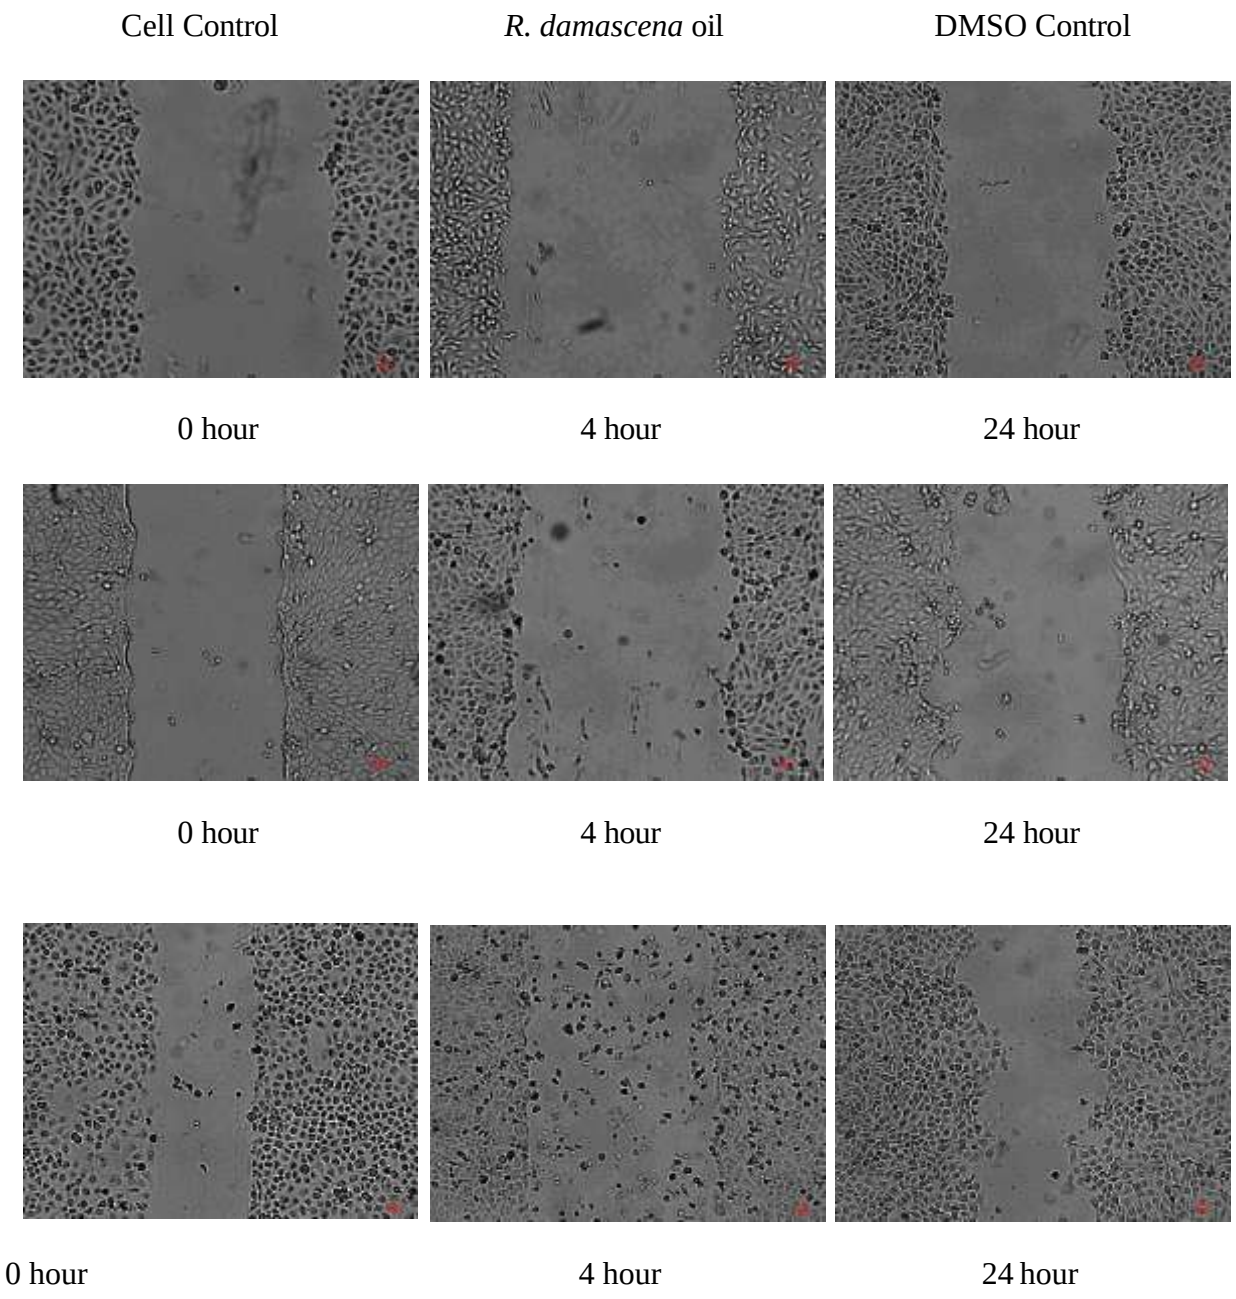

Figure 2. The images from each well of the scratched areas in HaCaT cells

To evaluate the wound closure effect, three main groups were established: a rose oil-treated cell group, a solvent control group (DMSO), and an untreated cell control group. Measurements were performed at three different time points (0, 4, and 24 hours). The 0-hour measurements served as the baseline, the DMSO control group was used to distinguish any potential effects of the solvent alone, and the cell control group allowed for the observation of time-dependent effects of the essential oil by referencing natural cell behavior. As a result, no significant change was observed in the rose oil-treated group at 4 hours compared to the control groups; however, a distinct trend was noted at 24 hours. In the cell control group, similar levels were maintained across all time points.

CONCLUSIONS

In conclusion, the present study demonstrated that *Rosa damascena* (Isparta rose) oil exhibits concentration-dependent cytotoxic activity against HaCaT keratinocytes, with the highest inhibitory effect observed at 10000 µg/mL. Moreover, at the IC_{30} concentration, the oil showed a notable wound closure effect at 24 hours, suggesting a potential wound-healing modulatory role. These findings indicate that Damask rose oil may serve as a promising natural candidate for topical applications in dermatology and cosmetic formulations. However, further in vivo studies and detailed mechanistic investigations are required to fully elucidate its therapeutic efficacy and safety profile**.**

EFFECT OF ORGANIC WASTE on SOIL MECHANICAL PROPERTIES and WORKABILITY

Coşkun GÜLSER

Ondokuz Mayıs University, Faculty of Agriculture, Soil Sciece and Plant Nutrition Department, Samsun Türkiye

Corresponding author email:cgulser@omu.edu.tr

ABSTRACT

Soil mechanical properties are useful to people interested in land planning, construction and maintenance projects, along with agricultural soil management. Atterberg limits describe the soil consistency under the different soil moisture contents. The objective of this study was to determine the effects of tobacco waste (TOW) application on Atterberg limits of a clay soil. Tobacco waste was incorporated to a clay field at four different doses (0, 2, 4, and 6 %) with three replications. After eight months, soil samples were taken from field and analyzed for liquid limit (LL), plastic limit (PL) and plasticity index (PI). The index of consistency (Ic) was calculated to evaluate optimum soil moisture contents for soil workability. Increasing the application doses of TOW increased LL and PL values and decreased PI value in the field. According to control treatment, while the highest increments for liquid and plastic limits were statistically determined with the highest application rate. Increasing TOW application doses increased soil moisture levels at 0,75, 1,00 and 1,30 of Ic values. It was determined that clay soil can be cultivated at higher soil moisture contents without structural damage compare with the control treatment. Using agricultural waste as a soil conditioner helps to soil structural development and allow soil workability at higher soil moisture contents.

Key words: Soil cultivation, Atterberg limits, consistency index, clay soil.

INTRODUCTION

Atterberg limits developed for engineering purposes evaluate soil engineering properties. They are useful to planning, construction and maintenance projects, along with soil management systems. Atterberg limits describe the soil mechanical properties under the different soil moisture contents. If water is added to dry soil, the moisture content at which the soil becomes plastic is the plastic limit (PL). If more water is added, the moisture content at which the soil changes from plastic to a fluid state is the liquid limit (LL). Plasticity index (PI) is the moisture content between plastic and liquid limit (Baumgarti, 2002). Soil moisture content is one of the most important factors for tillage operation. The optimum water content for tillage defined as the water content at which tillage produces the greatest proportion of small aggregates (Dexter and Bird 2001). The plastic limit is generally regarded as the most suitable moisture content for soil cultivation and seedbed preparation (Kirchhof, 2002).

Soil workability is related with soil moisture condition. Baumgartl (2002) indicated that index of consistency (Ic) value defines consistency condition of a soil at any given soil moisture content. Many studies showed that optimum soil moisture contents near the field capacity are highly related with index of consistency values of soils (Gülser et al., 2009; Gülser et al., 2010; Gülser, 2023). Gülser and Candemir (2006) found that optimum soil moisture contents near field capacity for workability would not have structural deformation in soil series of Ondokuz Mayis University Campus area. In this study, the effects of tobacco waste application on Atterberg limits and soil workability were investigated in a clay soil under field conditions.

MATERIAL AND METHODS

Tobacco waste (TOW) was mixed within 0 - 20 cm of a clay soil depth as four different doses (0, 2, 4, and 6 %) with three replications in a randomized block design at the Experimental Field of Agricultural Faculty in Ondokuz Mayıs University, Samsun. Some chemical and physical characteristics of the soil were determined in soil samples taken from 0 to 20 cm depth of the field as follows; particle size distribution by hydrometer method (Day, 1965), soil reaction, pH, in the 1:1 (w:v) soil water suspension by pH meter, electrical conductivity (EC_{25^oC}) in the same soil suspension by EC meter, organic matter content by Walkley-Black method (Jackson, 1962) and exchangeable cations by ammonia acetate extraction (Kacar, 1994). After eight months, soil samples were taken from each plot for chemical and mechanical analyses. Liquid limit, plastic limit and plasticity index values of the soil samples were determined according to Black (1965). The results can be summarized as follows; the textural class of soil is clay, neutral in pH, high in organic matter, none saline according to EC value (Soil Survey Staff., 1993) (Table 1).

Table 1. Some physical and chemical properties of the soil

Sand, %	18,94	NH_4OAc extractable	
Silt, %	24,82	K, cmol/kg	1,15
Clay, %	56,23	Na, cmol/kg	0,21
EC_{25^oC}, mmhos cm^{-1}	0,65	Ca, cmol/kg	34,87
PH	6,95	Mg, cmol/kg	8,13
Organic matter, %	3,85		

Statistical analysis of the results was done by standard analysis of variance, pairs of mean values compared by Duncan test and correlations among the Atterberg limits and soil properties estimated using the SPSS 17.0 package programme.

RESULTS AND DISCUSSION

Liquid limit values increased with increasing the application rates of TOW application (Figure 1). Liquid limit values varied between 62,5% for the control and 66,0% for the highest application dose of TOW. Increments in LL values for 4% and 6% doses of TOW were determined as significantly different from control treatment ($P<0,01$). Arthur et al. (2020) investigate the effect of rice straw biochar on the Atterberg limits and found that 30 t/ha treatment increased plastic limit (27%) and liquid limit (20%) significantly compared to the control ($P<0,05$). They

concluded that there is potential for increased optimum water content at tillage and increased workability after biochar application.

Plastic limit values also increased with increasing the application rates of TOW application (Figure 2). Plastic limit values varied between 35,8% for the control and 44,0% for the highest application dose of TOW. Increments in PL values for all doses of TOW were determined as significantly different from control treatment (P<0,01).

Plasticity index, which is the difference between LL and PL, was also significantly reduced by the TOW application (p<0.01). Plasticity index varied from 26,7% for the control to 21% for the lowest dose of TOW (Figure 3). All application doses of TOW significantly decreased the PI values compared to the control application.

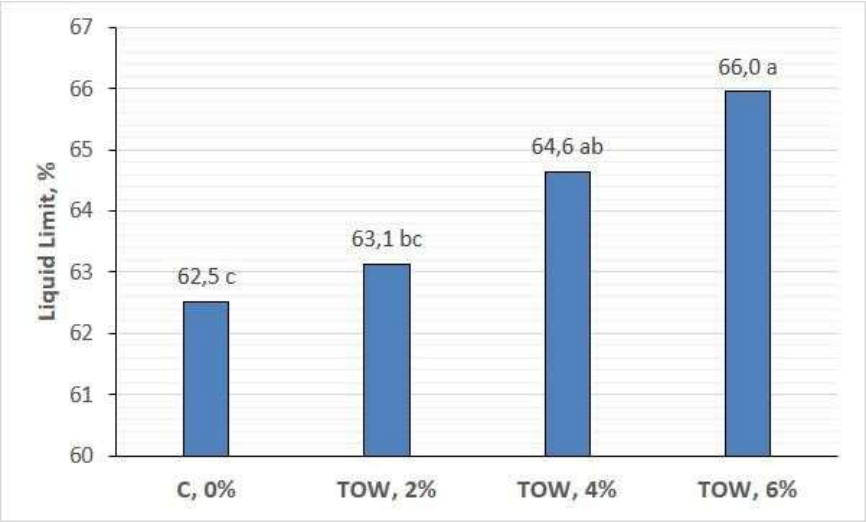

Figure 1. Changes in liquid limit values at the different tobacco waste (TOW) doses (P<0.01).

.

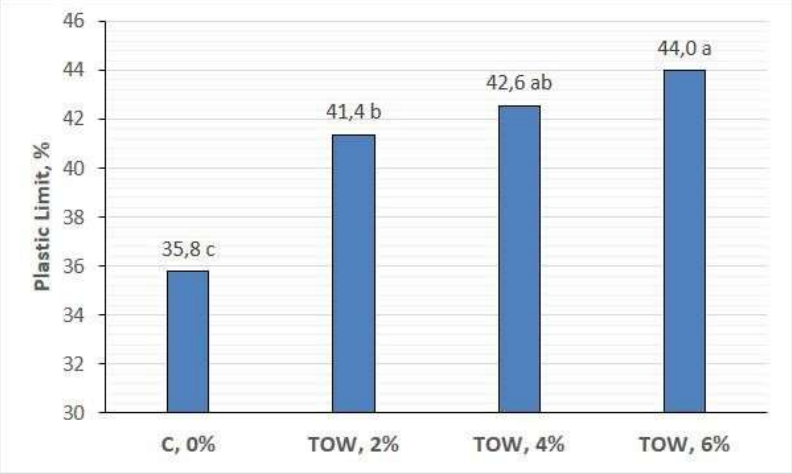

Figure 2. Changes in plastic limit values at the different tobacco waste (TOW) doses (P<0.01).

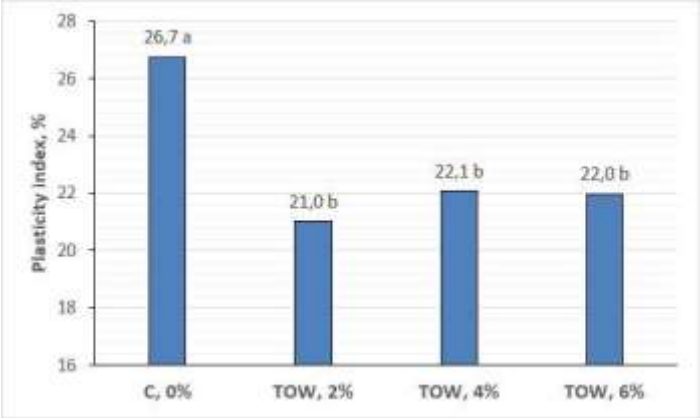

Figure 3. Changes in plasticity index values at the different tobacco waste (TOW) doses (P<0.01).

Percentage changes in the LL, PL and PI with different application dose of TOW treatments according to the control are given in Figure 4. While application doses increased from 2% to 6%, percentage increments in LL and PL over the control also increased. The highest dose of TOW showed the highest percent increase in LL (6%) and PL (23%) over the control. However, percentage changes in PI according to control reduced with all doses of TOW treatment. The lowest decrease in PI (21%) was obtained with 2% of TOW application.

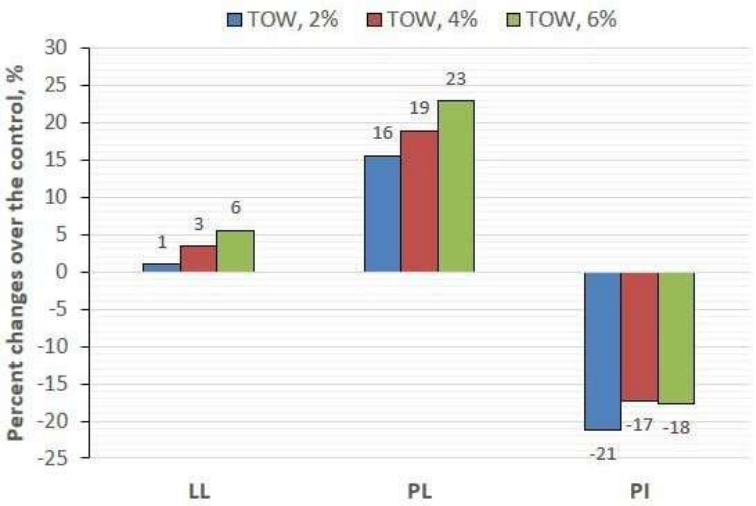

Figure 4. Percent changes in the LL, PL and PI with different doses of tobacco waste.

Descriptive statistic for the effects of TOW treatment on pH, EC, organic C and exchangeable cations is given in Table 2. While TOW application decreased soil pH slightly, all the other soil properties increased with the TOW application. Many studies reported that organic matter addition to soils improve most soil physical and chemical properties such as, soil water content, total porosity, soil organic C, EC, exchangeable cations (Gülser et al., 2008; Gülser and Candemir, 2012; Gülser and Candemir, 2015; Demir and Gülser, 2021; Mawalla and Gülser, 2025a; Mawalla and Gülser, 2025b; Demirkaya et al., 2025; Ay et al. 2026).

Table 2. Descriptive statistical results for the effects of tobacco waste (TOW) on some soil chemical properties

	Treatment	Minumum	Maximum	Mean	Std. Deviation
pH (1:1)	Control	6,95	7,10	7,01	0,076
	TOW	6,75	7,00	6,87	0,087
EC, dS/m	Control	0,46	0,88	0,69	0,213
	TOW	1,27	3,23	1,98	0,734
OC, %	Control	2,24	2,52	2,37	0,136
	TOW	2,52	5,13	3,75	0,830
K, cmol/kg	Control	0,64	1,66	1,12	0,515
	TOW	1,20	3,67	2,54	0,821
Na, cmol/kg	Control	0,20	0,21	0,21	0,006
	TOW	0,04	0,68	0,15	0,197
Mg, cmol/kg	Control	6,82	9,44	8,13	1,311
	TOW	9,97	13,11	12,03	1,035
Ca, cmol/kg	Control	34,62	35,14	34,88	0,262
	TOW	36,71	41,96	40,40	1,810

The relationships among the Atterberg limits and the soil properties are given in Table 3. The positive correlations among soil OC and Atterberg limits indicate that increasing application rates of TOW increased LL and PL. However, soil OC content had a significant negative relationship with PI. Kirchhof (2002) reported that soil organic matter has a high absorptive capacity for water and increases the Atterberg limits, but tends to have a little effect on the plasticity index. Demiralay and Güresinli (1979) found that LL, PL and PI were significantly correlated with organic matter (OM) contents of soils and these limits increased with increasing OM content. Plasticity index gave the significant negative correlations with PL. When the increase in PL was higher than the increase in LL due to TOW application, plasticity index decreased.

Soil pH had significant negative correlations with LL and PL while EC had significant positive correlations with LL and PL. Type of exchangeable cation in soil has an important effect on Atterberg limits. Kirchhof (2002) reported that divalent cations tend to increase Atterberg limits of soils due to their position in the lyotropic series. Generally, LL and PL had significant positive correlations with exchangeable Ca, Mg and K contents. Atanur (1973) found that PL of montmorillonit clay increased with the cation type in the following order: Na<H<Mg<Fe<Ca<K. In this study, PI significantly decreased with increasing divalent exchangeable cations (Ca, Mg) in the soil.

Table 3. The relationships among the limits and the soil properties

	PL	PI	OC	pH	EC	Ca	Mg	K	Na
LL	0,738**	-0,330	0,745**	-0,696*	0,833**	0,759**	0,385	0,890**	-0,482
PL		-0,881**	0,821**	-0,754**	0,800**	0,914**	0,739**	0,783**	-0,230
PI			-0,625*	0,565	-0,534	-0,745**	-0,763**	-0,470	-0,017
OC				-0,842**	0,834**	0,846**	0,489	0,866**	-0,331
pH					-0,801**	-0,820**	-0,554	-0,802**	0,483
EC						0,795**	0,630*	0,927**	-0,331

Mg								0,609*	-0,148
K									-0,502

** Correlation is significant at 1% level, * Correlation is significant at 5% level.

Mueller et al. (2003) compared the data of water retention, Atterberg limits, and Proctor compaction tests to select a methodology for estimating the maximum gravimetric soil water content for optimum tillage with preventing soil structural damage. They found that maximum soil water content for optimum tillage of cohesive soils was at a consistency index of 1.15 and 90% of the plastic limit value. The soil moisture contents at different index of consistency (Ic) values were calculated for different TOW application doses (Table 3). Optimum gravimetric soil water content for tillage operation of clay soil varied between 31,8% and 42,5% for control treatment and between 40,7% and 49,5% for 6% dose of TOW treatment. Gülser et al. (2009) studied mechanical properties and workability of soils in the field of Karadeniz Agricultural Research Institute. They reported that moisture contents for soil workability at 1,15, 1,00 and 0,75 of index of consistency (Ic) were 33,2%, 39,2% and 49,50%, respectively. They concluded that soil tillage can be operated without structural damage at the 40,4% of field moisture capacity in the experimental station field.

Table 3. The lower and upper soil gravimetric water contents for optimum soil workability

Treatments	**Ic: 0,75**	**Ic: 1,0 (PL)**	**Ic.1,15 (0,9*PL)**	**Ic: 1,30**
0% TOW	42,5	35,8	31,8	27,7
2% TOW	47,4	41,4	39,0	35,8
4% TOW	48,1	42,6	39,3	25,9
6% TOW	49,5	44,0	40,7	37,4

If the soil has the optimum water content for workability, tillage produces the greatest proportion of small aggregates. Dexter and Bird (2001) reported that the optimum water content for tillage was 90% of the water content at the PL. The range of water contents for tillage increases with increasing TOW application dose. Increases in the PL limit can be desirable for tillage in an early spring when soil has high moisture content. However if soil shows high plasticity index, tilling the soil when it is wet causes structural damage and muddy condition instead of friable condition in soil (Demiralay and Güresinli, 1979). TOW treatment decreased the plasticity index with increasing PL according to control.
As a result, TOW application into clay soils has a benefit to tilling soil at higher moisture content without structural damaging and having friable condition in soil. The results of this study indicate that manure application in to a clay soil allows for field operations at high moisture contents depends on the application doses.

Abstract

Flat-headed tree borer, *Sphenoptera servistana* Obenberger, 1929 [Coleoptera; Buprestidae] is an important wood-boring pest that threatens stone fruit tree species in many countries of the world, including Iraq. Borer eggs are oval and white. The larvae have an enlarged prothorax that gives a flat-headed appearance and are creamy in color; the pupae are creamy white in color; the adult beetles are bright metallic in color and are flattened in lateral profile. Field Surveys were conducted during 2023- 2024 to explore the spatial distribution of Flat-Headed Borer (FHB), *Sphenoptera servistana* through the entrance holes of newly hatched larvae (a small circular hole) and the exit hole of adults (a D- shaped hole) in Blood Plum (cherry-plum), apricot trees, Apple and Citrus, this is according to their distribution on the stems and branches of trees.

The results indicated that the spatial distribution of FHB *S. servistana* on apricot trees was: 23, 12, 10, 9, 6, 6, and 2 eggs per 10 cm of stem or branch in the middle third of the tree, the junction of two branches, the side facing the sun's rays, a middle-aged branch, an old branch, the side opposite the sun's rays, and the lower third of the tree, respectively, compared with 32, 21, 16, 15,9,8, 9, 8, and 4 in Blood plum trees. Also, the results indicated that the average number of FAB larval entry holes per 1 meter of the stem of a medium-aged apricot tree (moderate infestation) is 12 holes (Some larval entry holes cannot be detected due to cracks on the tree stems). The average number of FAB adult exit holes per 1 meter of the stem in a medium-aged apricot tree (moderate infestation) is 46 holes. The average number of adult tree borer exit holes per 1 meter on a mature Blood plum tree (with severe infestation) is 114 holes, compared with 23 larval entry holes. However, there are no entry or exit holes in the stems of apple and citrus trees. The parts of the tree most susceptible to infestation by FAB borers: The basal part of the infected tree's trunk, located at ground level; the point where two branches of the tree junction; the side of the tree trunk most exposed to the sun, as it is a vulnerable area; trees in open and sparse places; stems and

branches of trees that are cracked and wounded; and the insect prefers middle-aged branches to lay eggs. This field survey is extremely important for diagnosing the level of FAB infestation and identifying its entry and exit points on tree stems to determine an effective control method.

Keywords: Flat-headed borer, *Sphenoptera servistana*, spatial distribution, fruit trees, Iraq

Introduction.

Flat-headed tree borers (Coleoptera: Buprestidae) are significant pests that cause severe damage to trees. In North America, species of the genus *Chrysobothris* native to the eastern United States are considered major pests in modern orchards (Wiman *et al*., 2019; Oliver *et al.*, 2019). Research indicates that the flat-headed tree borer group includes the genus *Sphenoptera* (Ghahari *et al*., 2015). The Buprestidae comprises approximately 14,900 species worldwide. It belongs to the genus Sphenoptera. Included among the six are Subfamilies belonging to a single extended family, Buprestidae. Of these, 428 species are recorded in Iran, and 21 species are found in Iraq. Seagraves, *et al*. (2013) indicated that this pest prefers to lay its eggs on the southwestern side of the trees. Meanwhile, Brooks (1919) noted that the insect attacks the southern part of the tree. Khalaf and Al-Jubouri (2020a) demonstrated that the flat-headed tree borer *Sphenoptera servistana* (Synonyms: *S. dia-ahmedi* Cobos, *S. kambyses* benberger) prefers the following locations for laying eggs on the tree trunks: The spot on the ground where the remains of the infected tree trunk were cut, The junction where two branches of the tree meet, as it is a weak area, The side of the tree trunk most exposed to sunlight, due to the presence of cracks in the stem bark, Branches and stems with a diameter of 6–8 cm, Trees located in open areas and few trees, Stems and branches with cracks and wounds. Khalaf and Al-Jubouri (2020b) indicated that the flat-headed tree borer *S. servistana* is prevalent in orchards across central Iraq and has caused severe damage to stone fruit trees; this pest spends most of its life cycle within tunnels in the xylem (wood) of the trees' trunks. Olever *et al.* (2019) indicated that most of the damage caused by the flat-headed tree borer *S. servistana* occurs at heights of less than 30 cm; this may be attributed to the abundance of a suitable environment for larvae near the tree base, the availability of ample entry points for the larvae, and the presence of more Cracks and wounds on the tree trunks. Wood-boring insects are among the most destructive pests for trees and woody plants; they excavate tunnels that damage the water- and sap-conducting tissues, causing cracking, wilting, weakness, and even the death of susceptible trees. They also facilitate the entry of tree pathogens (Poter & Poter, 2008). Zahid *et al*. (2015) noted that the flat-headed peach borer *S. dadkhani* prefers peach trees, followed by apricot trees. Morrison (2024) studied some ecological aspects and attractive lures of the flat-headed borer. Williamson *et al*. (2026) noted that larvae of flat-headed tree-trunk borers tunnel into tree trunks, and boring and feeding damage eventually appear on the phloem surface as discoloration, sunken areas, cracks, or phloem sloughing. These borers pose a serious threat to various fruit trees, causing damage of significant economic importance. Due to the lack of detailed studies in Iraq regarding the spatial distribution of this pest, which has recently destroyed Blood plum and apricot orchard trees and has become a source of concern for farmers, leading some to

switch to other crops. Consequently, this study was conducted to identify the diagnostic spatial distribution to provide a clear understanding that facilitates its control and the mitigation of the damage it causes. The main objective of this study was to investigate the spatial distribution of flat-headed tree-trunk borers on different parts of apricot, pear, apple, and citrus trees in order to determine effective control methods for use in IPM programs.

Materials and Methods

Research Site

Research was conducted in two orchards featuring pear, apricot, apple, and citrus trees in the Al-Mada'in area (30 km south of Baghdad) at coordinates 33°9'8.082" N and 44°7'7.993" E, determined using the Global Positioning System (GPS) function on a mobile phone mapping application.

Experimental Orchards

The research was conducted in two orchards, each one hectare in area, planted with a variety of medium-aged fruit trees (7–10 years old) including apricot, Blood plum, apple, and citrus, where all standard agricultural maintenance operations were performed during 2023.

The number of trees used to calculate the spatial distribution of the flat-headed tree borer is 10 trees (5 from each orchard, with each tree treated as a replicate) of each type found in the experimental orchards, ranging in age from 7 to 10 years, were examined. The varieties included: blood plum (cherry plum), apricot, apple, and citrus. Infestation status was determined by the presence of larval entry holes, adult exit holes, and gumming spots on the trunks and branches. Trees were randomly selected from various locations within the orchard to determine which parts of the tree harbor the insect's different life stages.

Distribution of flat-headed tree borer eggs across different parts of trees

The number of eggs from flat-headed borer FHB and *S. servistana* was counted in various locations on the trees, including new branches, mid-aged branches, and old branches. Additionally, observations were made in the upper third, middle third, and lower third of the tree, considering the direction of the sun’s rays, the reverse direction, and the junction of two branches. The measurements were taken within a 10 cm section of both the stems and branches during the period

from May 15 to June 15, 2023. The number of eggs was recorded individually at each location on the tree (see Figure 1).

Figure 1. Flat-Headed Borer eggs on stem and branch of blood plum trees

Spatial distribution of Flat-Headed tree borer *Sphenoptera servistana* larval entry holes on tree parts

Larval entry points were recorded at various locations on tree trunks and branches: new branch, mid-aged branch, old branch, upper third of the tree, middle third of the tree, lower third of the tree, direction the sun's rays, reverse the sun's rays and junction of two branches were counted in 1m in stem and branch during the period from October 2023 – April 2024 visible as circular holes in the bark of tree trunk (Figure 2). The number of entry points of larvae was recorded at every location on the tree individually.

Figure 2. Entry holes made by newly hatched flat-headed tree borer *Sphenoptera servistana* larvae in the trunk and branches.

Distribution of Flat-Headed tree borer *Sphenoptera servistana* exit holes on various parts of trees

Adult exit points were recorded at various locations on tree trunks and branches: new branch, mid-aged branch, old branch, upper third of the tree, middle third of the tree, lower third of the tree, direction of the sun's rays, opposite the sun's rays, and junction of two branches. Counts were recorded within 1m of the stem and branch during the period from 11 May 2023 – 28 May 2023, visible as D-shaped adult holes in the bark of tree trunks (Figure 3). The number of adult exit holes at each location on the tree was recorded individually.

Figure 3. Exit holes (D-shaped) of adults of the flat-headed tree borer *Sphenoptera servistana*

Numbers of larvae, pupae, and adults of the flat-headed tree borer *Sphenoptera servistana* within the cross-sections of tree trunks and branches

The numbers of larvae, pupae, and adults were counted in tunnels within the cross-section of the xylem (wood) area of trunks and branches; tunnels were counted in new branches (diameter less than 5 cm), mid-aged branches (diameter 5-10 cm), and old branches (diameter more than 20 cm).

The number of tunnels for larvae, pupae, and adults was recorded at each location on the tree individually (Figure 4).

Figure 4. Larvae, pupae, and adults of the flat-headed tree borer *Sphenoptera servistana* within the cross-section of tree trunks

Experimental Design and Data Analysis

A Randomized Complete Block Design (RCBD) was used in the experimental orchards. The results were analyzed to determine means, and Duncan's Multiple Range Test was used to assess significant differences.

Results and Discussion

Spatial distribution of flat-headed tree borer *Sphenoptera servistana* eggs on tree parts

The results indicated that FHB *S. servistana* eggs were laid on the middle third of the tree, the junction of two branches, the side facing the sun's rays, a mid-aged branch, an old branch, the side opposite the sun's rays, and the lower third of the tree: 32, 21, 16, 15, 9, 8, and 4 eggs per 10 cm of branch in the Blood plum tree, respectively, compared with 23, 12, 10, 9, 6, 6, and 2 in the apricot tree (Table 1, Figure 1). However, no eggs were laid on the stems of apple and citrus trees (except for one egg). The percentages of eggs laid were 30.5%, 20.8%, 15.2%, 14.3%, 8.6%, 7.6%, and 3.8% on the middle third of the tree, the junction of two branches, the side facing the sun's rays, a mid-aged branch, an old branch, the side opposite the sun's rays, and the lower third of the tree of the Blood plum tree, respectively, compared with 33.8%, 17.6%, 14.7%, 13.2%, 8.8%,

8.8%, and 2.9% on the apricot tree. The results also showed that FHB did not lay eggs on the upper or lower parts of the tree or on new branches (Table 1).

Spatial distribution of flat-headed tree borer *Sphenoptera servistana* entry holes made by larvae on tree parts

The results indicated that the locations of entry holes for newly hatched larvae were in the lower third of the tree, in the direction of the sun's rays, on old branches, at the junction of two branches, and in the opposite direction of the sun's rays: 33, 31, 23, 18, and 8 holes per 1m of stem or branch of a blood plum tree, respectively (Table 2, Figure 2). The percentages of entry holes were 32.8%, 25.4%, 17.9%, 14.9%, and 8.9% in the lower third of the tree, in the direction of the sun's rays, on old branches, at the junction of two branches, and in the opposite direction of the sun's rays, respectively. These compare with 22, 17, 12, 10, and 6 holes per 1m of the stem of an apricot tree branch (Table 2), and as percentages: 29.2%, 27.4%, 20.4%, 15.9%, and 7.1% (Table 2). There were no entry holes for newly hatched larvae in the following parts of the tree: new branch, middle-aged branch, upper third of the tree, and middle third of the tree. The results also indicated the absence of any entry holes for larvae in apple and citrus trees (Table 2).

Spatial distribution of Flat-Headed tree borer *Sphenoptera servistana* exit holes in tree parts

The results showed that the locations of the adults' exit holes were on old branches, the lower third of the tree, the side facing the sun's rays, the junction of two branches, and the side opposite the sun's rays: 114, 45, 36, 18, and 16 exit holes per 1 m of stem or branch, respectively (Table 2, Figure 2), as percentages: 47.1%, 18.6%, 14.9%, 12.8%, and 6.6% in blood plum, compared with 46, 36, 25, 17, and 10 exit holes per 1 m of stem or branch, respectively, as percentages: 34.3%, 26.9%, 18.7%, 12.7%, and 7.5% in apricot trees. There were no exit holes for adults in the following parts of the tree: new branch, middle-aged branch, upper third of the tree, and middle third of the tree. Results also indicated the absence of any exit holes for adults in apple and citrus trees (Table 2).

Numbers of larvae, pupae, and adults of the flat-headed tree borer, *Sphenoptera servistana*, within the cross-sections of tree trunks and branches

Table 3 shows that tunnels for larvae, pupae, and adults were found in cross-sections of trunks and branches of blood plum trees, with 5 and 10 tunnels on middle-aged branches (diameter 5-10 cm) and more than 20 tunnels on branches >20 cm, compared with 3 and 7 tunnels in apricots. Results also indicated the absence of tunnels for larvae, pupae, and adults in apple and citrus trees

(Table 3). Results further showed that the FHB completes most of its life stages within tunnels in the xylem of tree stems.

These results indicate that FHB *S. servistana* lays its eggs in the middle third of the tree, on branches of intermediate age, on branches or stems facing sunlight, and at points where two branches join. These locations are where FHB most frequently lays its eggs. This may be attributed to cracks in the stem bark, which encourage the borer to lay its eggs there. This supports what Khalaf and Al-Jboory (2020 b) stated: FHB prefers to lay its eggs in these parts of the trees. As Slusher (2025) noted, FHB females lay their eggs in the trunk bark and in crevices of the trunk and large branches throughout the spring and summer. Overall, the results indicated that FHB is found in the middle part of the tree at heights of 1 to 1.5 meters above the ground, whereas entry holes of newly hatched larvae, adult exit holes, and the tunnels of larvae, pupae, and adults are located in the lower part of the tree, at heights between 0.5 and 1.5 m above the ground. This confirms the findings of Khalaf (2020a), who observed that the FHB's life stages are present at these heights on the tree. As observed in Table 2, the number of larval entry holes is lower than the number of adult exit holes. This is attributed to the duration of the period between larval entry and adult emergence (one year, from 15 May 2023 to 15 May 2024). Some entry holes disappear as the tree ages and are affected by environmental factors, given that these holes are small in diameter at the time of formation. The larval stage spanned the period from 30 June 2023 to 7 April 2024. The pupal stage lasted from 10 April 2024 to 21 May 2024, and the adult formation period extended from 15 May 2024 to 28 May 2024. All these stages take place within tunnels in the wood of the tree trunks (Figure 4).

We observed FHB infestation across tree ages from 3 to 12 years, and it was found in the following parts of the tree: the middle third of the tree, the junction of two branches, the side facing the sun’s rays, middle-aged branches, old branches, the side opposite the sun’s rays, and the lower third of the tree. These findings confirm those of Rajal and Seybold (2019), who demonstrated that the borer insect attacks trees ranging from young ones (2 years old) to those aged 15–20 years. Wiman et al. (2019) noted that FHB attacks the trunks of young trees, often girdling and killing the aboveground parts of the tree. These borers have caused significant economic damage to stone fruit trees such as plums, reaching 89% in Pakistan (according to William et al., 2025) and 100% in plum orchards in central and northern Iraq (according to Khalaf et al., 2020). Therefore, understanding the spatial distribution of the insect's various life stages is crucial for devising an appropriate control program and achieving optimal control results. The results of this study can be

used to determine appropriate control methods based on the spatial distribution of FHB, especially because most life stages are inside tunnels in the xylem of trunks. The appropriate stage for combating this insect is when adults emerge to lay eggs, during the period from 15 May to 15 June, when control work can be timed under environmental conditions in central Iraq.

Table 1. Number of flat-headed tree borer (*Spenoptera servistana*) eggs on some orchard trees in central Iraq during the summer of 2023.

Tree type	Average number of eggs per 10 Cm of the tree stem									Total
	new branch	Mid-aged branch	Old branch	Upper third of the tree	Middle third of the tree	Lower third of the tree	Direction of the sun's rays	Reverse the sun's rays	Junction of two branches	
Apricot	0	9 b	6 b	0	23 b	2 a	10 a	6 b	12 b	68
Blood plum (cherry-plum)	0	15 c	9 c	0	32 c	4 ab	16 b	8 bc	21 c	105
Apple	0	2 a	0 a	0	1 a	0 a	1 a	0 a	0 a	4
Citrus	0	1 a	0 a	0	0 a	0 a	1 a	0 a	0 a	2

Means followed by the same letters vertically did not differ significantly according to the Duncan test at the 5% probability level

Table 2. Number of entry holes made by flat-headed tree borer (*Spenoptera servistana*) larvae and exit holes made by adults on some orchard trees in central Iraq during the summer of 2023.

Tree type	Average number of holes per 1 m of the tree stem																		Total	
	new branch		Mid-aged branch		Old branch		Upper third of the tree		Middle third of the tree		Lower third of the tree		Direction of the sun's rays		Reverse the sun's rays		Junction of two branches			
	entry	exit	entry	exit	entry	exit	entry	exit	entry	exit	entry	exit	entry	exit	entry	exit	entry	exit	entry	exit
Apricot	0	0	0	0	12 b	46b	0	0	0	0	22 b	36 b	17b	25 b	6b	10 b	10b	17 b	67b	134

FROM THE BRONTLAND REPORT TO FOOD SECURITY IN THE SUSTAINABLE DEVELOPMENT GOALS

Ahmet NAYIR

ABSTRACT

The world today produces more food per capita than ever before in human history. Amidst this abundance, millions of people lack sufficient nutrition to sustain a fully productive working life. There are places where very little agriculture is done; there are places where many people cannot afford to buy food. The fifth chapter of the Brontland Report, published in 1987, addresses the potential for food security and its sustainability. The Sustainable Development Goals, developed in 2015, emphasized food security. This study examines food security through the annual reports of the Sustainable Development Goals, based on the Brontland Report. There are large areas for increases in food production in both industrialized and developing countries, parallel to climate change. These areas can be increased through global collaborative efforts.

Keywords: Food Security, Brontland report, Sustainable development goals, SDG, Our future,

INTRODUCTION

After rising sharply in the wake of the COVID-19 pandemic, global hunger and food insecurity remained persistently high and almost unchanged for three years. In 2023, about 733 million people faced hunger, and 2.33 billion people experienced moderate to severe food insecurity. Despite progress, 148 million children under age 5 suffered from stunting in 2022. If current trends persist, one in five children under age 5 will be affected by stunting in 2030. In 2022, almost 60 per cent of countries worldwide faced moderately to abnormally high food prices due to the spillover effects of conflicts, such as disrupted supply chains. Achieving zero hunger requires intensified efforts to transform food systems so they are sustainable, resilient and equitable. Moreover, accelerating improvements in diets, nutrition, health and hygiene is crucial to meeting the target of halving the number of children suffering from chronic undernutrition. Hunger, food insecurity and malnutrition remain prevalent, calling for intensified efforts Food insecurity is not just a problem today.

Climate change includes long-term changes in Earth's climate that have occurred previously. The current increase in global temperatures is caused by human activities, particularly the burning of fossil fuels since the Industrial Revolution. Fossil fuel burning, deforestation, and some agricultural and industrial practices release greenhouse gases. These gases absorb some of the heat radiated by Earth's sunlight, warming the lower atmosphere. Carbon dioxide, the primary gas responsible for global warming, has increased in concentrations by approximately 50% since the pre-industrial era, to levels not seen for millions of years. Climate change is hindering poverty reduction, and disasters result in millions of households becoming poor or remaining trapped in poverty. Ending poverty requires a wide-ranging approach that combines comprehensive social protection systems, inclusive economic

policies, investments in human capital, measures to address inequality and climate resilience, and international cooperation and partnership.

The concept of sustainable development was first officially used in 1987 in the report titled "Our Common Future" (Brundtland Report) published by the World Commission on Environment and Development (WCED) under the chairmanship of the Norwegian Prime Minister Gro Harlem Brundtland. Accordingly, sustainable development was defined as "meeting the needs of the present without compromising the ability of future generations to meet their own needs".

Our Common Future, From One Earth to One World
An Overview by the World Commission on Environment and Development

4. Institutional and Legal Change
4.1 Getting at the Sources
4.2 Dealing with the Effects
4.3 Assessing Global Risks
4.4 Making Informed Choices
4.5 Providing the Legal Means
4.6 Investing in our Future

At the same time, there is a widespread sense of frustration and inadequacy in the international community about our ability to address and effectively deal with vital global issues. The truth is compelling and should not be easily dismissed. Since answers to fundamental and serious concerns are not readily available, there is no alternative but to continue trying to find them.

Meeting humanity's goals and aspirations responsibly will require the active support of all of us. Scientists are drawing our attention to urgent but complex problems affecting our survival: a warming globe, threats to Earth's ozone layer, deserts depleting agricultural land. We respond by demanding more details and blaming institutions ill-equipped to address them. Environmental degradation, once seen primarily as a problem of wealthy nations and a side effect of industrial prosperity, has become a survival issue for developing nations. It is part of a downward spiral of interconnected ecological and economic decline that has trapped many of the poorest nations. Despite official hopes expressed on all sides, no identifiable trend, no program, or policy today offers any real hope of narrowing the widening gap between rich and poor nations. In this article, current food security is investigated with the Brantland report and sustainable development goals. Chapter 5 of the Brantland report deals with food safety. The subheadings are listed below.

Our Common Future, Chapter 5: Food Security: Sustaining The Potential

I. Achievements

5.3 Integrated Rural Development
5.4 Food Availability Fluctuations
V. Food for the Future

Our Common Future is not a prediction of increasing environmental degradation, poverty, and hardship in an increasingly polluted world amid dwindling resources. Instead, it posits a new era of economic growth based on policies that sustain and expand the environmental resource base. It is the belief that such growth is absolutely essential to alleviate the deepening poverty in many developing countries. Agricultural policies in nearly all countries focused on increasing production. Despite this, consistently increasing global agricultural production by 3% per year by the mid-1980s proved much more difficult than in the mid-1950s. Furthermore, production records were offset by the outlook. Chemical fertilizers and pesticides have played a significant role in increasing production since World War II, but clear warnings have been issued against over-reliance on them. Nitrogen and phosphate leaching from excessive fertilizer use is damaging water resources, and this damage is spreading. Forests are vital for maintaining and improving the productivity of agricultural land. Desertification results from a complex mix of climatic and anthropogenic influences. Human influences over which we have greater control include the rapid growth of both human and animal populations, harmful land-use practices, unfavorable trade conditions, and civil conflict. This visualization shows the total land used for agriculture (which is a combination of cropland and grazing land) over the long term, measured in hectares. In the following Figure (Figure 1), you can find disaggregated data on cropland land change over time.

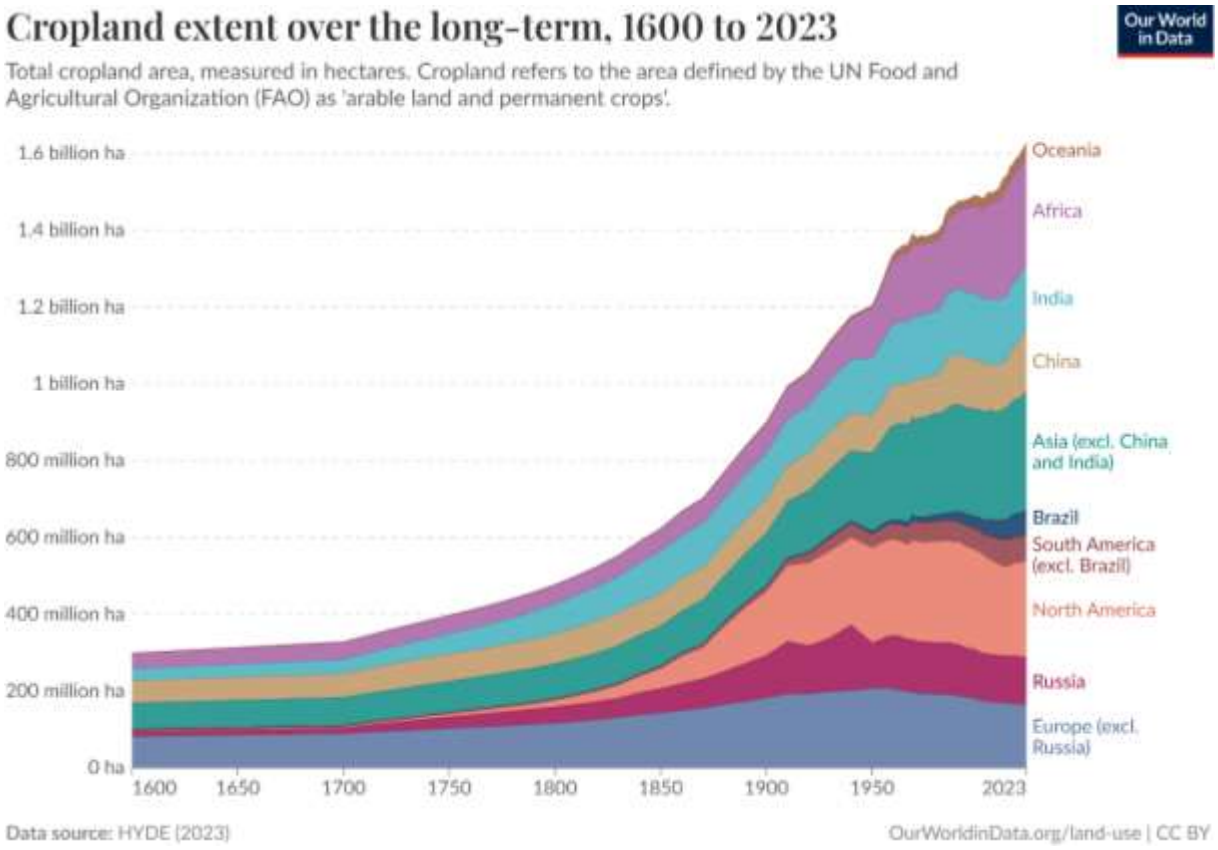

Figure 1: The total land used for agriculture over the long term

Global trends highlight the ongoing challenges for biodiversity and forests, despite their critical role as the planet's life-support systems. Despite significant progress in sustainable forest management, global forest area continues to decline, primarily due to agricultural expansion. There is also a growing global commitment to biodiversity conservation, as reflected in the adoption of the Kunming-Montreal Global Biodiversity Framework (2022). Addressing urgent environmental challenges—including climate change, biodiversity loss, pollution, desertification, and deforestation—and their underlying drivers and linkages, requires intensified and accelerated efforts at the local, national, and global levels and a comprehensive and integrated approach.

The UN Sustainable Development Goals

Sustainable development can be understood as primarily a process and as implying practical goals or desirable outcomes, such as the UN Sustainable Development Goals (SDG) being developed in 2015 (Figure 2). The 2030 Agenda for Sustainable Development, adopted by all United Nations Member States in 2015, provides a shared blueprint for peace and prosperity for people and the planet, now and into the future. At its heart are the 17 Sustainable Development Goals (SDGs), which are an urgent call for action by all countries - developed and developing - in a global partnership. They recognize that ending poverty and other deprivations must go hand-in-hand with strategies that improve health and education, reduce inequality, and spur economic growth – all while tackling climate change and working to preserve our oceans and forests. EU Missions aim to lead the way by bringing concrete solutions to achieve the SDG targets. They have ambitious targets and will deliver tangible results by 2030. The five EU Missions are:

Adapting to Climate Change: Supporting at least 150 European regions and communities to become climate resilient by 2030

Cancer: Working with Europe's Beat Cancer Plan to improve the lives of over 3 million people by 2030 through prevention, treatment, and solutions for longer and better lives
Restoring our Oceans and Waters by 2030
100 Climate-Neutral and Smart Cities by 2030
A Land Deal for Europe: 100 living laboratories and lighthouses to lead the transition to healthy lands by 2030
They are putting research and innovation in a new role, combining them with new forms of governance and cooperation, and engaging citizens.

Figure 2: The UN Sustainable Development Goals (SDG)

The Sustainable Development Goals targets on food and land systems are particularly off track. The Sustainable Development Reports (SDR) 2024 offer new FABLE pathways to support sustainable food and land systems.

By 2030, 600 million people worldwide will still be hungry, obesity is rising globally, and greenhouse gas emissions from Agriculture, Forestry, and Other Land Use (AFOLU) represent almost a quarter of annual global greenhouse gas emissions. The new FABLE pathways brought together more than 80 local researchers from 22 countries to assess how 16 targets on food security, climate change mitigation, biodiversity conservation, and water quality can be achieved by 2030 and 2050. Continuing current trends widens the gap with the targets on climate change mitigation, biodiversity, and water quality. Meeting the commitments already made by countries would improve the situation, but these remain largely insufficient. Significant progress can be made, but this will require several key changes:
1) Avoid overconsumption beyond recommended levels and limit animal protein consumption through dietary changes consistent with cultural preferences;
2) Invest in improving productivity, particularly for crops and areas with strong demand growth; and
3) Implement inclusive, robust, and transparent monitoring systems to halt deforestation. Our sustainable pathway prevents deforestation of up to 100 million hectares by 2030 and 100 Gt of CO_2 emissions by 2050. Additional measures will be needed to avoid trade-offs related to on-farm employment and water pollution from over-fertilizer application, and, in particular, to end hunger.

Government Intervention

Government intervention in agriculture is the rule in both industrial and developing countries, and it is here to stay. Public investment in agricultural research and extension services, assisted farm credit and marketing services, and a range of other support systems have

all played parts in the successes of the last half-century. In fact, the real problem in many developing countries is the weakness of these systems. Protecting and expanding agriculture's resource base will increase production and productivity. However, specific measures are needed to make inputs more efficient. This can best be achieved by strengthening the technological and human resource base for agriculture in developing countries.

Technological Base

Bringing together traditional and modern technologies offers opportunities to improve nutrition sustainably and increase rural employment. Biotechnology, including tissue culture techniques, technologies for preparing value-added products from biomass, microelectronics, computer science, satellite imagery, and communications technologies, are all leading technologies that can improve agricultural productivity and resource management. The technological transformation of traditional agriculture will be difficult without a concerted effort to develop human resources. Efforts to promote literacy should focus on functional literacy, encompassing the efficient use of land, water, and forests. Despite women's critical role in agriculture, their access to education and representation in research, extension, and other support services are crucial. The use of renewable energy is becoming increasingly important due to the dwindling availability of fossil fuel resources, rising costs, and environmental concerns. Recently, interest in solar energy as a renewable energy source has been growing. Electricity generation and cost analysis using solar panels in agricultural fences is supported by scientific studies.

CONCLUSIONS

Agricultural production can only be sustainable in the long term if the soil, water, and forests on which it depends are not degraded. Redirecting public intervention, as proposed, will provide a framework for this. Improvements in water management are essential to increase agricultural productivity and reduce land degradation and water pollution. Critical issues relate to the design of irrigation projects and water use efficiency. Many countries, especially developing countries, can and should increase yields through increased use of chemical fertilizers and pesticides. However, countries can also increase yields by helping farmers use organic nutrients more efficiently. Therefore, governments should encourage increased use of organic plant nutrients to complement chemical fertilizers. Protecting and expanding agriculture's resource base will increase production and productivity. However, specific measures are needed to make inputs more efficient. This can best be achieved by strengthening the technological and human resource base for agriculture in developing countries. Applying the concept of sustainable development to efforts to achieve food security requires systematic attention to the regeneration of natural resources.

This requires a holistic approach focused on ecosystems at the national, regional, and global levels, coordinated land and water use, and careful planning of forest exploitation. Recently established agricultural systems have contributed significantly to reducing hunger and raising living standards. These systems require agricultural systems that focus on people as much as technology, resources as much as production, and the long term as much as the short term. Only these systems can meet the challenges of the future.

STRUCTURAL MODELING OF COMBINE HARVESTER CUTTERBAR SERRATED KNIFE SECTIONS USING A STEPWISE FUNCTIONALLY GRADED MATERIAL APPROACH

Serhan KARAMAN GENÇ

Trakya University, Faculty of Engineering, Department of Mechanical Engineering, Edirne, Türkiye
Corresponding author e-mail: serhankaraman@trakya.edu.tr

ABSTRACT

Serrated knife sections used in combine harvester cutterbars are critical components responsible for efficient crop cutting during harvesting operations. Owing to continuous reciprocating motion and repeated cutting loads, these components are exposed to severe mechanical stresses, localized stress concentrations, edge wear, and progressive cutting edge dulling, which eventually reduce harvesting efficiency and service life. Conventional knife sections are generally manufactured from homogeneous steel, making it difficult to simultaneously achieve the high hardness required at the cutting edge and the toughness needed around the mounting holes to resist impact and fracture.

In this study, a stepwise functionally graded material (FGM) approach **was proposed** as an alternative structural design concept for combine harvester serrated knife sections. The proposed model **was designed** to provide enhanced hardness in the cutting region while maintaining improved toughness in the mounting region through a gradual variation of material properties represented by a stepwise configuration. A three-dimensional model of the existing knife geometry was established, and homogeneous and stepwise functionally graded material models were developed. Their structural behaviors were comparatively evaluated under identical loading conditions using the finite element method.

The numerical results showed that both FGM configurations reduced the maximum deformation compared with the homogeneous 75Cr1 reference model. The Layered Graded model provided the most balanced global structural response, reducing maximum deformation by approximately 5.4% and total strain energy by approximately 5.5%, while limiting the increase in maximum von Mises stress to approximately 1.2%. These findings demonstrate that not only the WC content but also its geometric distribution plays an important role in the structural response of the knife section.

Keywords: Combine harvester, Serrated knife section, Functionally graded material (FGM), Finite element analysis (FEA), Structural modeling.

INTRODUCTION

The efficiency of the cutting process in combine harvesters used for cereal harvesting is an important factor in reducing crop losses, increasing harvesting capacity, and ensuring the reliability of the cutting system. Serrated knife sections in the cutterbar system are key components that cut plant stems through reciprocating motion and are subjected to repeated mechanical loading during operation (Song et al., 2016; Wang et al., 2022). In addition to plant material, the interaction of the cutting edges with dust, soil, and other abrasive particles encountered during harvesting may lead to progressive wear and dulling of the cutting surfaces

(Jankauskas et al., 2024). Studies on combine harvester cutting components have shown that the mechanical properties of the blade material, as well as cutting-edge hardness and geometry, have a significant influence on wear behavior. In particular, cutting-edge hardness and geometry have been reported as important parameters governing wear behavior (Jankauskas et al., 2024).

Achieving high wear resistance together with sufficient toughness and structural strength represents an important material-selection challenge in the design of cutting components. Although increasing cutting-edge hardness is advantageous in terms of wear resistance, imparting high hardness to the entire component may increase the risk of brittle behavior under impact and bending loads (Jankauskas et al., 2024; Xu et al., 2021). Comparative studies on combine harvester knife sections have shown that abrasive wear alters the cutting-edge geometry and consequently deteriorates cutting performance, while blades with different hardness levels and geometric characteristics exhibit different wear behavior (Jankauskas et al., 2024). Surface-hardening and coating approaches aimed at combining a hard, wear-resistant working region with a tougher load-bearing structure have also been investigated for agricultural cutting components (Xu et al., 2021; Xu et al., 2022). These approaches highlight the need for different mechanical characteristics in different regions of a single knife section.

Functionally graded materials (FGMs) enable spatially varying material properties within a component through controlled changes in composition or microstructure (Saleh et al., 2020). In contrast to the sharp material interfaces that may occur in conventional composites, a controlled variation in properties can enable different mechanical and functional requirements to be addressed within the same structure (Saleh et al., 2020; Martínez-Pañeda, 2019). This approach offers particular potential for applications requiring the integration of a surface with high hardness and wear resistance and a more ductile and tougher load-bearing region within a single component. FGM structures can be designed with continuously varying properties or modeled in a stepwise manner using successive regions with different compositions (Saleh et al., 2020). Various approaches based on spatially varying material properties have been developed for implementing functional gradation in finite element models. In particular, Martínez-Pañeda focused on the finite element implementation of functionally graded materials (Martínez-Pañeda, 2019).

The use of tungsten carbide (WC) in steel- and iron-based matrices has been widely investigated in metal-matrix composites intended for applications requiring high hardness and wear resistance. WC reinforcement has been shown to significantly influence the hardness, strength, and tribological properties of iron-based composites, and composites containing different WC fractions have been successfully produced (Chen et al., 2020; Zhao et al., 2023). In particular, substantial increases in hardness have been reported in steel-based systems containing relatively high WC fractions, although the resulting hardness–toughness balance must also be considered. Chen et al. experimentally investigated WC-reinforced iron-based composites, whereas Zhao et al. examined the hardness–toughness balance in steel-matrix systems containing WC (Chen et al., 2020; Zhao et al., 2023).

The application of WC reinforcement to agricultural cutting components is also of particular interest. A highly wear-resistant silage knife exhibiting self-sharpening behavior was developed using a Ni–WC-based laser-cladded layer, and subsequent research demonstrated the potential of WC-containing hard phases for preserving the cutting edges of agricultural cutting components (Xu et al., 2021; Xu et al., 2022). These findings indicate that WC-based hard phases are applicable not only to general industrial wear-resistant systems but also directly to cutting components used in agricultural machinery. The study by Xu et al. specifically aimed to develop a long-service-life agricultural knife with enhanced wear resistance (Xu et al., 2021).

More recent studies have also demonstrated the feasibility of producing WC–steel systems directly in a functionally graded configuration (Moreira et al., 2025). A functionally

graded WC-reinforced stainless-steel composite was produced, exhibiting a marked improvement in abrasive wear resistance in WC-rich regions. Similarly, manufacturing approaches based on controlled variation of WC content have demonstrated the feasibility of creating graded hard-phase distributions in iron- and steel-based matrices (Chen et al., 2020; Moreira et al., 2025; Li et al., 2026).

In this study, a steel–WC-based stepwise functionally graded material approach is proposed for the structural design of serrated knife sections used in combine harvester cutterbars. By gradually reducing the WC fraction from the cutting edge toward the mounting region, the design aims to promote high hardness and wear resistance in the cutting region while retaining the comparatively tougher characteristics of the steel matrix in the mounting region. Based on the geometry of an existing knife section, homogeneous steel and stepwise FGM models are developed, and their structural responses under identical loading conditions are compared using the finite element method. The study thereby aims to provide a fundamental numerical assessment of the applicability of a stepwise material gradation approach to the structural design of combine harvester cutting components.

MATERIALS AND METHODS

Material Selection

Combine harvester cutting blades are subjected not only to repeated cutting loads during operation but also to contact with plant material, soil, and hard foreign objects. Therefore, in addition to providing sufficient mechanical strength, the blade material should exhibit high hardness and wear resistance at the cutting surfaces. In this study, 75Cr1 (1.2003) steel was selected as the base material of the knife section and as the homogeneous reference material. 75Cr1, specified according to DIN EN 10132, is a low-alloy, high-carbon tool steel. According to Thyssenkrupp, its nominal chemical composition ranges are 0.70–0.80 wt.% C, 0.25–0.40 wt.% Si, 0.65–0.80 wt.% Mn, and 0.30–0.40 wt.% Cr, with the material designation 1.2003 **(Thyssenkrupp Steel Europe AG, 2024)**. Based on the density of 7.85 kg/dm³ reported by Walzwerke Einsal, a density of 7850 kg/m³ was assigned to 75Cr1 in the numerical model **(Walzwerke Einsal GmbH, n.d.)**.

In addition to the mechanical characteristics provided by 75Cr1 as the metallic matrix, tungsten carbide (WC) was selected as the hard reinforcement phase to enhance the potential hardness and wear resistance, particularly in the serrated cutting regions. WC, as a hard ceramic phase, has been reported to improve the wear resistance of metal-matrix systems, while increasing WC content can significantly affect their mechanical and tribological properties **(Xu et al., 2021; Chen et al., 2020; Zhao et al., 2023; Moreira et al., 2025)**. However, it should be considered that increasing the hard-phase fraction may involve a trade-off with other mechanical properties, particularly the hardness–toughness balance. WC is a carbide phase with a hexagonal crystal structure and is characterized by high elastic stiffness. Although the elastic behavior of single-crystal WC is anisotropic, high elastic modulus values have been reported for polycrystalline WC. In the present study, **E = 722 GPa** and **ν = 0.197** were adopted as the input elastic properties of WC **(Golovchan and Litoshenko, 2010)**. Similar micromechanical studies have employed values of approximately **E = 707.7 GPa** and **ν = 0.197** for WC, further supporting its high elastic stiffness on the order of 700 GPa **(Tkalich et al., 2017)**.

For the micromechanical homogenization calculations performed in this study, E = 210 GPa, ν = 0.30, and ρ = 7850 kg/m³ were used for the 75Cr1 matrix, while E = 722 GPa, ν = 0.197, and ρ = 15,800 kg/m³ were adopted for the WC phase. The density of 75Cr1 was based on manufacturer data (Walzwerke Einsal GmbH, n.d.), whereas its Young's modulus and Poisson's ratio were adopted as engineering values for the isotropic elastic modeling of the steel matrix. The elastic properties of WC were based on literature data (Golovchan and Litoshenko,

2010; Tkalich et al., 2017). The fundamental material properties of 75Cr1 steel and the WC phase used in the numerical modeling are summarized in Table 1.

Table 1. Fundamental material properties of 75Cr1 steel and the WC phase used in the numerical modeling.

Property	**75Cr1 (1.2003)**	**WC**
Density, ρ (kg/m³)	7850	15 800
Young's modulus, E (GPa)	210	722
Poisson's ratio, ν	0.30	0.197
C (wt.%)	0.70–0.80	—
Cr (wt.%)	0.30–0.40	—
Mn (wt.%)	0.65–0.80	—
Si (wt.%)	0.25–0.40	—

Stepwise FGM Definition and Micromechanical Homogenization

For the stepwise functionally graded material model, 75Cr1 steel was used as the matrix and WC as the reinforcement phase. Previous studies have demonstrated that steel–WC composites can be produced with different WC contents and that increasing the WC fraction can enhance particularly the hardness and wear resistance of these materials (Xu et al., 2021; Chen et al., 2020; Zhao et al., 2023; Moreira et al., 2025). Accordingly, in addition to the homogeneous 75Cr1 reference material (0 vol.% WC), two equivalent composite material levels containing 10 and 20 vol.% WC were defined. The upper limit of 20 vol.% WC was selected considering literature data demonstrating the experimental feasibility of producing steel-matrix composites with WC contents up to this level (Zhao et al., 2023).

In the FGM model, 0 vol.% WC (homogeneous 75Cr1 steel) was assigned to the mounting region, 10 vol.% WC to the transition region, and 20 vol.% WC to the cutting region. Thus, a stepwise FGM structure was represented in which the WC content gradually decreased from the cutting edge toward the mounting region.

The equivalent elastic properties of the 75Cr1–WC composite regions were determined using the Mori–Tanaka micromechanical homogenization method, based on the material properties of the 75Cr1 matrix and WC reinforcement phase. The effective Young's modulus and Poisson's ratio were calculated using the Mori–Tanaka approach, while the density was determined using the linear rule of mixtures based on the volume fractions of the constituent phases. In this way, the influence of increasing WC content on the effective Young's modulus and Poisson's ratio was accounted for micromechanically, whereas the density values were determined from the corresponding phase volume fractions. In this approach, the WC phase was assumed to be a homogeneously dispersed, isotropic reinforcement phase within the steel matrix.

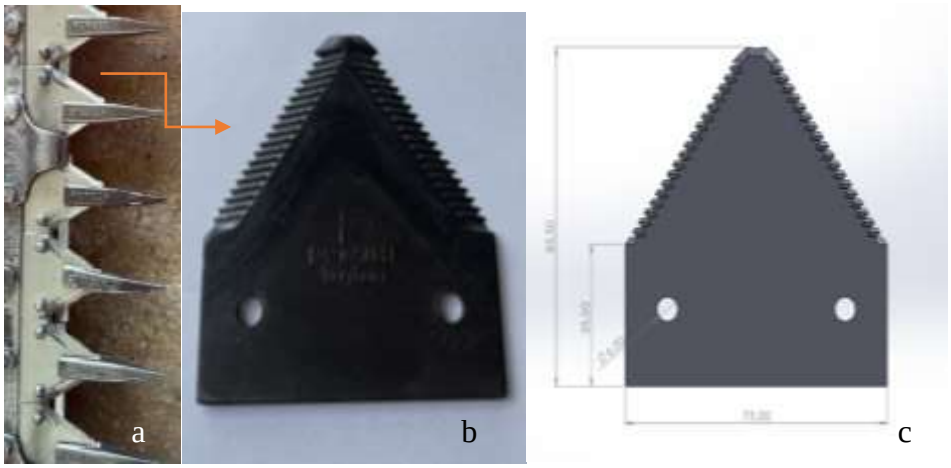
The equivalent material properties obtained for 0, 10, and 20 vol.% WC were defined as separate material cards in ANSYS Engineering Data and subsequently used in the finite element analyses. The resulting effective material properties are presented in Table 2.

Table 2. Effective material properties of 75Cr1–WC compositions used in the finite element analyses.

Material Description	WC Volume Fraction (%)	Density, ρ (kg/m³)	Young's Modulus, E (GPa)	Poisson's Ratio, ν
75Cr1	0	7850	210.000	0.30000
75Cr1–10WC	10	8645	234.934	0.29174
75Cr1–20WC	20	9440	262.851	0.28343

Blade Segment Geometry and Numerical Model

In this study, the structural behavior of a commercial serrated knife section used in a combine harvester cutterbar was investigated using the finite element method. The principal geometric dimensions of the knife section were determined from the actual component, and its three-dimensional solid model was created in **SolidWorks**. The model includes the serrated cutting edges, the main body region, and the mounting holes used to attach the knife section to the cutterbar mechanism. The model dimensions were defined as **75 mm in base width, 83.5 mm in overall height, and 2.5 mm in thickness.**



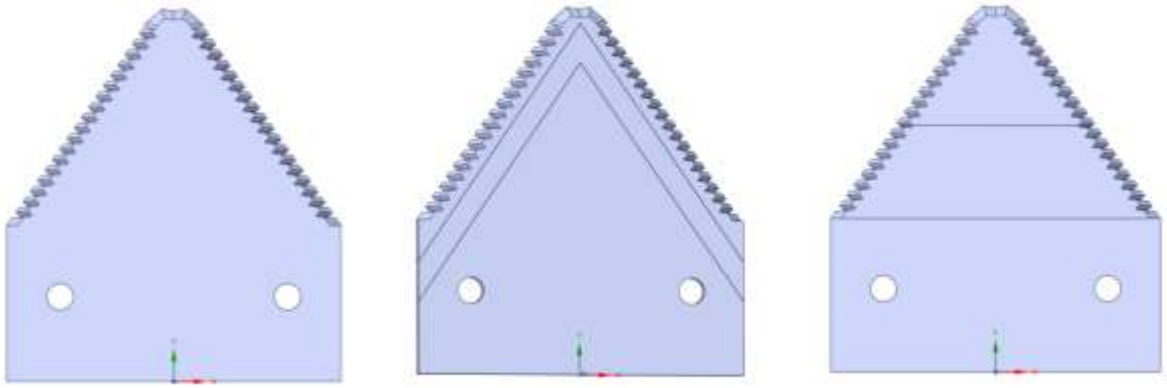


Figure 1. Investigated combine harvester knife section: (a) actual knife sections mounted on the cutterbar, (b) individual knife section, and (c) CAD model with its principal dimensions.

The developed three-dimensional model was imported into ANSYS Workbench in STEP format, and the finite element analyses were performed using ANSYS Mechanical. The geometric dimensions and external boundary conditions were kept identical for all models to enable a direct comparison of the effects of material distribution and gradation geometry on the structural response. Accordingly, one homogeneous reference model (Homogeneous 75Cr1) and two different stepwise functionally graded material models (Edge-Following Graded Model and Layered Graded Model) were developed.

a b c

Figure 2**.** Investigated material configurations: (a) Homogeneous 75Cr1, (b) Edge-Following Graded Model, and (c) Layered Graded Model.

Homogeneous 75Cr1 – Reference Model**:** In the first model, the entire knife section was defined as homogeneous 75Cr1 steel. This configuration was used as the reference model for evaluating the structural effects of the FGM configurations.

Edge-Following Graded Model**:** In this FGM configuration, the material distribution was designed to follow the actual cutting geometry of the knife section. While the main body was maintained as 75Cr1 steel, the WC content was increased to 10 vol.% toward the cutting region and further increased to 20 vol.% in the outermost serrated cutting region. The main concept underlying this configuration was to localize the WC-rich material near the cutting surface, where frictional contact and wear are expected to occur, rather than distributing it throughout the entire component. The literature on cutting tools indicates that wear behavior depends on several parameters, including tool geometry, contact conditions, material properties, and friction, while the FGM concept enables different functional requirements to be addressed in different regions of a component. Therefore, the Edge-Following model does not represent a direct wear simulation. Instead, it represents a function-oriented FGM design in which the WC-rich region, with its potential for increased hardness and wear resistance, is strategically positioned along the cutting edge.

Layered Graded Model: In the second FGM configuration, the same 0, 10, and 20 vol.% WC levels were maintained; however, the material regions were arranged in a layered/regional distribution rather than directly following the cutting-edge geometry. This configuration was designed to investigate the effect of gradation geometry on the structural response while maintaining the same material constituents and WC volume fractions.

By evaluating the Edge-Following and Layered models together, the study aimed to investigate the influence of not only WC content but also the geometric distribution of the WC-rich regions on deformation, stress distribution, and strain-energy storage.

Finite Element Analysis Conditions

The finite element mesh for all models was generated by considering the geometric partitioning and material regions. A finer mesh was employed in critical geometric regions to adequately capture the stress gradients around the serrated cutting surfaces, material transition regions, and mounting holes. Depending on the geometric partitioning, the investigated models contained between **44,534 and 58,000 nodes** and between **19,486 and 29,231 elements**. A global element size of **1.5 mm** was adopted, with local mesh refinement applied where necessary (**Figure 3**).

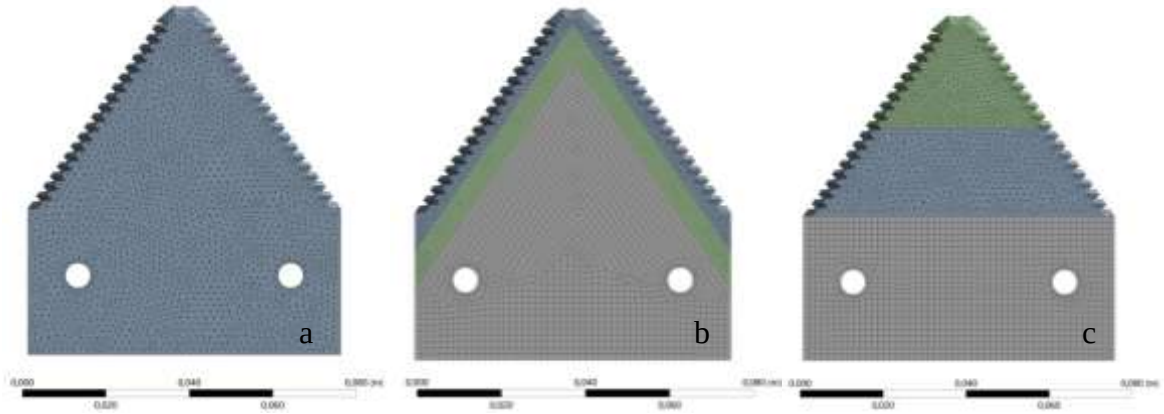

Figure 3. Finite element meshes and local mesh refinements of the investigated models: (a) Homogeneous 75Cr1, (b) Edge-Following Graded Model, and (c) Layered Graded Model.

In the FGM models, adjacent material regions were modeled to form a mechanically continuous structure, thereby ensuring load transfer between the regions. To represent the mechanical attachment of the knife section to the combine harvester cutterbar, a Fixed Support boundary condition was applied to the two mounting holes (Figure 4).

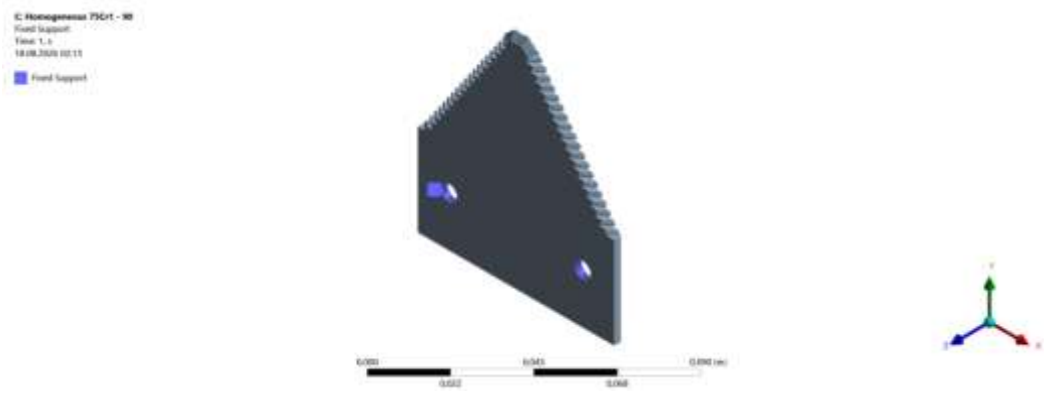

Figure 4**.** ANSYS view of the finite element model showing the two mounting holes subjected to the Fixed Support boundary condition.

Fully constraining the mounting holes represents an idealized approximation of the actual attachment conditions. Since this idealization may induce localized stress concentrations around the holes, the spatial distribution of stress throughout the model was also considered when evaluating the maximum stress values.

Under actual operating conditions, combine harvester knife sections may experience localized contact with stones and other hard foreign objects in addition to cutting plant material. Rather than modeling the actual time-dependent impact behavior associated with such contacts, an equivalent static local pressure approach was adopted in the present study to compare the relative effects of different loading intensities on the investigated material configurations.

The pressure was applied to five adjacent serrated surfaces in the cutting region (Figure 5). The area of each selected surface was approximately 4.28 mm², resulting in a total effective loading area of approximately 21.4 mm².

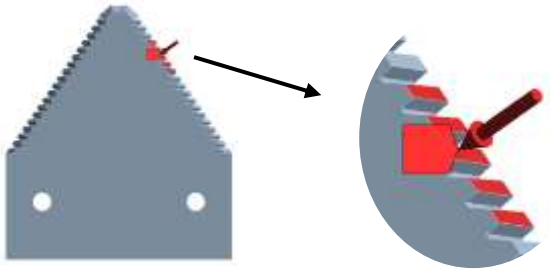

Figure 5. Application of the equivalent static local pressure to five adjacent serrated surfaces in the cutting region of the blade segment.

To compare the behavior of the material configurations under different loading intensities, three equivalent static local pressure levels of 30, 60, and 90 MPa were applied. The corresponding approximate equivalent forces were calculated using the pressure–area relationship and are presented in Table 3.

Table 3. Equivalent static local pressure levels and corresponding forces applied to the cutting region.

Pressure (MPa)	Effective Area (mm^2)	Approximate Equivalent Force (kN)
30 MPa	21.4 mm^2	0.642 kN
60 MPa	21.4 mm^2	1.284 kN
90 MPa	21.4 mm^2	1.926 kN

These pressure levels were used as equivalent static loading levels to compare the effects of increasing load intensity on different material configurations over the same local contact area. The same solution procedure was applied to all three material configurations at pressure levels of 30, 60, and 90 MPa, resulting in a total of nine analysis cases. For each analysis, the structural response parameters Total Deformation, Equivalent (von Mises) Stress, Maximum Principal Stress, and Strain Energy were obtained. The Homogeneous 75Cr1 model was taken as the reference for all comparisons. The relative changes in the structural response parameters of the FGM models were expressed as percentage changes with respect to the corresponding values of the homogeneous reference model. Negative values indicate a reduction relative to the reference model, whereas positive values indicate an increase.

RESULTS AND DISCUSSION

The structural behavior of the serrated knife section used in a combine harvester cutterbar was compared among a reference model consisting of homogeneous 75Cr1 steel and two functionally graded material (FGM) designs. To evaluate the influence of WC reinforcement distribution within the blade geometry on the structural response, two different material configurations, namely the Layered Graded Model and the Edge-Following Graded Model, were investigated. All models were subjected to surface pressures of 30, 60, and 90 MPa under identical boundary conditions, and the maximum total deformation, maximum equivalent (von Mises) stress, maximum principal stress, and total strain energy were compared. The values obtained from the analyses are presented in Table 4.

Table 4. Structural response of homogeneous and functionally graded blade segment models under different equivalent local pressure levels.

Model	Pressure (MPa)	Max. Deformation (mm)	Max. von Mises Stress (MPa)	Max. Principal Stress (MPa)	**Total Strain Energy (J)**
Homogeneous 75Cr1	30	1.3900	757.95	1088.6	0.20095
Homogeneous 75Cr1	60	2.7801	1515.9	2177.2	0.80381
Homogeneous 75Cr1	90	4.1701	2273.8	3265.8	1.8086
Edge-following graded	30	1.3347	861.06	1275.4	0.19259
Edge-following graded	60	2.6695	1722.1	2550.9	0.77037
Edge-following graded	90	4.0042	2583.2	3826.3	1.7333
Layered graded	30	1.3152	767.25	1146.5	0.19000
Layered graded	60	2.6304	1534.5	2293.0	0.75999
Layered graded	90	3.9456	2301.8	3439.5	1.7100

For all three models, the deformation and stress values increased approximately linearly as the applied pressure increased from 30 to 90 MPa. For example, in the homogeneous model, the maximum deformation increased from 1.3900 mm at 30 MPa to 2.7801 mm at 60 MPa and 4.1701 mm at 90 MPa. Similarly, the maximum von Mises stress values were 757.95, 1515.9, and 2273.8 MPa, respectively. The same trend was observed for both FGM designs.

In contrast, the total strain energy did not increase linearly with the applied load but exhibited an approximately quadratic dependence on pressure. For example, in the Layered Graded Model, the total strain energy increased from 0.190 J at 30 MPa to approximately four times this value (0.760 J) at 60 MPa and approximately nine times this value (1.710 J) at 90 MPa. This behavior is consistent with the expected energy response of the models under the adopted linear elastic material assumption.

The percentage changes obtained for the FGM models relative to the homogeneous 75Cr1 reference model are summarized in **Table 5**. Under the investigated linear elastic loading conditions, deformation and stress magnitudes scaled linearly with the applied pressure. Consequently, the percentage changes exhibited by the FGM models relative to the homogeneous reference model remained nearly constant at **30, 60, and 90 MPa**. Therefore, rather than repeating the percentage changes separately for each load level in **Table 5**, a single representative value is presented for each FGM configuration. Overall, both gradation approaches reduced the **maximum deformation** and **total strain energy**, whereas their effects on the maximum stress values varied depending on the **geometry of the material distribution**.

Table 5. Percentage changes in the structural response of FGM models relative to homogeneous 75Cr1.

Model	Max. Deformation Change (%)	Max. von Mises Stress Change (%)	Max. Principal Stress Change (%)	**Total Strain Energy** Change **(%)**
Edge-following graded	−3.98	+13.60	+17.16	−4.16
Layered graded	−5.38	+1.23	+5.32	−5.45

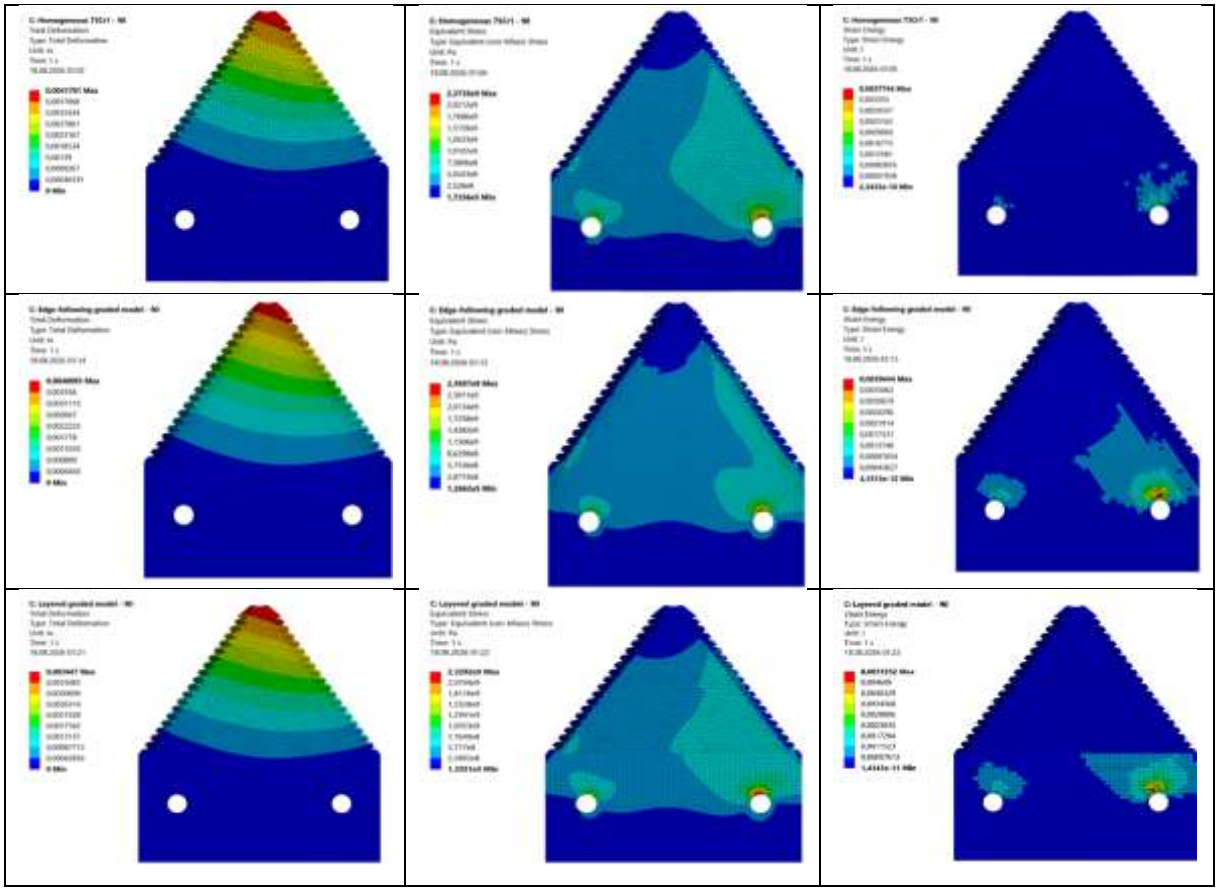

Figure 6. Total deformation, equivalent (von Mises) stress, and strain energy distributions of the blade segment models under an equivalent local pressure of 90 MPa: homogeneous 75Cr1 (top row), Edge-following graded (middle row), and Layered graded (bottom row).

The corresponding deformation, equivalent stress, and strain energy distributions for the investigated material configurations at 90 MPa are presented in Figure 6. One of the most pronounced effects of the FGM implementation was observed in the total deformation response. Compared with the homogeneous 75Cr1 model, both graded models exhibited lower maximum deformation at all loading levels.

At a pressure of 30 MPa, the maximum deformation was 1.3900 mm for the homogeneous model, compared with 1.3347 mm for the Edge-Following Graded Model and 1.3152 mm for the Layered Graded Model. The same relationship was maintained at the 60 and

90 MPa loading levels. Relative to the reference model, the Edge-Following design reduced the maximum deformation by approximately 4.0%, whereas the Layered design achieved a reduction of approximately 5.45%. These results indicate that the regions with increased elastic modulus resulting from higher WC content contributed to an increase in the global stiffness of the knife section. However, not only the WC content but also the geometric arrangement of the reinforced regions influenced the global stiffness. The Layered model exhibited the lowest deformation at all loading levels, indicating that, under the investigated loading and boundary conditions, the layered gradation was more effective in limiting the overall bending deformation of the knife section. In terms of maximum von Mises stress, the FGM models exhibited a different trend from that observed for deformation. The Layered model produced maximum equivalent stress values very close to those of the homogeneous model. At 30 MPa, the maximum equivalent stress was 757.95 MPa for the homogeneous model and 767.25 MPa for the Layered model, corresponding to a difference of only approximately 1.23%. The same relative difference was maintained at the 60 and 90 MPa loading levels. In contrast, the maximum equivalent stresses in the Edge-Following model were approximately 13.6% higher than those in the homogeneous model. For example, at the 90 MPa loading level, the maximum equivalent stress increased from 2273.8 MPa in the homogeneous model to 2583.2 MPa in the Edge-Following model.

This finding demonstrates that the use of an FGM does not necessarily result in a reduction in the maximum local stress. Spatial variations in material stiffness alter the load-transfer paths and local stress distribution within the component. In particular, in the Edge-Following design, the high-stiffness WC-rich regions following the outer cutting geometry of the knife section resulted in higher localized stress levels in certain regions. Therefore, the performance of the Edge-Following design should not be evaluated solely on the basis of the maximum von Mises stress. The primary objective of this configuration is to position the WC-rich material close to the serrated cutting edges, where its functional properties are required, while maintaining regions with lower WC content in the mounting and main body regions. Accordingly, rather than representing a strategy aimed solely at minimizing global stress, the Edge-Following design represents an approach in which the material distribution is geometrically tailored to the mechanical and tribological requirements of the cutting edge.

The maximum principal stress results exhibited a trend similar to that observed for the von Mises stress. Compared with the homogeneous 75Cr1 model, the maximum principal stress was approximately **5.3% higher** in the Layered model and approximately **17.2% higher** in the Edge-Following model. At the **90 MPa** loading level, the maximum principal stress was calculated as **3265.8 MPa** for the homogeneous model, **3439.5 MPa** for the Layered model, and **3826.3 MPa** for the Edge-Following model. These values represent numerical stress magnitudes calculated within the framework of the linear elastic model and should not be interpreted as physical strength values under conditions in which the actual yielding or damage limits of the material may be exceeded.

Examination of the stress contours revealed that the high-stress regions were concentrated particularly around the mounting holes and in regions involving geometric and material transitions. It should be noted that the **Fixed Support** idealization applied to the mounting holes may increase localized stress concentrations in these regions. Therefore, the maximum stress values were evaluated not solely on the basis of individual peak values but also in conjunction with the stress distribution in the cutting region and the overall structural response.

The total strain energy results further support the global stiffness behavior of the FGM designs. Compared with the homogeneous model, the total strain energy decreased by approximately **4.2%** in the Edge-Following model and by approximately **5.45%** in the Layered model. At a pressure of **90 MPa**, the homogeneous model stored **1.8086 J** of strain energy, whereas the corresponding values were **1.7333 J** for the Edge-Following model and **1.7100 J**

for the Layered model. The fact that the Layered model exhibited both the lowest maximum deformation and the lowest total strain energy supports its characterization as the configuration with the highest global elastic stiffness among the three models.

The reduction in strain energy should not be interpreted directly as indicating greater **impact-energy absorption**. Under the same loading conditions, lower elastic energy storage primarily reflects a stiffer structural response within the framework of the present linear elastic model. A meaningful comparison of actual impact-energy absorption or damage tolerance would require additional modeling of **plastic deformation, fracture or damage mechanisms, and dynamic material behavior.**

Considering the results as a whole, the **Layered Graded Model** exhibited the most balanced global structural response under the investigated linear elastic loading conditions. Compared with the homogeneous 75Cr1 model, this configuration reduced the maximum deformation and total strain energy while limiting the increase in maximum von Mises stress to a relatively small level. Although the **Edge-Following Graded Model** exhibited more pronounced increases in the maximum stress values, it provided a functionally tailored material distribution by allowing the WC-rich region to directly follow the serrated cutting-edge geometry, thereby addressing the mechanical and tribological requirements of the cutting region. Overall, the results demonstrate that the mechanical response of the FGM design depends not only on the WC content but also significantly on the **geometric distribution of the reinforcement phase within the knife section.**

CONCLUSIONS

In this study, the structural behavior of serrated knife sections used in combine harvester cutterbars was numerically investigated using a functionally graded WC reinforcement approach within a 75Cr1 steel matrix. In addition to the homogeneous 75Cr1 reference model, Layered Graded and Edge-Following Graded designs representing different geometric distributions of WC-rich regions were developed and compared using the finite element method under equivalent local pressure levels of 30, 60, and 90 MPa.

The following main conclusions were drawn:

- For all three models, the maximum deformation, equivalent von Mises stress, and maximum principal stress increased approximately linearly with the applied pressure, whereas the total strain energy varied approximately with the square of the pressure. This behavior is consistent with the load–response relationship expected from a linear elastic solution.
- Both FGM configurations reduced the maximum deformation compared with the homogeneous 75Cr1 model. The Edge-Following Graded Model showed an approximately 4.0% reduction, whereas the Layered Graded Model showed an approximately 5.45% reduction in maximum deformation.
- Among the investigated designs, the Layered Graded Model provided the most balanced global structural performance. Compared with the homogeneous model, it reduced the maximum deformation by approximately 5.45% and the total strain energy by approximately 5.45%, while limiting the increase in maximum von Mises stress to approximately 1.2%.
- Although the Edge-Following Graded Model reduced the maximum deformation and total strain energy by approximately 4.0% and 4.2%, respectively, its maximum von Mises and maximum principal stresses increased by approximately 13.6% and 17.2%, respectively, compared with the homogeneous model. This result indicates that the

geometric arrangement of high-stiffness WC-rich regions can significantly influence local stress concentrations.

- Nevertheless, the Edge-Following approach enables the WC-rich material to be positioned along the serrated cutting edge. Therefore, this design is important not only in terms of the global structural response but also in terms of the functional placement of WC-rich regions at the cutting edges where high hardness and wear resistance are required.
- The relative differences among the models remained nearly unchanged at 30, 60, and 90 MPa, indicating that, within the investigated linear elastic range, the relative mechanical effect of the FGM design was governed primarily by the material distribution and gradation geometry rather than by the applied load level.

Overall, the results indicate that WC-reinforced functional gradation in combine harvester knife sections offers potential as a design strategy for balancing the high stiffness, hardness, and wear-resistance requirements of the cutting region with the mechanical requirements of the body and mounting regions through spatially tailored material design. However, increasing the WC fraction alone was found to be insufficient; the geometric distribution of the reinforcement phase was identified as a critical design parameter affecting structural performance. Among the investigated configurations, the Layered Graded design was more advantageous in terms of global elastic behavior, whereas the Edge-Following configuration provided an alternative FGM design strategy for the functional placement of WC-rich regions along the cutting edge.

The present study was conducted within the framework of linear elastic static structural analysis. Therefore, the high localized stresses obtained should not be interpreted as direct indicators of the actual damage or fracture behavior of the material. Future studies should incorporate the elastoplastic behavior of the 75Cr1–WC system, realistic impact loading, fracture/damage criteria, wear behavior, and experimental validation. Optimization of the WC distribution and transition geometry would also be important for evaluating the performance of the proposed FGM knife designs under actual operating conditions.

ABSTRACT

Anemone blanda Schoot & Kotschy is a perennial geophyte of the Ranunculaceae family, it is northeastern Steno Mediterranean species of Balkan Peninsula. It is native and registered in the Albanian National Herbarium and in Flora of Albania v.1, as grown in a single locality, Bzhet/ Malesi e Madhe, in Northern Albania. According to IUCN categories this species is classified as endangered EN (A1B) and listed in National Red List. During field surveys in March 2026 on two protected areas of Dajti and Qafshtama Mountain, two new records of the species were discovered at the distance of 161 km and 144 km from the previously known site, respectively. The current findings comes from *Fagus sylvatica* and mixed *Fagus sylvatica* , *Pinus nigra* and *Erica carnea* communities, on calcerous well drained substrat, where typical ecological conditions of mountain belt of Dajti and Qafe-Shtama were favorable for this species growth. In this contribution, new data concerning the distribution of native species *A. blanda* in Albania are presented. These findings extend the known range of *A. blanda* in the country and suggest that the species may be more widespread than previously documented, contributing to more comprehensive mapping of rare and endangered species within Albania

Keywords: *Anemone blanda,* Albania, distribution range, national park

INTRODUCTION

Anemone blanda Schott &Kotschy is a perennial herbaceous geophyte with a tuberous underground rootstock of Ranunculaceae family. The flowing stems are erect, simple and relatively slender, generally reaching 5-30 cm in height. Basal leaves are usually one or two, long petiolate and deeply divided into three main segments, which are further lobed, the leaves are glabrous, particularly on the lower surface. The involucral leaves are stalked and deeply divided, resembling the basal foliage. Flowers are solitary, terminal and conspicuous borne above the foliage. The perianth consist of numerous petaloid segments, usually blue to violet-blue, although paler or white forms may occur. The perianth segments are glabrous and narrowly oblong to elliptic. Numerous stamens surround the central group of carpels. Following flowering numerous small achenes develop, forming a characteristic fruiting head. The species is a spring-flowering geophyte occurring in open rocky habitats, grasslands and pastures, scrum land, forest cleaning and forest margines. Its native through Southeastern Europe and Western Asia. (Paparisto et al., 1988). The specie is currently accepted as Anemone blanda Schott & Kotschy. and is considered native to Albania, with a natural distribution from Southeastern Europe through the Caucasus and Western Syria (POWO 2026)

According to Albanian National Herbarium *Anemone blanda* is reported only in a small area in the district of Malesia e Madhe in the North of Albania. The vegetation of its location, Bzhete area in the Shkrel region of Northern Albania, is characteristic of a sub-Mediterranean to Mediterranean influenced calcareous landscape, with a mosaic of woodland, open rocky habitat and shrubland. The area is developed mainly in limestone substrates, shallow soils and roadside habitats at approximately 550m above sea level (Colacino 2023). The woody vegetation includes elements of thermophilous oak woodland and Mediterranean-type shrub vegetation. In the region *Quercus trojana* and *Juniperus oxycedrus* have been recorded at approximately 450m above sea level, indicating the presence relatively dry open woodland and shrub communities adapted to calcareous substrate (Colacino 2023). These communities form a heterogeneous vegetation with open grassy and rocky microsite which provide suitable condition for *Anemone blanda*. According to Vangjeli et al., 2000 the ecological characteristic of this area consists with the broader vegetation where Mediterranean shrubs thermophilous oaks and open rocky land form an important component of the vegetation landscape. The occurrence of *Anemone blanda* in such open calcareous environments is also consistent with species flowering in rocky slopes, scrubs and forest margins (Rak 2015). In the figure 1 is presented the distribution of this species in Europe.

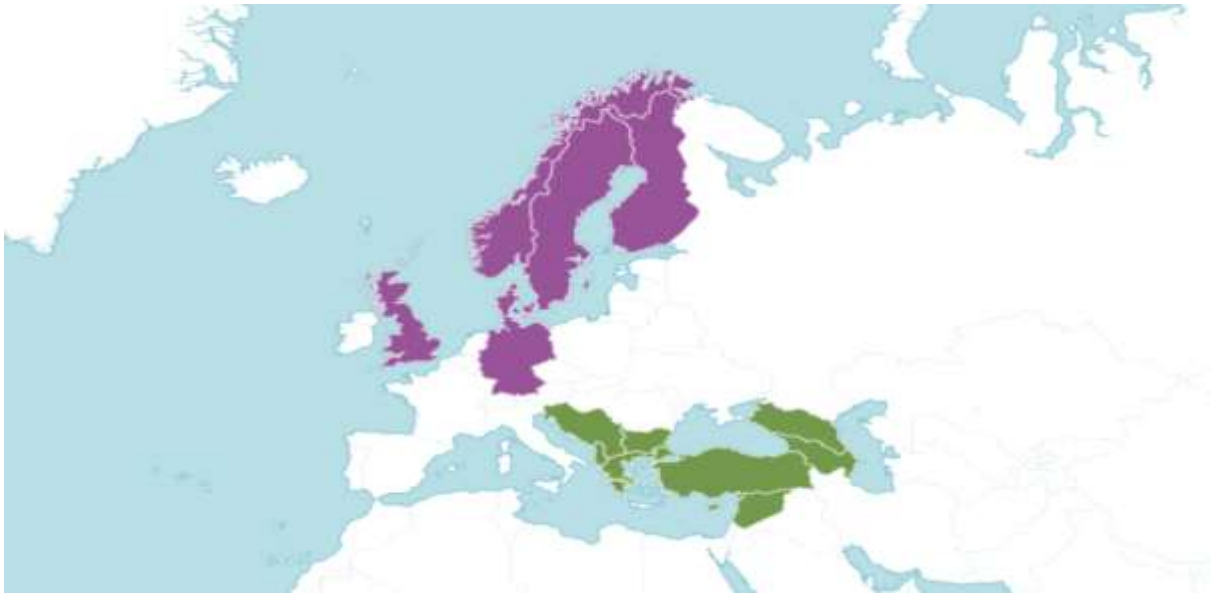

Figure 1. POWO 2026. The distribution of Anemone blanda Scott & Kotschy in Europe

MATERIAL AND METHOD

The surveys were conducted on two National Natural Parks included in the list of protected areas mountain of Dajti dhe Qafshtame in the central Albania, to investigate the flora composition under protected criteria. The trips were carried out during spring 2026. The plants were collected in flowering stage and a voucher of each representative population was deposited in National Herbarium under the Research Center of Flora and Fauna, Albania.

The plants were taxonomically identified using Albanian flora and taxonomic keys guidelines. During the sample collection data for the sites where the new records of *Anemone blanda* were recorded, including geographical coordinates and elevation using GPS system, the associated vegetation, habitat characteristics such as substrate, slope, exposure and associated species were recorded for each locality.

RESULTS AND DISCUSSION

Anemone blanda new records were found into two new not previously reported localities in Dajti and Qafshtama Mt.. The localities are given in the figure 2

Locality 1- Mt Dajti

Number of Populations: 3

Size of the populations: approximately 25 individuals per m^2

Population 1 Geographical coordinates:N 41^0 21'41'' E 19^0 54'47'', elevation 1080 m a.s.l

Population 2 Geographical coordinates: N 41^0 21'42'' E 19^0 54'19'', elevation 1100 m a.s.l

Population 3 Geographical coordinates: N 41^0 21' 53'' E 19^0 54'26'', elevation 1050 m a.s.l

Locality 2- Mt Qafshtama

Number of Populations: 2

Size of the populations: approximately 10-15 individuals per m^2

Population 1 Geographical coordinates: N 41^0 31' 11'' E 19^0 53' 52'', elevation 1220 m a.s.l

Population 2 Geographical coordinates: N 41^0 31' 06;; E 19^0 53' 46'', elevation 1190 m a.s.l

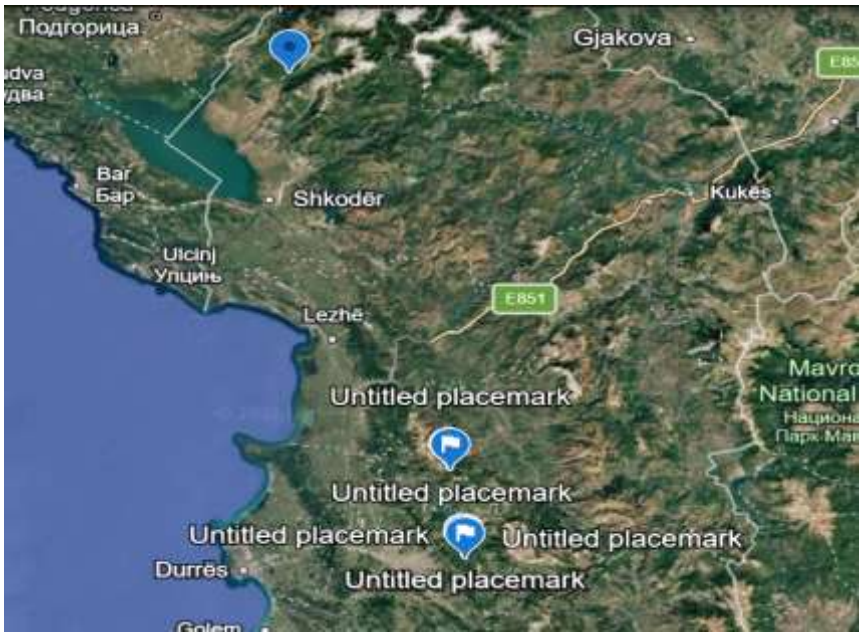

Figure. 2 Distribution map showing the previously known locality and the two new localities of Anemone blanda in Albania.

Habitat characteristics

Fagus sylvatica L represents one the main component of montane forest vegetation in Albania. The distribution of beech forest is closely associated with increasing altitude, lower temperature and more mesic environmental conditions. In Albania *Fagus sylvatica* forest occur across relatively broad altitudinal range, forming both pure stands and mixed communities with other tree species (FAO 2004; Fanelli et al., 2020).

The populations of *Anemone blanda* found in the Dajti and Qafshhtama mountain areas occur in mixed montane *Fagus sylvatica* forests with *Pinus nigra* and *Erica carnea*, mainly on calcareous, well-drained and heterogeneous mountain soils (Fig. 3 |A, B).

A- *Anemone blanda* in Qafshtama

B- Anemone blanda population in Dajti Mountain

Figure 3. Anemone blanda collected at Qafshatama and Dajti and their new habitats

At both localities, *Anemone blanda* occurs in montane beech forest communities dominated by Fagus sylvatica, where *Pinus nigra* and *Erica carnea* occur as important associated species. These communities are developed on calcareous substrates (on Mt Dajti) and serpentine substrate (on Mt. Qafshtama), generally on mountain slopes with well drained

moderately deep and humus rich soils. The habitats are characterized by cool and relatively humid microclimatic conditions, particularly during winter and early spring, followed by dry summer.

In Dajti Mountain forest vegetation had a district altitudinal zonation. According Kalajxhiu et al (2012), from 13 woodland communities identified five of these were assigned to the Order *Fagetalia sylvaticae* highlighting the importance of beech forest within the montane vegetation of Dajti. The composition and distribution of these communities are influenced by a combination of geological substrate, soil characteristic, altitude, topography, anthropogenic disturbance and overgrazing.

The beech forest in Dajti National Park is dominated by *Fagus sylvatica*, while the composition of shrubs and herbs layer varies according to local ecological conditions. This forest occurs mainly between 1000-1500 m above sea level, particularly on northern and northwestern slopes, where Fagus sylvatica is associated with other montane forest element (Mecaj &Muharremaj 2002).

A phytosociological assessment of beech forest in Albania demonstrated considerable ecological differentiation within *Fagus sylvatica* community. There are identified several ecological types, including thermos-basophilous, meso-basophilous and acidophilous beech forest as well as communities characterized by the association of *Corylus avellana* and *Ostrya carpinifoli*a with *Fagus sylvatica*. This indicates that in Albania beech forests do not constitute a homogeneous vegetation unit, but rather a complex of communities differentiated by topographic, climatic and edaphic conditions (Fanelli et al 2020)

Qafshtama National Park provides an additional example of the ecological differentiations of montane forest vegetation in Albania. The upper vegetation belt between 1400-1700m above sea level is characterized by beech forest and coniferous formations, dominated by *Pinus nigra*. The coexistence between them, together with substrate, exposure and soil moisture contribute to the heterogenous forest mosaic. The ecological relationship between beech and black pine is particularly relevant for understanding the vegetation structure of Qafshtama. *Pinus nigra* occupy dry and exposed faces, whereas *Fagus sylvatica* requires more mesic conditions. The variation in exposure, substrate and soil moisture may contribute to the spatial differentiation of these forest communities. The vegetation is therefore characterized by a mosaic of *Fagus sylvatica* forest, scattered *Pinus nigra*, and patches of *Erica carnea*, together with a diverse spring herbaceous layer. Other associated species recorded include *Ostrya carpinifolia*, *Acer pseudoplatanus*, *Fraxinus ornus*, *Helleborus odorus*, *Galanthus nivalis*, *Crocus* spp., *Primula vulgaris* and *Viola* spp. (Fanelli et al 2020).

CONCLUSIONS

Anemone blanda is a rare and endangered specie in Albania, previously known from one location in Bzhet Malesia e Madhe. The field survey conducted in March 2026 identified two new locations of the specie in the protected areas of Dajti Mountain and Qafshtama Mountain. These findings significantly extend the previously known distribution range of *Anemone blanda* in Albania with two new localities located approximately 161 km and 144 km from the previously recorded site. The species was found mainly in *Fagus sylvatica* and mixed *Fagus sylvatica-Pinus nigra-Erica carnea* communities, on calcareous and well drained substrates. The discovery of these two localities suggests that *A. blanda* may have wider distribution in Albania than previously documented. Additional field survey and monitoring are recommended to determine the population size, distribution, ecological requirements and conservation status of the species. These two new records provide additional data crucial for the conservation and more accurate mapping of this rare and endangered plant species in Albania.

VALORIZATİON OF MOROCCAN AROMATIC AND MEDICINAL PLANTS: A CRITICAL REVIEW OF SORPTION THERMODYNAMICS, DRYING KINETICS, AND PHYTOCHEMICAL QUALITY

BDAA MAROINE[1*], LATİFA ZERROUK[1], FATİMA BENRADİ[1], ABDERRAHMAN NOUNAH[1]

[1] Civil engineering and environmental laboratory, Higher School of Technology of Sale, Mohammed V University of Rabat, Morocco

ABSTRACT

Morocco, benefiting from its Mediterranean bioclimates, is home to a rich biodiversity of over 4,200 species of aromatic and medicinal plants (AMPs). Although AMPs represent a strategic sector on a global scale, their valorization faces significant post-harvest losses (estimated at 30% in Morocco) due to poor control over drying and storage processes.

This literature review examines the socio-economic, scientific, and technological contexts of aromatic and medicinal plants in Morocco, while integrating the thermodynamic and kinetic principles governing moisture and AMP drying, utilizing sorption isotherms as a central characterization tool.

The study addresses the AMP sector, their valorization, and their active compound composition. It also analyzes water within biological matrices and sorption thermodynamics (water state, sorption isotherms, modeling, thermodynamic properties, etc.), AMP drying (fundamental principles, kinetics, methods, and impacts, etc.), and the effect of thermal processes on the integrity of phytochemical quality (essential oils and polyphenols).

Despite the importance of drying for post-harvest stability, current scientific literature focuses predominantly on traditional species and is often limited to the physical modeling of mass loss. A critical scientific barrier exists regarding the lack of studies linking fundamental hygroscopic behavior to the degradation kinetics of active molecules.

The identified scientific gaps justify an experimental approach combining multi-temperature isotherms, convective kinetics, and the biochemical quality monitoring of AMPs. This synthesis serves as the methodological foundation for an original and rigorous experimental protocol.

Key words: Aromatic and medicinal plants, drying, sorption isotherms, post-harvest preservation, phytochemical quality

INTRODUCTİON

Endowed with diverse Mediterranean bioclimates, Morocco boasts an exceptional floristic heritage, comprising a rich variety of aromatic and medicinal plants AMPs. Globally, the valorization, exploitation, and processing of natural resources, particularly AMPs, represent a rapidly expanding strategic sector driven by an increasing demand for their bioactive molecules. (1)

Among the primary unit operations used to valorize this botanical heritage is drying; however, the optimal processing of these plant resources faces major technical and operational challenges. (1)

At the national level, post-harvest losses remain alarming. These losses, both quantitative and qualitative, stem primarily from inadequate control over post-harvest stabilization processes, notably drying and storage. (2)

Although drying is the fundamental unit operation for lowering water activity and ensuring the long-term stability of biological matrices, conventional practices often overlook the sensitivity of high-value compounds. (2)

Furthermore, a critical analysis of current scientific literature reveals notable limitations, such as a predominant focus on conventional plant species and an emphasis limited to macroscopic physical modeling of mass loss. (2)

Consequently, a critical scientific gap persists regarding the direct relationship between the fundamental hygroscopic behavior of the plant matrix and the degradation kinetics of its active molecules during coupled heat and mass transfer.

In light of these challenges, this review aims to critically examine the socioeconomic, scientific, and technological landscape of the Moroccan AMP sector, while providing an in-depth exploration of the thermodynamic and kinetic fundamentals governing moisture content and drying behavior. It positions sorption isotherms not merely as descriptive models, but as essential, centralized tools for characterizing and preserving AMP quality.

This review is structured around the following key axes:

- An exploration of valorization challenges and the nature of bioactive compounds in AMPs.
- A detailed analysis of the state of water in plant matrices, covering sorption isotherm models and the determination of associated thermodynamic properties.
- A study of drying fundamentals, drying kinetics, and the direct impact of thermal processing on phytochemical integrity.

Ultimately, this synthesis highlights the necessity of an integrated experimental framework combining sorption isotherm determination, drying kinetic modeling, and biochemical quality assessment.

Review methodology

This review follows a narrative-critical rather than a fully systematic methodology, prioritizing synthesis and gap identification over exhaustive coverage. Peer-reviewed articles and institutional/statistical reports addressing sorption isotherms, drying kinetics and phytochemical stability of aromatic and medicinal plants were retrieved from literatture from Scopus, Web of Science, Google Scholar…, using combinations of the keywords “sorption isotherm,” “water activity,” “drying kinetics,” “essential oil degradation” and relevant species or family names, covering the period 2000–2026. A study was retained if it reported at least one isotherm, kinetic or degradation parameter for an aromatic or medicinal plant matrix ; purely agronomic or ethnobotanical studies with no drying or storage component were excluded.

The AMP Sector

Aromatic and Medicinal Plants

Aromatic and medicinal plants (AMPs) are botanical resources utilized as raw materials for their diverse functional properties across the healthcare, agrifood, and cosmetic industries. (3)

Since antiquity, numerous civilizations have relied on AMPs for their therapeutic properties as the cornerstone of traditional medicine, for their cosmetic applications driven by their abundance of active compounds, and for industrial manufacturing. (4)

Presently, there is a renewed interest in these botanical matrices owing to their high content of bioactive constituents, which provides a natural alternative to synthetic pharmaceuticals. In the scientific literature, the value of aromatic and medicinal plants is primarily characterized

along three major dimensions: biochemical complexity (4), floristic biodiversity, and the rapid expansion of their global market (5).

Biochemical Richness of AMPs

Extensive scientific research corroborates the empirical benefits of these plants due to their richness in secondary metabolites, and their chemical composition is highly varied, depending on the species, the region, and the extraction method. (3), (6)

These molecules, which do not participate directly in the basic growth of the plant, constitute its defense system and confer its unique therapeutic properties. (6), (7)

AMPs synthesize flavonoids, polyphenols, alkaloids, glycosides, saponins, coumarins, tannins, phenolic acids, as well as terpenoids and sesquiterpenes. These compounds act in a targeted manner on the organism and are responsible for antioxidant, antimicrobial, antifungal, anti-inflammatory, analgesic, or antidiabetic activities. (8)

- ✓ **Alkaloids:** Endowed with potent physiological activity, these nitrogenous compounds often constitute major active principles in the pharmacopoeia (9). Comprising approximately 12,000 molecules (10), examples include rhoeadine, which is very abundant in corn poppy (11), rhoeagenine, cotisine, and sanguinarine, which confer analgesic, anti-inflammatory, and antidepressant effects to the plants. (11)
- ✓ **Phenolic Compounds:** These include polyphenols, flavonoids, and tannins. They are molecules particularly sought after for their anti-inflammatory, protective, and antioxidant properties, enabling them to neutralize free radicals (12), (9). With more than 8,000 types (10), they are found in *Mentha suaveolens* (145 ± 7.48 mg GAE/g of powder) (12), in the leaves of *Papaver rhoeas* (24.24 mg GAE/g), and in the stems of *Papaver rhoeas* (10.58 mg GAE) (11).
- ✓ **Essential Oils and Volatile Substances:** Highly concentrated odoriferous compounds extracted from various parts of AMPs for their numerous benefits. Essential oils contain volatile substances, specifically volatile terpenoid compounds (13). With around 25,000 molecules and representing 55% of secondary metabolites, terpenes possess several antimicrobial and therapeutic properties (10); they are found in the essential oil of blue chamomile for its chamazulene content (14), in the essential oil of round-leaved mint which contains piperitenone oxide, and in *Ammi visnaga*, which is rich in linalool (4).
- ✓ **Other Compounds of Interest:** These include quinones, saponoids, polyterpenes, and sterols (9).

Uses of AMPs

The utilization of aromatic and medicinal plants, their various parts, and their derived products spans several domains and addresses numerous aspects:

Traditional Use: In many regions of Morocco, the use of AMPs remains deeply rooted in traditional phytotherapy. Local populations utilize various plant parts (leaves, stems, roots, etc.) in the form of infusions or decoctions to treat specific aliments. (6)

- ✓ **Digestive and Respiratory Systems:** Plants such as oregano (*Origanum compactum*) or pennyroyal (*Mentha pulegium*) are widely known for their ability to treat gastrointestinal disorders and are also recommended for alleviating colds and coughs. (6)
- ✓ **Neurological Disorders and Pain:** Corn poppy (*Papaver rhoeas*) is traditionally used for its capacity to relieve pain, inflammation, and insomnia, and is also known for its antidepressant activity. (7)

Therapeutics, Aromatherapy, and Modern Pharmacy: In this field, the added value of active plant molecules is most prominent, and they are utilized in various ways:

- ✓ **Traditional Medicine:** AMPs, traditionally prepared in various forms, are used to treat specific pathologies due to their therapeutic efficacy derived from their richness in polyphenols, alkaloids, etc. (8), such as *Alstonia* bark rich in alkaloids, conferring the capacity to fight malaria, and other AMPs to combat rheumatism, hypertension, coughs, etc. (9)
- ✓ **Modern Pharmacy:** Natural substances derived from AMPs currently serve as the basis for nearly 25% of modern drugs. Plants provide essential chemical precursors such as quinine from *Cinchona officinalis* or digitoxin from *Digitalis purpurea*. (4)
- ✓ **Aromatherapy:** This involves the therapeutic use of specific essential oils to treat certain conditions, given that various essential oils exhibit major antimicrobial and anti-inflammatory properties. (1)
- ✓ **Dietary Supplements:** This relies on concentrated AMP extracts for well-being and health preservation, experiencing strong growth in pharmacies and parapharmacies. (8), (5)

Food and Nutrition: AMPs are also exploited for the creation of consumable goods and are part of daily use:

- ✓ **Spices and Condiments:** Many dried or fresh plants are used directly to enhance culinary flavors, such as cumin, pepper, fennel, etc. (1)
- ✓ **Agri-food Industry:** Aromatic extracts serve as flavoring agents or flavorings in the manufacturing of various food products. (1)
- ✓ **Infusions:** A significant portion of dried biomass is directly consumed in the form of infusions, herbal teas, and decoctions. (8)

Cosmetics, Perfumery, and Detergents: AMPs are rich in aromatic substances that confer distinct characteristics:

- ✓ **Perfumery and Cosmetics:** AMP extracts obtained through distillation or solvents contain volatile fragrant substances, essential for formulating perfumes, creams, body lotions, etc. (8) (1)
- ✓ **Organic Cosmetics:** The search for natural ingredients stimulates the growth of organic cosmetics, which incorporate plant active principles for targeted skincare. (8) (5)
- ✓ **Household Products:** Aromatic extracts of AMPs are incorporated into detergents to provide notes of natural freshness highly sought after by consumers. (1)

Agricultural and Environmental Uses: Essential oils are used as alternatives to synthetic chemicals for sustainable agriculture; they serve as natural herbicides, repellents, and growth stimulators for crops. (1)

Industrial Uses: Certain plants are specifically listed for veterinary use (traditional treatment of livestock), while others serve as industrial ingredients for specific technical applications (such as dyes/colorants). (5)

Families of AMPs

In Morocco, phytotherapy remains extremely active due to a highly diversified and rich flora, comprising nearly 743 medicinal taxa. (7)

Ethnobotanical surveys conducted in the Zaër region recorded approximately 228 plant species used for therapeutic purposes. (6)

The Moroccan flora inventory also records a total of 743 AMP taxa, 40 of which are endemic to Morocco, divided into 101 botanical families and 371 genera. (5)

The majority of this biodiversity is concentrated within four dominant families, supplemented by other notable botanical groups.

These four families alone represent over 32% of the AMP taxa recorded in Morocco: (5) (15)

Family	Share of AMP taxa	Endemism / conservation status	Representative species
Asteraceae	10.92%	16.66% of national AMP endemics; 12.5% rare/threatened	White wormwood, absinthe, wild chamomile (Matricaria pubescens)
Lamiaceae	10.78%	~50% of national AMP endemics; 15.6% rare/threatened	Rosemary, thyme, lavender
Fabaceae	5.93%	5.2% rare/threatened	Carob, sweet clover
Apiaceae	5.12%	-	Coriander, dill
Brassicaceae	-	4.76% of national AMP endemics	-
Amaranthaceae	-	5.2% rare/threatened; arid/steppe species	-
Malvaceae	-	Mucilage-rich, of cosmetic interest	-
Papaveraceae	-	Alkaloid- and anthocyanin-rich	Corn poppy (Papaver rhoeas)

1: Dominant AMP families in the Moroccan flora

Socio-Economic Context of AMPs

Benefiting from a wide diversity of Mediterranean bioclimates, Morocco possesses an exceptional floristic heritage with more than 4,200 identified species. The AMP sector, encompassing high-value species such as blue chamomile, corn poppy, or apple mint, constitutes a major ecological asset and a leading scientific resource. (1)

AMP production in Morocco relies primarily on the exploitation of natural stands, covering a total area of 311,862 hectares nationwide, with over 90% of plant biomass derived from wild harvesting, while cultivated areas represent only a marginal share estimated at approximately 2% (1). The most commonly harvested wild species generally belong to Asteraceae or Lamiaceae. Furthermore, wild rosemary, gathered mainly in the Oriental region, generates over 60 tonnes of essential oil annually, positioning Morocco among the top three global producers alongside Spain and Tunisia (5).

AMP processing is carried out through an infrastructure composed of (1):

- ✓ **Artisanal Extraction:** Small-scale distillation enterprises utilizing mobile units, readily transportable directly to harvest sites to extract crude essential oils.
- ✓ **Modern Industry:** Large units equipped with advanced technologies for extracting absolutes intended for fine perfumery, or specialized in large-scale irrigated crops.

The AMP sector represents a fundamental driver of rural development and solidarity-based agriculture. It relies on a dense territorial network of over 1,000 operational structures. According to the Moroccan Cooperation Development Office (ODCO), the sector is structured around 1,309 cooperatives, 228 of which are exclusively female-led, thereby promoting women's empowerment. Currently, the sector is engaged in a process of structural organization and upscaling. Evidencing this quality momentum, 112 cooperatives have recently benefited from support toward product certification (PDO certifications, Organic labels, and ONSSA approvals) (16).

Aromatic and medicinal plants are distributed and heavily concentrated across specific regions of Morocco, starting with the Oriental region representing 39% of exploited areas, followed by Fès-Meknès at 29%, Béni Mellal-Khénifra at 20%, with Drâa-Tafilalet, the North, and the High Atlas completing the national geographical distribution. (5)

Economically, Morocco ranks as the 12th largest global exporter, generating an average export revenue of 615 million dirhams (approximately 55.9 million euros). Commercial dynamics are driven by an annual volume of 52,000 tonnes sold, representing average sales revenues of 5.63 million dirhams. (16)

Half of the dried AMP exports consist of products destined for the food sector in the form of spices and flavorings. In addition, the demand for natural ingredients stimulates the growth of organic cosmetics, a market expanding at over 25% annually. (8)

Despite undeniable socio-economic potential, the value chain suffers from post-harvest vulnerabilities. Losses are estimated at nearly 30%, primarily due to a lack of control over drying and storage conditions (2). This technical deficiency compromises the traceability and microbiological quality required by target markets. Consequently, a transition toward precision engineering, centered on the scientific optimization of drying processes, becomes imperative. Such mastery will substantially curb biomass losses, ensure sanitary safety for export, and maximize the economic and therapeutic valorization of Moroccan AMPs.

Scientific and Technological Context

Drying of AMPs represents the most proven and strategic preservation method to ensure their long-term stability. Fresh AMPs are characterized by high moisture content, making them highly unstable and susceptible to microbiological, enzymatic, and biochemical degradation. (9)

When conducted rigorously, drying plays a fundamental role in maintaining the integrity of biomaterials and ensuring their quality over the long term. However, ensuring the quality of AMPs requires an in-depth understanding of their physicochemical characteristics. This fundamental control is the sole lever for accurately evaluating their purity, guaranteeing impeccable sanitary safety, and ensuring optimal stability during storage. (9)

Scientifically, the approach within the sector has shifted substantially, focusing on water thermodynamics rather than on a simple global measurement of product moisture content.

Several key gaps emerge: (17) (18)

- ✓ **Optimization of Preservation:** Although Morocco is a leading producer and exporter of AMPs, the AMP value chain faces a critical issue: post-harvest stability, which threatens their chemical quality.
- ✓ **Characterization of Endemic Species:** While conventional species such as *Mentha pulegium* or *Thymus satureioides* are documented, numerous high-value plants of Moroccan heritage remain scientifically unexplored and lack sufficient data to establish post-harvest processing protocols.
- ✓ **Sorption Isotherms and Degradation:** Studies on sorption isotherms and drying of AMPs have predominantly focused on physical modeling and mass loss. The lack of studies linking sorption isotherms to the degradation kinetics of active molecules in species of high chemical value constitutes a major scientific gap.

- ✓ **Evolution of Drying Processes:** The sector is evolving from a traditional harvesting and open-air drying model toward closed and controlled drying technologies that require process adaptation.

Water and AMPs

Water Activity

Generally denoted a_w, water activity is a crucial thermodynamic parameter for characterizing the state of water within products, particularly aromatic and medicinal plants. A fundamental distinction exists between water activity and moisture content X: X is a quantitative parameter, whereas a_w is a qualitative and thermodynamic concept. (19)

Although moisture content measures the gross amount of water in a product, water activity describes the availability, binding state, and reactivity of the water present within the matrix. (15)

Thermodynamically, the water activity of a specific material corresponds to the ratio of the partial vapor pressure of water above the product to the saturation vapor pressure of pure water at the same temperature: (19)

$$a_w = \frac{p_w}{p_0}$$

At equilibrium, this water activity also corresponds to the relative humidity (RH) of the surrounding air, expressed as a fraction: (19) (20)

$$a_w = \frac{\%HR}{100}$$

Water activity is a dimensionless quantity strictly ranging between 0 for a completely dry material and 1 for pure water. (19)

In plants, the contained water is not always entirely available, as a portion is chemically and physically bound to the plant framework and does not participate in reactions, whereas another portion is free and acts as a solvent. Consequently, the total amount of water in a product does not determine its stability or deterioration, but rather the state, nature, and availability of this water. (21)

By precisely measuring the free water fraction in the product, aw indicates whether the environment is conducive to the proliferation of microorganisms (bacteria, molds, etc.) or to enzymatic and biochemical reactions (browning, lipid oxidation, etc.). Reducing water activity slows down the growth rate of microorganisms by extending their lag phase. (21)

Thus, water activity serves as the true indicator of the stability and shelf life of a product, and represents the key parameter that must be controlled during the processing or valorization of matrices such as AMPs. (21)

At a constant equilibrium moisture content, an increase in temperature directly results in an increase in water activity; conversely, at constant water activity, an increase in temperature reduces the product's equilibrium sorption capacity. (15)

Nature and State of Water in AMPs

Residual moisture in fresh medicinal plants commonly exceeds 80% on a wet basis. However, not all of this water is equivalent in terms of its energetic availability and its involvement in deterioration processes. The thermodynamics of water in biological matrices distinguishes several fractions according to their degree of interaction with structural macromolecules (cellulose, hemicellulose, pectin, proteins): (15)

- ✓ **Free water:** Exhibits the physical properties of pure water, acts as the solvent for metabolic and biochemical reactions, and represents the fraction accessible to microorganisms and enzymes.

- ✓ **Bound water:** Strongly adsorbed onto the polar hydrophilic sites of biopolymers (carboxyl, hydroxyl, and amine groups). It is unavailable for biological reactions and requires substantial energy for evaporation.
- ✓ **Multilayer water:** Weakly bound water occupying successive layers around the monolayer, exhibiting intermediate properties between free water and bound water.

This conceptual distinction is fundamental, as it represents a key challenge for biological matrices.

Moisture-Induced Degradation Mechanisms

The availability of free water is an indicator of the potential degradation of biological matrices. This degradation occurs via three key mechanisms, all controllable through the regulation of the product's water activity.

Microbial Proliferation

Microbial proliferation represents the primary and most rapid cause of deterioration in fresh AMPs. Above $a_w > 0.91$, virtually all pathogenic and spoilage bacteria (*Salmonella*, *Escherichia coli*, *Pseudomonas*) proliferate rapidly. Within the 0.80-0.87 range, common yeasts and molds, as well as *Staphylococcus aureus*, actively develop. Reducing aw exponentially prolongs the lag phase of microorganisms and selectively inhibits their growth rate, thereby extending the microbiological shelf life of the product. (15)

Enzymatic Reactions

Endogenous enzymes present in plant tissues (peroxidases, lipases, polyphenol oxidases) catalyze degradation reactions in the presence of residual water. These enzymatic reactions are responsible for enzymatic browning, which severely impairs the visual and chemical quality of the plant. Peroxidases and amylases are completely inactivated when aw drops below 0.85; however, other degradation enzymes, notably lipases, can maintain residual activity at extremely low moisture levels (aw between 0.1 and 0.3). Paradoxically, moisture-related hydric stress at the onset of drying can transiently stimulate enzymatic activity and temporarily increase essential oil content, but prolonged moisture exposure inevitably leads to their decline through oxidative degradation. (21)

Non-Enzymatic Chemical Reactions

Even below the threshold for microbiological stability ($aw < 0.60$), purely chemical degradation reactions persist. Lipid oxidation and non-enzymatic browning (Maillard reaction) cause the destruction of sensitive compounds (anthocyanins, carotenoids, vitamins, polyphenols) alongside alterations in color and aroma profile. These reactions often exhibit minimal kinetics within the aw = 0.20-0.30 range, referred to as the "optimal chemical stability zone." (9)

Drying and AMPs

Drying principles

Drying is a fundamental preservation method aimed at lowering the moisture content and water activity a_w of a product to inhibit harmful degradation, thereby considerably extending its storage life. To prevent fungal contamination, the final moisture content of dried products, such as AMPs, should ideally be reduced to approximately 10% (wet basis). (22)

However, the drying operation significantly affects the color, porous microstructure, rehydration capacity, and, above all, the concentration of active principles in these thermosensitive plant matrices. (23)

Drying is a complex unit operation that does not merely consist of removing water, but of executing coupled heat and mass transfer under rigorous control to preserve the integrity of the matrix. (17)

The fundamental principles governing this process include: (23)

Dual Transfer Mechanism: Drying relies on the physical superposition of two simultaneous transfer phenomena: heat transfer, in which hot, dry air transfers thermal energy to the moist product to raise its temperature and supply the energy required for water vaporization; and mass transfer, in which water first migrates from within the plant tissues to its surface and then evaporates from this surface into the ambient air.

Crucial Influence of Drying Air Parameters: The thermohydrometric properties of the air introduced into the dryer dictate the drying rate and the final quality of the product:

- ✓ **Temperature:** It increases the saturation vapor pressure of water and accelerates molecular diffusion. However, for medicinal plants, it must be moderated to prevent oxidative darkening as well as the degradation or volatilization of valuable essential oils.
- ✓ **Air Velocity:** It reduces the thermal and mass boundary layers around the leaf, facilitating the removal of water vapor. In the case of verbena, air velocity was found to exert a more significant impact than temperature on reducing drying time.
- ✓ **Relative Humidity:** It determines the driving force of the transfer. If the air is excessively dry and drying is overly aggressive, surface case-hardening can occur, sealing the surface and entrapping moisture within the core of the leaf.

In the case of AMP leaves and flowers, drying kinetics are generally characterized by: (23)

- ✓ **The absence of a constant-rate drying period (or a very short one):** The surface of thin leaves dries rapidly, and internal resistance to moisture transfer dominates from the onset of drying;
- ✓ **A predominant falling-rate period:** The diffusion of bound water from the interior to the surface controls the process, in accordance with Fick's second law. It is during this phase that the most significant degradation of active compounds occurs.

The moisture ratio (MR) is defined as: (23)

$$\mathbf{MR} = \frac{\mathbf{X} - \mathbf{X_{eq}}}{\mathbf{X_0} - \mathbf{X_{eq}}}$$

where X is the moisture content at time t, X_0 is the initial moisture content, and X_{eq} is the equilibrium moisture content. MR varies from 1 (initial product) to 0 (product at equilibrium with the drying air). Modeling MR as a function of time constitutes thin-layer drying kinetics.

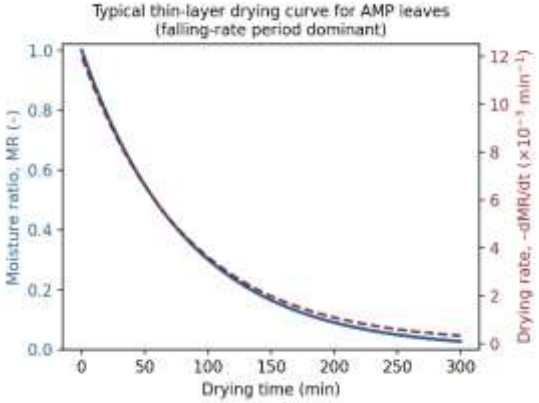

Figure 1. Typical thin-layer drying curve for AMP leaves: moisture ratio (left axis) and drying rate (right axis) against time, showing the dominant falling-rate period.

Drying methods

The drying sector is evolving from an open-air, bulk harvesting and drying model toward closed and controlled technologies. Each method has its own advantages and limitations, and selection is based on biological quality retention, energy efficiency, and economic viability: (24), (23)

Method	Advantages	Limitations
Open-air sun drying	Low-cost, low temperature, favorable to retention of some compounds	Slow, weather-dependent, exposes plants to dust/insects/microbial contamination; UV and thermal fluctuation cause discoloration and loss of thermosensitive compounds
Convective hot-air drying	Widely used industrially; fast, scalable	Energy-intensive; induces cell-wall hardening (reducing solvent extraction), essential-oil loss, and non-enzymatic browning
Freeze-drying (low-T sublimation)	Achieves near-complete retention of cellular structure and active principles	High energy and capital cost; limited to ultra-high-value species (e.g., saffron)
Indirect solar drying	Well suited to Morocco's solar resource; separate collector protects product from direct UV exposure	Requires dedicated equipment; performance depends on solar availability

2: Different drying methods

Modeling of drying kinetics

In the study of dryers (particularly solar dryers), modeling serves to describe the evolution of plant temperature and moisture content over time. Literature sources classify drying models into three main categories: (25)

- ✓ **Empirical Models:** Derived directly from experimental data, they describe drying kinetics but remain strictly limited to the initial experimental conditions.
- ✓ **Diffusive Models:** They rely on physical equations (Fick's law) to describe moisture migration within the product.
- ✓ **Coupled Heat and Mass Transfer Models:** These are the most complex (such as Luikov, Whitaker, or Philip & De Vries models), detailing internal transport phenomena through energy and mass conservation equations.

In practice, integrating drying equations and isotherm models into computational programs (e.g., in FORTRAN) enables numerical simulations. These virtual simulations make it possible to predict product behavior within a dryer and optimize system design while avoiding lengthy and costly experimental testing campaigns. (23)

The effective moisture diffusivity D_{eff} (m^2/s) quantifies the ease with which water migrates from the interior to the surface of the product. It is calculated from Fick's diffusion model for an infinite slab geometry (leaves): (23)

$$MR = \frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\exp\left(-\frac{(2n+1)^2\pi^2 D_{eff}t}{4L^2}\right)$$

where L is the half-thickness of the leaf or the dried layer. For AMPs, D_{eff} values reported in the literature typically range between 10^{-12} and 10^{-8} m^2/s depending on the species and drying temperature, with higher values corresponding to higher temperatures and vacuum- or microwave-assisted drying methods.

The activation energy Ea (kJ/mol) is calculated via the Arrhenius equation:

$$D_{eff} = D_0 \exp\left(-\frac{Ea}{RT}\right)$$

It quantifies the temperature sensitivity of the diffusion process. Typical Ea values for convective hot-air drying of AMP leaves range from 15 to 50 kJ/mol, depending on the botanical species and drying technique. Elevated values indicate a pronounced temperature dependence -beneficial for convective drying efficiency- yet potentially detrimental to thermolabile compounds such as chamazulene in blue chamomile. (14)

Phytochemical impact of drying on AMPs

The phytochemical quality of a dried AMP is governed by a balance between two antagonistic effects: on the one hand, the relative concentration of active compounds due to water removal (concentration effect); on the other hand, the thermal, oxidative, or enzymatic degradation of these compounds under the combined action of heat and residual moisture (degradation effect). The net outcome of these two mechanisms strongly depends on the plant matrix, the drying temperature, and the exposure duration. (9) (17) (2)

- ✓ **Essential Oils**: The volatile compounds constituting essential oils are particularly sensitive to drying processes. For mint species, convergent studies demonstrate that increasing the drying temperature beyond 40–50°C leads to a significant decrease in essential oil yield via direct volatilization and/or oxidative degradation of terpenes. Research by Blanco et al. on peppermint reported an essential oil content of 1.0% (v/w) at 40°C, dropping to 0.14% at 60°C and 0.12% at 80°C. For spearmint (*Mentha spicata*), hot-air drying (HAD) methods yield the highest essential oil contents at moderate temperatures; however, these yields decrease with increasing air velocity and drying temperature. For chamomile (*Chamaemelum nobile*), Omidbaigi et al. demonstrated that shade drying at 30°C preserves essential oil quality and yield better than sun drying or oven drying. Chamazulene, the primary active compound in blue chamomile, is particularly thermolabile and serves as a critical quality marker for drying conditions.
- ✓ **Polyphenols and Flavonoids:** Phenolic compounds (phenolic acids, flavonoids, anthocyanins) exhibit distinct thermal sensitivities: flavonoids and phenolic acids show enhanced extractability at moderate temperatures (40–60°C), but degrade significantly above 80°C through reaction with oxygen. Anthocyanins, the primary pigments in corn poppy (*Papaver rhoeas*), are exceptionally sensitive to heat and oxidative stress. For *Mentha aquatica*, a comparative study (Zare et al., 2022) reported that shade drying (SD, 30°C) and oven drying (OV, 50°C) achieved the highest essential oil yields; the highest quercetin concentration was obtained via OV at 50°C, whereas total polyphenols were maximal in the fresh plant.

These findings highlight the necessity of establishing an optimal trade-off between drying rate (critical for microbiological stability) and the chemical integrity of high-value bioactive compounds.

High-Performance Liquid Chromatography (HPLC) is the benchmark analytical tool for assessing the phytochemical quality of dried AMPs. Its separation and quantification capabilities enable: (26) (27)

- ✓ **The establishment of reference chromatographic profiles** for the chemical markers of each species before and after different drying treatments;
- ✓ **The precise quantification** of target compound concentrations (piperitenone oxide in *M. suaveolens*, chamazulene in *T. annuum*, anthocyanins in *P. rhoeas*);

- ✓ **The detection of degradation or newly formed products** generated by thermal exposure or oxidative reactions (disappearance of existing peaks, emergence of neoformed peaks);
- ✓ **The statistical comparison of chromatographic profiles** across drying methods and temperatures, allowing the identification of optimal processing conditions for quality preservation.

Sorption Isotherms and Modeling

Significance of sorption

A sorption isotherm represents a hygroscopic identity card. It is a fundamental curve in food science, particularly for aromatic and medicinal plants. (23)

It describes the equilibrium relationship between the equilibrium moisture content of a matrix and the relative humidity of the ambient air surrounding it, at a constant temperature. (23)

It also translates the microscopic interactions between water and the plant into macroscopic terms. (28)

It is highly useful for determining the target final moisture content required to ensure optimal preservation, as well as for estimating shelf life and energy requirements for drying. (28)

Graphically, the equilibrium moisture content of the product Xeq (kg water/kg dry matter) is plotted on the ordinate (y-axis), and the water activity a_w (RH/100), ranging from 0 to 1, is plotted on the abscissa (x-axis).

Two types of sorption isotherms exist, depending on the pathway followed to establish the curve: (28)

- ✓ **Adsorption:** Occurs when an initially dry product absorbs moisture. It takes up water from the surrounding atmosphere until reaching hygroscopic equilibrium. This is important for modeling product behavior during storage and assessing the risks of accidental rehydration.
- ✓ **Desorption:** Describes the process of moisture loss from a water-saturated product until hygroscopic equilibrium is attained. It is a fundamental curve for designing dryers and calculating the time required to achieve a target a_w.

The study of sorption isotherms is an essential step to: (23)

- ✓ **Optimize Drying:** The curves define the equilibrium limit moisture content a product can reach under specific air temperature and relative humidity conditions. This is crucial for dryer sizing and process modeling.
- ✓ **Ensure Preservation and Storage:** They identify stability zones that prevent deterioration caused by microbial growth and aid in selecting appropriate packaging to extend product shelf life.
- ✓ **Calculate Thermodynamic Properties:** They provide key parameters such as the monolayer moisture content and the isosteric heat of sorption.

At constant relative humidity, the equilibrium moisture content decreases with increasing temperature. This is explained by the fact that higher temperatures thermally excite water molecules, breaking their bonds with the product's active sorption sites and thereby reducing its water retention capacity.

Types of Sorption Isotherms

According to IUPAC, sorption isotherms are classified into six distinct types. These profiles directly reflect the physical and chemical characteristics of a material, such as its porosity, pore structure, and the interaction strength between the substrate and water molecules: (29)

Type	Shape	Typical materials
I (Langmuir)	Concave, rapid plateau; monolayer only	Microporous solids (pore size < 2 nm) – activated carbons, zeolites
II (sigmoidal)	S-shaped, unrestricted multilayer adsorption	Most food products, including AMPs
III ("Flory–Huggins")	Convex throughout	Sugar-rich products, hydrophobic materials
IV	Type II with high-aw plateau (capillary condensation)	Mesoporous solids (2–50 nm)
V	Type III with high-aw plateau	Mesoporous, weak water–substrate interaction
VI (stepped)	Layer-by-layer, stepwise sorption	Extremely uniform surfaces; rare

3. *IUPAC classification of sorption isotherms.*

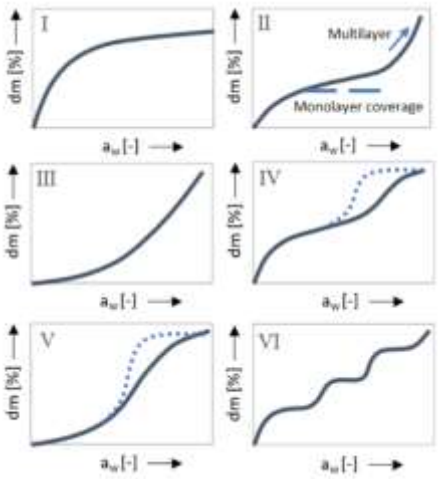

Figure 2. IUPAC classification of sorption isotherms.

Hysteresis Phenomenon

For the same product and in most cases, the desorption and adsorption curves do not overlap; this systematic deviation is termed hysteresis. It is observed that for a given water activity, the equilibrium moisture content is higher during the desorption process than during adsorption. This shift indicates that the drying process induces irreversible modifications in the internal structure and porosity of the matrix. The physical thermodynamic mechanisms explaining this phenomenon have been documented in the literature: (19)

- ✓ **Ink-Bottle Effect:** Within the matrix, pores having a geometry similar to an ink bottle—with a wide body relative to a narrow neck connecting it to the surface—govern the sorption mechanisms. During desorption, the pore is initially filled with liquid water trapped behind the narrow neck; its release requires a substantial drop in the surrounding

vapor pressure. Conversely, during adsorption, pore filling is constrained by this same neck, requiring higher relative humidity to fill the empty pore cavity.

- ✓ **Glass Transition:** Physical state changes in the matrix from a flexible rubbery state to a rigid glassy state physically entrap certain water molecules within the solid framework, generating an additional retention force.
- ✓ **Structural Swelling:** Drying causes the collapse of cell walls and the reorganization of polymers, reducing the availability of hydrophilic binding sites during rehydration. Inversely, water adsorption induces the expansion of plant polymers, creating new sorption sites that do not immediately close during subsequent desorption.
- ✓

Sorption Isotherms of AMPs

For the majority of plant matrices, particularly aromatic and medicinal plants, sorption isotherms exhibit a sigmoidal shape and are classified as Type II isotherms. (23)

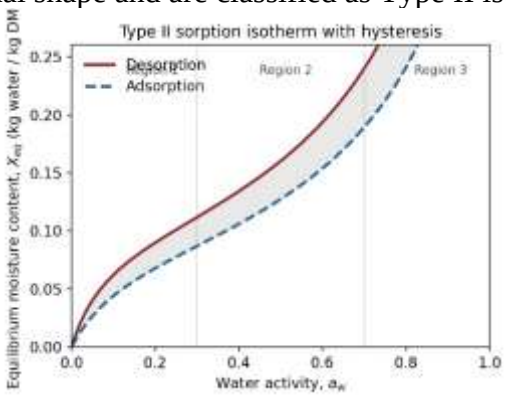

Figure 3. Schematic Type II sorption isotherm for an AMP matrix, showing desorption/adsorption hysteresis and the three sorption regions.

This profile reflects the distinct stages of physical and chemical binding of water onto the solid matrix, comprising three distinct regions: (23)

- ✓ **Region 1:** At a water activity below 0.3, water is present in very small amounts and is strongly bound to polar, high-energy hydrogen-bonding sites. This water, corresponding to constitutional or monolayer water, is non-freezable and unavailable as a solvent. The energy required to remove this water is significantly higher than the heat of vaporization of pure water, and it is within this region that the plant exhibits maximum stability.
- ✓ **Region 2:** At a water activity between 0.3 and 0.7, multilayer water adsorbs in successive layers and begins to fill the micropores. This represents a transition zone where chemical and biochemical reactions requiring water initiate or accelerate.
- ✓ **Region 3:** At a water activity above 0.7, excess water completely fills the large pores of the plant. This water exhibits the same physical and thermodynamic properties as pure or free water. Within this zone, the stability of the plant drops precipitously.

Characterization Methods

Sorption isotherms can only be determined experimentally, and their determination primarily relies on methods divided into two approaches: static and dynamic. (19)

Static Approach (23) (20)

The principle of this approach is as follows: the sample is placed in an enclosure maintained at a constant temperature and constant relative air humidity. This induces exchange processes with the product, such as the plant matrix. (23)

The sample is weighed at regular intervals until its mass no longer varies, indicating equilibrium with the air.

Knowing its wet mass, the sample is dried, and the dry mass is then used to calculate the equilibrium moisture content at the constant temperature and RH, representing a single point on the isotherm. (28)

This method has the drawback of process duration, as reaching equilibrium between the plant and the air can take several weeks. This extended time frame can compromise results, as biological products subjected to high relative humidities may undergo spoilage caused by mold before equilibrium is attained. (23)

This approach can be applied using two methods:

- ✓ **Saturated Salt Solutions Method:** This traditional method is widely used in the study of Moroccan AMPs. Plant samples are suspended inside hermetic jars above a saturated salt solution and placed in a thermostatic chamber to ensure a strictly constant target temperature. At this temperature, the saturated salt solution generates and maintains a constant, precisely known relative humidity within the jar headspace. To cover the entire relative humidity range (from 0 to 100%), different salts are utilized. It is a simple and cost-effective method, but time-consuming. (30)

  $p_v = HR \times p_{sat}(T)$

- ✓ **Sulfuric Acid Method**: Similar to the saturated salt solutions method, the sample is brought into equilibrium with solutions, in this case sulfuric acid solutions of fixed concentrations.

  $$\log\left[\frac{p_v}{p_{sat}}\right] = \left(a_1 - \frac{a2}{T}\right) + \frac{1}{\log[p_{sat}(T)]}$$

Dynamic approach (19)

This modern automated technique circumvents the slowness of the conventional static method. (19)

The principle is simple: the product is placed in a climatic micro-chamber where a moist airflow is actively regulated and continuously circulated around the sample at a constant temperature. (19)

Continuous real-time weighing: a highly sensitive microbalance integrated into the instrument automatically records the mass evolution of the product in real time, without any human intervention. (19)

As soon as the device detects that the mass no longer varies (the product has reached equilibrium with the air humidity), it automatically advances to the next pre-programmed higher or lower humidity step.

This technique offers significant advantages due to dramatic time savings (isotherm measurements are completed in a few days instead of several months), complete elimination of external weighing errors, and full automation of entire adsorption-desorption cycles. (19)

Mathematical Modeling and Thermodynamic Properties

The modeling of sorption isotherms consists of transforming discrete experimental data into continuous predictive tools, applicable for sizing drying equipment and optimizing storage conditions. The literature distinguishes various models, which also assist in determining several thermodynamic properties useful for completing the study. (21)

Main Sorption Isotherm Models

Main sorption models have been summarized in the table below: (23)

Author	Parameters	range
Langmuir	C, X_{12}	Zone 1
GAB	$C=C_0 \exp(\frac{H_1-H_m}{RT})$ $K=K_0 \exp(\frac{H_1-H_q}{RT})$ X_{12}	Entire range
BET	C, X_{12}, n number of layers	Zone 2
	C, X_{12}, n=1, HR^2 negligible	Zone 1
Harkins	K, n	Entire range
Peleg	A, B, C, D	Entire range
Smith	K, n	Entire range
Henderson	A, B, C	Entire range
OSWIN	A, B, C	Entire range
Chung	K, n	Entire range

4. Models used for the modeling of sorption isotherms in the case of AMPs

The Guggenheim-Anderson-de Boer (GAB) model represents the standard in agri-food literature and the model recommended by the European project COST 90 for the characterization of food and plant products. It is an extension of the BET (Brunauer-Emmett-Teller) model incorporating a correction factor K for multimolecular water layers, which extends its range of validity up to a_w = 0.95. Its equation is: (28)

$$X_e = \frac{(X_m \times C \times K \times aw)}{[(1 - K \times a_w)(1 - K \times a_w + C \times K \times a_w)]}$$

where Xm is the monolayer moisture content (kg water / kg DM), C is the Guggenheim constant related to the binding energy of monolayer water, and K is the multilayer water factor. These parameters possess direct physical significance and allow for the calculation of the sorption enthalpy. Its primary limitation is the failure to strictly adhere to Henry's law at very low a_w. (23)

The four-parameter empirical Peleg model (A, B, C, D) provides maximum statistical flexibility to describe curves of various shapes, both sigmoidal and non-sigmoidal, across the entire a_w range (0 to 0.99). Studies on mint, marjoram, and chamomile consistently report the best fitting statistics (highest R^2, lowest RMSE) for this model. However, the lack of physical significance of its parameters confines it to a numerical prediction role, without contributing to the mechanistic understanding of water-plant interactions. (23)

The modified Henderson model offers the unique advantage of explicitly incorporating temperature into its equation, allowing for the prediction of equilibrium curves over a wide thermal range without recalculating parameters. It is particularly suitable for fibrous materials and has demonstrated good performance for several AMPs, notably mint (Kouhila et al., 2001). However, local inaccuracies have been reported for certain a_w ranges. (23)

The Halsey model excels in describing multilayer adsorption in fibrous and lipid-rich materials, and has proven particularly relevant (along with Peleg) for chamomile (*Matricaria pubescens*).

The three-parameter Oswin model is recommended for products rich in proteins and starch. The selection of the optimal model is guided by the following statistical criteria: R^2 to 1, and simultaneous minimization of RMSE, chi^2, MRE (< 10%), and SSE. (23)

Thermodynamic Properties Derived from Isotherms

Monolayer moisture content

The monolayer moisture content represents the exact amount of water required to cover the entire internal surface and pores of the product with a single molecular layer of water. (23)

At this moisture level, water molecules are strongly bound via multiple high-energy hydrogen bonds to primary active hydrophilic sites (polar groups) on the solid surface. (15)

This water exhibits virtually zero thermodynamic mobility and is considered an integral part of the plant's solid phase rather than a free fluid.

This parameter defines the optimal moisture limit to maximize product preservation. (23)

Below this moisture content, biological, enzymatic, and chemical degradation reactions are extremely slow or completely halted, as water is too rigidly bound to participate in reactions (with the exception of certain lipid oxidation reactions that can be initiated at very low moisture levels). (23)

Above this moisture content, water begins to adsorb in multilayers. It becomes mobile again, regains its solvent properties, and actively begins to facilitate biochemical deterioration (such as non-enzymatic browning or the Maillard reaction) as well as microbial proliferation as water activity increases. (23)

Isosteric Heat of Sorption

The net isosteric heat of sorption q_{st}, in kJ/mol) quantifies the additional energy - beyond the simple latent heat of vaporization of pure water L_{vap} -required to remove water molecules bound to the plant matrix. It is calculated using the Clausius-Clapeyron equation applied to isotherms measured at different temperatures: (30)

$$\frac{d(\ln(a_w))}{d(\frac{1}{T})} = \frac{-q_{st}}{R} \Rightarrow Q_{st} = q_{st} + L_{vap}$$

where R is the universal gas constant and T is the absolute temperature. This quantity exhibits an inverse relationship with moisture content: at low moisture levels (monolayer level), water is strongly bound to active sites and the required energy is maximal; as moisture content increases, water occupies progressively fewer active sites and q_{st} converges toward L_{vap}. This exponential relationship is fundamental for dryer design: it demonstrates that the energetic costs of water removal increase drastically toward the end of drying. (30)

Differential Entropy and Enthalpy-Entropy Compensation

The differential entropy of sorption (ΔS, $J \cdot mol^{-1} \cdot K^{-1}$) is derived from the intercept of the isosteric plot ln(aw) = f(1/T) via the Gibbs-Helmholtz relationship:

$$\ln(a_w) = \frac{-q_{st}}{(R \times T)} + \frac{\Delta S}{R}$$

A low entropy value indicates a high degree of structuring and reduced mobility of water molecules -water rigidly trapped on active sites-whereas a high entropy reveals a disordered system where water is more mobile and accessible. Entropy is directly proportional to the number of available sorption sites. (31)

The enthalpy-entropy compensation theory (or isokinetic theory) predicts a linear relationship between q_{st} and ΔS across all moisture contents of the same plant. This correlation makes it possible to diagnose whether the dominant evaporation mechanism during drying is enthalpically driven (binding energy to be overcome) or entropically driven (structural reorganization of the plant matrix), providing information directly applicable to optimizing drying parameters. (31)

Gibbs Free Energy and Spreading Pressure

Gibbs free energy ($\Delta G = \Delta H - T \cdot \Delta S$) characterizes the spontaneity of water adsorption. A negative ΔG indicates spontaneous adsorption. Spreading pressure quantifies the surface energy involved in sorption and constitutes an additional parameter for comparing sorption capacities across species and drying methods. These quantities are calculated from experimental isotherm data and serve as key indicators of the energetic efficiency of drying. (23)

Integration: From sorption equilibrium to phytochemical stability

The preceding sections describe three bodies of work that are conceptually continuous but have rarely been connected for the same species.

The sorption fixes X_{eq} (a_w,T°) and, through it, the endpoint that drying kinetics asymptotically approach. The isosteric heat qst, derived from the same isotherm, rises sharply as moisture nears the monolayer, which is precisely why the energetic cost of drying increases disproportionately in its final stages. Finally, the trajectory of aw during drying- not moisture content alone- determines which degradation pathways (microbial, enzymatic, non-enzymatic, marker-specific) are active at any given point, so the same isotherm that sets the drying target also sets the stability outcome. Treating these as one coupled system, rather than three separate literatures, is the integrative contribution this review argues the field needs.

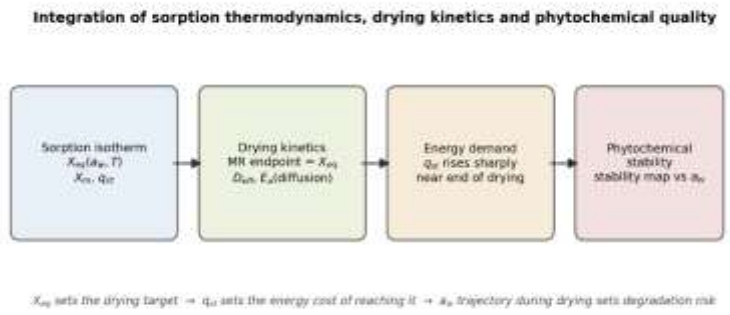

Figure 4. Conceptual integration of sorption thermodynamics, drying kinetics and phytochemical stability.

Research gaps and perspectives

Three gaps emerge from this review. First, sorption isotherm data remain sparse for high-value, endemic Moroccan AMPs, despite the economic and therapeutic importance of the sector. Second, almost no published study integrates sorption isotherms, drying kinetics and phytochemical degradation kinetics for the same species – each is typically studied in isolation. Third, available data specific to Moroccan climatic conditions remain limited relative to the diversity of species and production regions, constraining the guidance available to cooperatives and processors.

Closing these gaps calls for four complementary lines of work: comprehensive thermodynamic characterization, through experimental adsorption/desorption isotherms for priority AMP species at multiple temperatures; systematic comparative modelling, evaluating the models against multi-criteria statistics to identify the best-fit model per species; coupled drying-kinetics characterization, determining thin-layer kinetics, Deff and Ea,diff across temperatures and air velocities; and – the piece this review identifies as missing – degradation-kinetics characterization, quantifying reaction order, rate constants and Ea,degr for target markers (piperitenone oxide, chamazulene, anthocyanins) as a function of drying condition and aw, and expressing the result as the stability map described previously.

CONCLUSİON

Sorption isotherms are more than a descriptive curve: through Xeq and qst they set both the target and the energetic cost of drying, and through the aw axis they organize the degradation pathways that determine phytochemical quality. For Moroccan AMPs, the literature reviewed here establishes the sector's scale and biochemical richness, the Type II sorption behaviour and hysteresis typical of these matrices, and scattered but consistent evidence that drying temperature governs essential-oil and polyphenol retention. What is missing is the kinetic bridge between these two bodies of evidence: a quantitative description of how degradation rate constants for specific markers vary with water activity and temperature, tied back to the same isotherms used to design the drying process. Building that bridge - through coordinated isotherm, drying-kinetics and degradation-kinetics studies on the same, ideally endemic, species - is the concrete direction this review recommends for future work on Moroccan AMPs.

SOFTWARE ENGINEERING IN AGRICULTURE

ZEYNEP ALTAN

Istanbul Beykent University, Faculty of Engineering and Agriculture, Software Engineering Department, Turkey

ABSTRACT

Many progresses have been made in solving today's agricultural problems with the increasing usage of automation in agricultural processes Thus, a new innovation field has emerged by offering solutions to the pressing problems encountered in today's agriculture. The integration of AI, machine learning, and data analysis technologies into the agricultural sector optimize resource use, increase crop yields, and improve sustainability. This study examines applications of software solutions in the fields of precision agriculture, automated irrigation systems, and crop monitoring. However, user-friendly software tools that encourage farmers and stakeholders to make data-driven decisions are also explored. As collaboration between agricultural engineers and software engineers increases, innovations in food safety and sustainable agricultural practices are inevitable. Increased efficiency and productivity on solutions will allow for the efficient use of resources such as water, fertilizers, and pesticides. The use of data analytics and machine learning algorithms helps farmers make informed decisions by analyzing large datasets related to weather patterns, soil conditions, and crop performance. Software engineering plays a crucial role in the development of automated machinery and robotics for tasks such as planting, harvesting, and weeding. Farmers can monitor and manage their environmental footprint more effectively using software tools. Software solutions result with significant cost savings by optimizing all resource usages. IoT devices and sensors implementing real-time monitoring such as the crop health, the soil moisture measurements enable timely interventions. Global population increase and the effects of climate change necessitate innovative approaches to agriculture. Software engineering provides the tools to address these challenges effectively. Advances in agricultural nanotechnology contribute positively to both food security and public health.

Key words: Precision Agriculture, Smart Agriculture, Digital Agriculture, Artificial Intelligence, Big Data Analytics, Decision Support Systems, Sustainable Agriculture

INTRODUCTION

Traditional agricultural practices are currently undergoing a transformation driven by data-driven and software-supported solutions, integrating cloud computing, decision support systems, and cyber-physical technologies. Digital transformation plays a significant role in addressing global-scale challenges such as population growth, climate change, water scarcity, food security, resource depletion, and the need for sustainable production systems (Anjum et al., 2025; Walter et al., 2017). As modern agriculture relies on software-intensive systems, software engineering has moved to the center of this transformation. Software systems collect data from a wide range of sources, such as sensors, drones, satellites, agricultural machinery, mobile applications, and environmental monitoring platforms. That huge information is processed using cloud-based platforms, AI models, optimization algorithms, and decision-support tools to enable timely and accurate decision-making (Wolfert, et al, 2017; Verdouw, et

al., 2021). As a result, these developments have transformed agriculture from a purely biological and mechanical field into an interdisciplinary domain where software engineering provides the architectural, methodological, and technological foundation for smart and sustainable farming. Precision agriculture emerged from this context with the aim of enhancing agricultural productivity and sustainability. Precision agriculture entails the use of digital technologies, sensing systems, geospatial data, automation, and data analytics to observe, measure, and manage spatial and temporal variability in agricultural lands. It aims to apply agricultural inputs—such as water, fertilizers, pesticides, and seeds—at the right time, in the right place, and in the right quantities (Stafford, 2020). Precision agriculture relies on the collection, processing, integration, analysis, and visualization of large volumes of heterogeneous agricultural data, a fact that highlights the steadily increasing need for software systems over the years. Precision agriculture is closely linked to smart agriculture and data-driven farming practices. Smart agriculture systems analyze crop development, soil quality, water resources, weather conditions, and any risks that could harm the environment. All these activities are carried out using IoT sensors, wireless communication, machine learning, automation, and real-time monitoring technologies. Big data and AI have facilitated precision agriculture by supporting processes such as crop monitoring, yield forecasting, disease detection, and resource optimization. Precision agriculture is closely linked to smart agriculture and data-driven farming practices. Smart agriculture systems analyze crop development, soil quality, water resources, weather conditions, and any risks that could harm the environment. All these activities are carried out using IoT sensors, wireless communication, machine learning, automation, and real-time monitoring technologies. Big data and AI have facilitated precision agriculture by supporting processes such as crop monitoring, yield forecasting, disease detection, and resource optimization (Bhat & Huang, 2021). Farooq et al. (2019) examined the role of IoT technology in agriculture and its importance in the implementation of smart farming. The article details the fundamental components and network technologies of IoT-based smart farming, as well as their connections to related technologies such as cloud computing and big data analytics. This review indicates that security issues, various smartphone- and sensor-based applications, and standardization policies for IoT-based agriculture have been the primary areas of research in modern agriculture over the last decade.

From a software engineering perspective, the development of precision agriculture systems entails designing software architectures that are scalable, reliable, maintainable, interoperable, and secure. These systems must integrate heterogeneous data sources, process large volumes of real-time and historical data, support predictive analytics, and provide user-friendly interfaces for farmers, agronomists, researchers, and supply chain stakeholders.

Consequently, fundamental software engineering principles—such as requirements engineering, modular design, layered architecture, software quality assurance, system integration, human-computer interaction, cybersecurity, and data governance—play a significant role in the development of precision agriculture platforms. Furthermore, the integration of IoT, cloud computing, and big data analytics technologies is further strengthening precision agriculture systems. IoT devices, which enable real-time monitoring and automation, boost productivity while reducing the need for manual labor. Meanwhile, detailed agricultural datasets are managed through cloud computing, which provides scalable storage and processing capabilities. Big data analytics supports informed decision-making by facilitating actions based on vast amounts of data. The continued development of precision agriculture is essential; the ongoing integration of cutting-edge software engineering technologies will make significant contributions to addressing challenges in global agriculture and ensuring sustainable food production.

Precision Agriculture

Precision agriculture is a data-driven production approach that aims to optimize resource use, increase crop productivity, and reduce environmental impacts in agricultural production (John & James, 2025). The growing global population, climate change, the exhaustion of water resources, and challenges in accessing safe food have necessitated a reconsideration of traditional agricultural practices (Balafoutis et al. 2017). In this context, precision agriculture which enables the collection, analysis, and transformation into management decisions of data has introduced a modern perspective to the agriculture (Table 1).

Table 1. Conceptual Classification of Precision Agriculture

Dimension	Description	Role
Data collection	To get oil, plant, climate, other data via sensors and monitors	Forms the decision-making process
Data analysis	Evaluation of the data using software, modeling, AI or statistics	Enables understanding of variability
Location management	Separate assessment of different areas using GPS and GIS	Enables area-specific application
VRT	Application of inputs to different areas in varying amounts	Increases resource efficiency
Automation	Automating irrigation, planting, fertilization and pest control.	Reduction of labor, increased precision of application
Decision support	Generating recommendations using AI and data analytics	Enables accurate and on time interventions

The information on planting, crop, soil, and climate is supplied by the usage of sensors, satellite imagery, drone systems, GPS/GIS, IoT, artificial intelligence (AI), and variable rate technology (VRT) (Ghosh & Kumpatla, 2022). The fundamental principle of precision agriculture is to apply agricultural support where it is needed, in the required amount, and at the appropriate time. Thus, the using of basis inputs—such as water, fertilizer, seeds, and pesticides—is optimized, production costs are reduced, and environmental sustainability is supported. At the same time, variability in cultivation areas necessitates the development of regional management strategies. Farmers are increasingly moving away from traditional homogeneous practices, as differentiated management strategies offer significant advantages in terms of yield and quality. In precision agriculture, parameters such as soil moisture, temperature, pH value, electrical conductivity, and nutrient levels are measured using soil

sensors (Table 2). These measurements form the basis for irrigation and fertilization decisions.

Table 2. Functional classification of soil sensors

Sensor Type	Measured Parameter	Management Decision
Moisture sensor	Soil water content	Determination of irrigation timing and quantity
Nutrient sensor	Nitrogen, phosphorus, and potassium levels	Variable-rate fertilization
pH sensor	Soil acidity and alkalinity	Planning soil conditioning applications
Temperature sensor	Soil temperature	Determination of sowing time and germination conditions
Electrical conductivity sensor	Salinity and ion concentration	Salinity management and soil health monitoring

Satellite imaging and remote sensing technologies are widely used, particularly across large agricultural areas, to monitor yield-related variables, including planting activities, water distribution, and disease occurrence. Drone systems provide high-resolution data with greater

Fig. 1: Modern agricultural practices with VRT technology (Source: Created by the author using AI)

temporal flexibility. These systems are particularly effective for plant disease and pest detection, plant stress analysis, and in the planning of local interventions. Variable rate technology (VRT) (Fig.1) is a key component of the implementation phase of precision agriculture (Li et al., 2026). Inputs such as seeds, fertilizers, water, and pesticides are applied at varying rates across different areas of the field based on specific needs (Table 3). Preventing unnecessary usage leads to significant reductions in economic losses and environmental risks. This enables farmers to focus more intensively on areas with low yields. GPS (Global Positioning System) captures location data from agricultural machinery, while GIS (Geographic

Information System) handles the mapping and analysis of various data layers and the creation of management zones. The integration of data as soil properties,

Table 3. The Classification of Variable Rate Technology

VRT Type - Input	Purpose	Benefit
Planting- Seed	Adjusting seeding density based on soil productivity	Seed savings and optimization of plant density
Fertilization - Fertilizer	Applying appropriate dosages to areas with nutrient deficiencies	Reduction of fertilizer costs and environmental pollution
Irrigation-Water	Irrigating based on moisture requirements	Water conservation and prevention of water stress
Spraying - Pesticide, Herbicide, Fungicide	Focusing on areas affected by pests or diseases	Reducing chemical use

crop development, yield maps, water distribution, and pest density is achieved through the GPS-GIS combination.

IoT-based sensor networks and smart systems enable real-time decision-making. Soil and plant sensors, weather stations, and automated irrigation systems facilitate critical things such as the continuous monitoring of production processes and the timely execution of required interventions (Priya et al., 2021). Data analytics and AI-driven systems enable the processing of large datasets to facilitate soil fertility forecasting, plant disease risk assessment, irrigation scheduling, fertilization strategies, and plant pest management. However, the dissemination of precision agriculture currently faces several challenges. High initial investment costs, and the requirement for maintenance and update for the devices owned by farmers can pose challenges in regions across all categories. Technical knowledge requirements and inadequate digital infrastructure in rural areas constitute another significant obstacle for all farmers engaged in precision agriculture. The most significant integration challenge in these applications is the complexity of data management and the lack of compatibility between software and various mobile devices.

Table 4: Future trends in precision agriculture

Trend	Description	Expected Impact
Autonomous agricultural machinery	GPS and AI powered tractors, seeding machines, and harvesters	Reduced labor requirements
Agricultural robots	Weed control, harvesting, and crop monitoring robots	Increased application precision
AI-powered decision systems	Disease, yield, and irrigation forecasts	Early identification of risks
Blockchain	Crop traceability, supply chain transparency	Enhanced food safety, consumer trust
Sustainable intensification	Greater crop with fewer resources	Increasing yield, reducing environmental impact
Climate-resilient crop	Adaptation strategies based on climate and soil	Resilience against aridity, extreme weather events

Despite all its limitations, precision agriculture will continue to develop and expand through the adoption of autonomous machinery, agricultural robots, AI-driven decision-support systems, blockchain-based traceability, and sustainable intensification practices across many agricultural regions worldwide (Manono et al., 2026). In conclusion, precision agriculture offers optimal solutions to challenges regarding resource utilization, productivity, environmental impact, and food security (Table 4). The widespread adoption of data-driven production will eliminate the need for farmers to rely on intuitive decision-making. Therefore, decisions based on measurable and analyzable data will ensure sustainability in agricultural production, boost farmer profitability, and lead to significant improvements in crop quality.

Agriculture 5.0

Agriculture 4.0, a human-centric, sustainable, and technology-driven paradigm that emerged from adapting the Industry 4.0 concept to the agricultural sector, has gained increasing attention since the late 2010s (Klerkx et al., 2019). Agriculture 4.0 refers to the integrated use of technologies such as digitalization, automation, the internet of things, AI, robotic systems, big data, sensors, drone technologies, and precision farming applications in agriculture. It signifies not merely the use of technology, but also the management of agricultural production through data-driven, connected, and automated systems.

Agriculture 5.0 is the customization of the Society 5.0 concept to the agricultural sector; it aims to integrate cyber-physical systems, AI, IOT, robotics systems, and big data analytics in accordance with human requirements and societal benefits (Bissadu et al., 2025). In addition to

these, advanced technologies such as edge computing, cloud computing, blockchain, digital twins, 6G communication technologies, quantum technology, and collaborative robots are the core technological components of Agriculture 5.0. In this approach, technology certainly does not replace farmers; on the contrary, it supports them and acts as a tool to strengthen their decision-making processes.

The increasing global population, rising food demand, climate change, agricultural labor shortages, an aging farmer population, shrinking arable land, increasing input costs, and diversifying consumer preferences are making it difficult to continue farming with current production models. Agriculture 5.0 develops more efficient, flexible, personalized, and sustainable production systems.

Table 3. Future trends in precision agriculture

Trend	Description	Expected Impact
Autonomous agricultural machinery	GPS- and AI-powered tractors, seeding machines, and harvesters	Reduced labor requirements
Agricultural robots	Weed control, harvesting, and crop monitoring robots	Increased application precision
AI-powered decision systems	Disease, yield, and irrigation forecasts	Early identification of risks
Blockchain	Crop traceability and supply chain transparency	Enhanced food safety and consumer trust
Sustainable intensification	Greater crop with fewer resources	Increasing yield, reducing environmental impact
Climate-resilient crop	Adaptation strategies based on climate and soil data	Resilience against aridity and extreme weather events

It utilizes high levels of automation, human-machine collaboration, resource-efficient use, and environmentally friendly production strategies in solving problems. Agricultural collaborative robots, in particular, enable humans and machines to work together safely and efficiently in the same production environment. Digital twins and big data analytics strengthen decision support mechanisms in farm management, production forecasting, and resource planning processes. IoT-based sensors, satellite imagery, and drone systems support real-time data collection and monitoring processes.

In summary, Agriculture 5.0 integrates smart decision-making based on data collection, processing, and analytics within a holistic architecture that encompasses farm management automation, sustainable practices, integrated supply chains, efficient resource use, mass personalization, collaboration, cybersecurity, and adaptive agricultural system applications (Saiz-Rubio et.al, 2026). When evaluated from a software engineering perspective, Agriculture 5.0 is not merely the use of agricultural technology; it is a complex digital ecosystem comprising various software infrastructures that encompass data architecture, system integration, security, user experience, and decision support systems (Wolfert et al., 2017; Pylianidis, et al., 2021; Abbasi et al., 2022; Tiganis, 2023).

Fig. 2: Contributions of HDRs to digital agriculture (Source: Created by the author using AI)

Human Digital Twins

Placing the human factor at the center, which is a fundamental principle of Agriculture 5.0, has led to the emergence of human digital twins (HDTs), a new technology designed to facilitate information sharing while supporting worker health, safety, ergonomics, and decision-making processes (de Oliveira Garré et al., 2026). Although its global adoption is currently limited, this technology aims to strengthen human-machine collaboration through the integration of human physiological, behavioral, and operational data with smart machines, sensors, and cyber-physical systems, ultimately supporting more sustainable and adaptable production.

The posture, fatigue, physical load, and risk factors associated with agricultural workers (Zhang et al., 2023) are continuously monitored, and records regarding the farmer's ergonomics and safety (Benos et al., 2020) are maintained by HDTs. Furthermore, human-robot interaction is facilitated through the support of autonomous machines and agricultural robots (Moysiadis et al., 2024). Like other smart farming tools, HDT systems utilize cyber-physical systems that incorporate sensor data, AI algorithms, real-time data processing, user interfaces, and decision-support software (Pal et al., 2024). Human data is utilized within agricultural decision-making processes to achieve optimal outcomes. Deficiencies regarding data integration, standards compliance, ethical issues, and field validation are identified, and relevant information is provided. The features of this application constitute the software engineering dimension of Agriculture 5.0. Consequently, integrating the digital representation of human operators into agricultural systems represents a valuable application for the future of agriculture. In summary, from the perspective of Agriculture 5.0 software engineering, the development of HDTs requires robust software architectures to handle sensor data integration, real-time data processing, interoperability, privacy protection, and human-centric interface design, consumption (Fig. 2).

Explainable Artificial Intelligence in Agriculture

Uncertainty regarding the realizing of AI models has raised concerns about reliability in the agricultural sector as well. To address this issue across all fields where AI is utilized, research into Explainable AI (XAI) has accelerated since 2017. XAI aims to enhance transparency in decision-making processes by making the internal workings of AI models more comprehensible (Rajbongshi et al, 2026). It is well known that while black-box models may offer high prediction accuracy, their interpretability is limited. This situation leads to reliability issues among farmers, agricultural engineers, and decision makers. The increasing usage of AI in the agricultural sector offers significant advantages to countries in terms of productivity, efficiency, and sustainability. Machine learning and deep learning models are extensively used for crop yield prediction, disease detection, irrigation system management, remote sensing analysis, and decision support systems. In this context, the role of XAI in agriculture is becoming increasingly significant. Key tools used in this field include Local Interpretable Model-agnostic Explanations (LIME) (Ribeiro et al., 2016), SHapley Additive Explanations (SHAP) (Lundberg & Lee, 2017) and Gradient-weighted Class Activation Mapping (Grad-CAM) (Selvaraju et al., 2017). LIME explains individual predictions by perturbing interpretable parts of an input and fitting a simple surrogate model that approximates the complex model's behavior in the input's local neighborhood. It can be applied to image, text, and tabular data. The reliability of its explanations depends on how well the perturbations represent plausible inputs and how accurately the surrogate approximates the model locally. Sampled points may fall off the data manifold. Since LIME is an interpretability tool designed to explain the predictions of black box models, the black box may then behave in ways it never would on real data. Poor local fidelity, instability and sensitivity to settings are other weaknesses of LIME (Slack et al., 2020). Because LIME fits a locally weighted linear surrogate, it may fail to capture a highly nonlinear decision boundary, produce different explanations from different perturbation samples, and yield results that are sensitive to the kernel width and the definition of local. SHAP uses Shapley values to assign feature attributions. Under a specified definition of missing features, SHAP values satisfy properties such as local accuracy. Some explainers estimate them by sampling feature subsets, while others use different algorithms. How attribution is distributed across features depends on the model and the chosen background distribution. Grad-CAM highlights image regions that influence a model's prediction, while LIME and SHAP explain predictions by assigning importance to input features. Grad-CAM is commonly used to explain a convolutional neural network (CNN) prediction for a particular class. Grad-CAM produces a spatial heatmap for an image model (Ji et al., 2024). LIME approximates a model locally with a simpler model, whereas SHAP attributes a prediction to features using Shapley-value principles. These methods clarify the internal workings of complex AI models and make their decision-making processes more understandable. Consequently, they address the disadvantage of black-box models by identifying the contributions of input variables or image regions to the model's outputs. XAI supports more transparent, reliable, and actionable agricultural decision-making processes by linking model predictions derived from agricultural reasoning to field management practices (Abou Samra and Ali, 2026).

However, XAI evaluation metrics are seldom studied in agricultural applications. Future works should assess explanation quality and validity, rather than treating a plausible-looking plot as sufficient evidence. Spectroscopic measurements can change with environmental and instrument conditions. Researchers should examine whether explanations remain stable when data, preprocessing, or experimental conditions change. There can be no doubt that test explanation will increase the robustness and reliability. Spectra often contain many collinear wavebands. Future works should investigate how correlated wavelengths affect attribution methods such as SHAP and LIME, and how explanations can be made easier to interpret. Domain-specific and physics-informed machine learning include promising directions.

Explanations should be checked against known chemical or physical relationships, rather than interpreted in isolation. User-friendly, interactive XAI tools could make explanations more accessible to researchers and practitioners. This is especially relevant when users need to inspect wavelength contributions, local predictions, or Grad-CAM heatmaps. Deep-learning models can be demanding on embedded or mobile devices. Future researches should consider the computational cost of producing explanations as well as the cost of making predictions. In conclusion, according to the perspectives of these three methods; SHAP has the strongest reported presence in agricultural spectroscopy examples, particularly for identifying important wavelengths. Grad-CAM is relevant mainly to CNN-based image or hyperspectral-image applications, where it provides coarse visual localization. LIME is a promising local surrogate approach. For all three, the future need is to establish that explanations are valid, stable, useful to domain experts, and consistent with the underlying science (Ahmed et al., 2025).

Small Language Models

Small Language Models (SLMs) are language models designed to use fewer computational resources than large language models. SLMs could make agricultural AI more practical by running on phones, sensors, or local computers with limited connectivity. XAI can help users to inspect the evidence behind their recommendations. But an SLM's fluent explanation should not automatically be treated as a faithful account of its reasoning (Jacovi & Goldberg, 2020). They can only be adapted to agricultural terminology and tasks. For example, they can answer farmers' questions about crop management, pests, or livestock care; summarize sensor readings, weather data, and farm records; and help to interpret spectroscopy or hyperspectral imaging results (Fig. 3). SLMs can provide decision support through these locally deployed applications, including in areas with limited internet connectivity. The smaller size of SLMs may enable lower costs, faster responses, and on-device deployment. However, SLMs may have narrower knowledge than large language models (LLMs) and can still produce inaccurate or unsupported answers.

Fig.3: What does SLMs do? (Source: Created by the author using AI)

XAI is not only a single technique; it also includes methods that help users to understand a model's predictions or the evidence used to produce them. Explainability approaches in SLM-based agricultural systems include feature attribution, visual explanations, and local surrogate models. Methods such as SHAP can identify which input variables mostly influenced a prediction. These variables may include wavelengths, soil measurements, or weather features. Grad-CAM can highlight the image regions that mostly contributed to the output of a CNN or other vision model used for disease or quality assessment. LIME can approximate a model's behavior around an individual prediction (Linardatos, et al., 2021). In addition, retrieval-augmented systems can cite the agricultural documents, manuals, or datasets used to generate an answer, thereby providing evidence and supporting source tracing. Finally, a system can communicate uncertainty. It can also show how a recommendation might change if a specific input, for example soil moisture, were different. This approach is known as counterfactual

explanation. Such XAI methods can complement an SLM. For example, a system might use a model to detect crop disease from an image, apply Grad-CAM to highlight the affected region, and then use an SLM to communicate the result in accessible language.

There is a clear distinction between SLM generating an explanation and the model being explainable. An SLM can produce a natural-language explanation, but that explanation may not be faithful to the factors that actually produced its output (Turpin et al, 2023). In other words, it is not, in itself, proof of transparency. To enhance the trustworthiness of agricultural AI systems, explanations should be grounded in verifiable evidence. Such evidence may include (i) relevant input features or image regions; (ii) cited source documents or sensor measurements; (iii) calibrated confidence or uncertainty estimates; and (iv) validation through expert review by agricultural specialists and field testing.

In this context, SLMs can improve the accessibility and usability of agricultural AI by enabling natural-language interaction, whereas XAI can improve the transparency and inspectability of model decisions. Their integration is most beneficial when the SLM communicates evidence that has been generated or verified by validated methods, rather than producing explanations that may not faithfully reflect the underlying decision process.

Global Agricultural Policies

The European Commission (2019) published the European Green Deal communication with the aim of transforming Europe into a climate-neutral continent by 2050. This agreement adopts a new sustainable growth model, emphasizing the need to simultaneously achieve decarbonization, sustainability, the preservation of natural resources, public health, and economic competitiveness. The Farm to Fork (F2F) Strategy is its main tool for transforming agriculture and food. The European Commission published F2F in May 2020. F2F Strategy as a component of the European Green Deal, aims to develop a fairer, healthier, and more sustainable food system within the EU (European Parliament, 2026). This strategy encompasses every stage of the food supply chain from production to consumption, thereby establishing a comprehensive approach that supports farmers in adapting to the process.

As Turkey is not an EU member, it is under no obligation to comply with this agreement. Turkey Ministry of Agriculture and Forestry (2026) Performance Program sets 2026 targets for sustainable agriculture, including 6.5 million decares of organic farming area, land-use planning for

Fig. 4: Global agricultural policies and intellectual property rights in digital agriculture (Source: Created by the author using AI)

5 million hectares, and monitoring water quantity and quality at 1,953 points. The program also emphasizes digital agriculture, artificial intelligence-supported crop monitoring, planned

production, water efficiency, and rural development as policy instruments for strengthening natural resource management and food supply security. These priorities reflect Turkey's long-term efforts to develop a more sustainable and resilient farm-to-consumer agricultural system. Turkey's digital agriculture policies are more likely to yield effective results when supported by a multi-layered governance framework that draws on examples from the EU and East Asia and integrates technological advancement with social inclusion and sustainability goals. Unless social policies are developed to ensure the active participation of women and young farmers in this process, the transformative potential of digitalization will remain limited. Ultimately, the digital transformation of agriculture in Turkey is not merely intended to increase agricultural productivity; it is also essential for supporting rural development, strengthening resilience to climate change, and enhancing the sector's competitiveness and sustainability. One of the recent digital systems Tarım Cebimde (Agriculture in My Pocket) both increase the efficiency of public services and offer practical solutions that save producers time and costs (Turkey Ministry of Agriculture and Forestry, 2026).

Fig. 4 illustrates the intersection of global agricultural policies and intellectual property rights in digital agriculture. On the other hand, some impact analyses conducted by the U.S. government department responsible for agriculture, food, farming, and rural development. Studies conducted by the United States Department of Agriculture (USDA) and the European Commission's Joint Research Centre (JRC) primarily focus on the input-reduction targets of the Farm to Fork strategy, including reductions in pesticide use, livestock antibiotics, and nitrogen inputs, as well as increases in organic farming and agroecological infrastructure, while paying limited attention to dietary changes, reductions in food loss and waste, agricultural innovation, supply chain transformation, and international trade.

The strategy seeks to make Europe a global pioneer of a food system that benefits climate, biodiversity, and health (Aubert&Poux, 2021). Additionally, USDA and JRC primarily focused on the input-reduction targets of the F2F strategy. The F2F strategy should be viewed not merely as a reduction in production inputs, but as a systemic food transformation that addresses nutrition, production, innovation, the supply chain, and environmental sustainability in an integrated manner.

Intellectual Property Rights

Digitalization in agriculture generates numerous information-based assets, such as sensor data, artificial intelligence models, drone imagery, satellite analyses, software, databases, and smart agricultural equipment. Consequently, intellectual property rights (IPRs) are not merely a legal detail, but serve as fundamental assurance for investment, innovation, data security, and fair value sharing within the digital agriculture ecosystem. As digitalization in agriculture expands, value will derive not only from physical produce but also from data and technology. This elevates the importance of IPRs

The development of solutions such as smart irrigation, disease detection, yield forecasting, and early fire-warning systems requires substantial investment in research and development (R&D). Accordingly, protecting the software code and associated algorithms developed for these purposes through appropriate intellectual property mechanisms is important, subject to the requirements of applicable law. Data on soil conditions, climate, crops, yields, sensors, and drones underpin agricultural decision-support systems and can generate significant economic value when collected, processed, and applied effectively. Clearly defining access rights to data collected from farmers' fields, as well as the purposes for which that data may be used, is essential to safeguarding producers' rights. Where a sensor, a drone-mounted component, or a piece of smart agricultural equipment embodies a technical invention, it may be eligible for patent or utility model protection, subject to the applicable legal requirements. Trademark and

copyright protection, together with appropriate licensing arrangements, may also support the commercialization of agricultural technologies and help strengthen investor confidence.

Software code developed for agricultural decision-support systems, image-processing applications, drone-image analysis tools, and data-visualization dashboards may be protected by copyright. The same may apply to original content created for mobile applications for farmers, including user-interface elements, training materials, and technical documentation, provided that the relevant material meets the applicable originality requirements. Copyright protection generally arises automatically upon the creation and fixation of an original work. However, registration, notarization, timestamping, or secure digital archiving may help establish or prove authorship, ownership, and the date of creation, depending on the applicable national law.

Legal and contractual safeguards against the unauthorized reproduction or use of proprietary technologies, as well as the unlawful acquisition, use, or disclosure of trade secrets, can help mitigate unfair competition. Although raw data, as such, is generally not protected by copyright, agricultural datasets may be protected under applicable legal regimes—for example, where they involve original selection or arrangement, qualify for database protection, or are subject to contractual confidentiality or trade-secret protections. Data-governance frameworks can further clarify the conditions governing access to, use of, and sharing of such data.

In digital agriculture, data-use agreements are among the key instruments for governing the collection, access to, and use of agricultural data. Such agreements should clearly specify the parties' respective rights and responsibilities, the purposes for which the data may be used, applicable retention periods, and anonymization requirements. They should also address data sharing with third parties, the use of data to train artificial intelligence systems, farmers' rights to access and delete their data, the conditions for commercial use, and the parties' cybersecurity obligations.

In Turkey, if a farmer's data qualifies as personal data, the provisions of the Turkish Personal Data Protection Law (Law No. 6698; KVKK) must also be taken into account. Know-how and production methods may also be protected in Türkiye as trade secrets when they are kept confidential and appropriate measures are taken to safeguard their confidentiality. Registering an industrial design makes it possible to protect the visual appearance of a device or interface.

In short, protecting innovations through IPRs in digital agriculture can strengthen confidence in these technologies and support their sustainable development and adoption. Intellectual property issues become more complex in the context of AI-based agricultural technologies, raising several important questions. These include identifying the model's developer, determining which data were used to train it, and assessing whether the use of those data was properly authorized. Further questions concern the allocation of rights in the model's outputs, the use of the same data in other commercial projects, and compliance with applicable license terms when open-source code is used.

Conclusions and Future Studies

Digital technologies can support more productive and sustainable agriculture, but their contribution depends on how well they are designed, integrated, and governed. This paper has considered the role of software engineering in that process, from precision agriculture and Agriculture 5.0 to the development of an end-to-end, layered architecture. By bringing together IoT sensors, cloud computing, big data analytics, data fusion, and decision-support services, the architecture offers a way to translate agricultural data into actionable insights that inform farm-level decisions. Technology alone, however, does not determine whether these systems will be useful in practice. They must also reflect the needs and working conditions of the people who rely on them. HDTs for instance, could help represent interactions between farmers, agricultural workers, and the systems they use. XAI may make algorithmic recommendations

easier to understand, while SLMs could support context-sensitive applications in environments with limited computing resources. In each case, practical contribution will depend on the quality of the data, careful evaluation, and whether the technology supports rather than complicates farmers' decisions.

Agricultural software is also shaped by the policies and legal arrangements surrounding its development and use. Global agricultural policies influence priorities such as sustainability, food security, and digital infrastructure. IPRs and data-governance arrangements, in turn, affect how software, datasets, and AI-based systems can be developed, accessed, shared, and commercialized. Addressing these issues is important not only for encouraging innovation but also for protecting the interests and rights of the people and organizations involved.

Future Research Directions

A practical next step is to test the proposed architecture in real agricultural settings. Studies involving different farm sizes, crops, regions, and levels of connectivity could reveal how well the system performs under varied conditions. Its interoperability, scalability, security, and reliability should be assessed alongside measures such as resource-use efficiency, system latency, data quality, operating costs, and the usefulness of its recommendations. Domain-based evaluation would show whether the architecture can meet the requirements of day-to-day agricultural practice, rather than only functioning as a conceptual design.

Further research is needed to determine how HDTs, XAI, and SLMs can be effectively applied in agriculture. Work on HDTs could examine the data and modelling assumptions required to represent farmers and agricultural workers, as well as the ethical concerns that such representations may raise. Research on XAI should assess whether explanations genuinely help farmers understand and evaluate recommendations. SLMs, meanwhile, need to be tested for accuracy, robustness, and safety across agricultural tasks, including in local contexts and underrepresented languages. These studies should account for practical risks, such as incomplete data, biased recommendations, and inaccurate generated content.

An important area for future investigation is how agricultural data and AI-enabled technologies are governed in practice. This includes questions of data access, privacy, cybersecurity, retention, and sharing, as well as the rights associated with software, datasets, and AI-generated outputs. Comparative studies of national and international policies could clarify where existing frameworks support responsible innovation and where gaps remain. Finally, long-term studies involving farmers, developers, policymakers, and other stakeholders could provide a fuller picture of adoption barriers, the distribution of benefits, and environmental effects. These findings would help to guide the development of agricultural software that is not only technically effective but also trustworthy, inclusive, and suited to the diversity of farming communities.
